1 Abstract

The goal of this work is to estimate systematically the sensitivity of COSMO model over a large number of expected high impact parameters, using objective criteria for their selection. The proposed methodology is based on the relative average values of certain meteorological fields over a considered model domain and time period. Its main advantages are its economy as well as its flexibility, due to its *ab initio* character, as observations do not enter into the decision process. In this way, the calibration procedure is considered as a separate independent stage of the model optimization according to the computational resources available to the user and in reference to the available observations. Another important feature of the method deals with the selection of the proper domain in case of nesting by employing the similarities of the parameter sensitivities between the wider and the internal domain. Twelve parameters were examined over the wider Mediterranean area for a period of 62 dates from February, June, and December of 2013 and a horizontal grid of 0.0625° ($\sim 7\,Km$). The validity of the method is demonstrated via the resulting sensitivities of this domain compared with those of internal domains over the areas of Greece, Italy, Israel and Switzerland leading to a distinct hierarchy regarding the parameter choice as well as the dominant interaction terms of the parameter combinations.

2 Introduction

Numerical weather prediction (NWP) models are tools of exceptional complexity both from the computational perspective regarding the applied numerical schemes as well as the physical processes included along with their approximations. From the operational standpoint, the physical processes are implemented by means of parameters that are either user defined or hardcoded into the model software (default values herein). However, the optimization of the model performance depends significantly on these parameter values. The process of finding the default parameter values is generally addressed as model tuning (Skamarock 2004; Duan et al., 2006). The more physical processes are included in the NWP model, the larger is the number of parameters expected to be tuned to control and optimize its performance. This feature leads usually to a task of employing complicated methodologies of relatively high computational cost (Annan and Hargreaves 2007). This is also the case for COSMO, a state of the art non-hydrostatic local NWP model developed and supported by the synonymous COSMO consortium (COnsortium for Small-scale Modeling, www.cosmo-model.org) consisting of the national meteorological services of Germany, Greece, Israel, Italy, Poland, Romania, Russia and Switzerland. In our previous works (Khain et al., 2015, 2017; Voudouri et al., 2016, 2017, 2018, 2019), there have been performed extensive efforts to increase the performance of COSMO model over the area of Switzerland and Northern Italy through the choice of an optimum set of tunable model physics parameters. The optimization process was based on the use of an objective calibration procedure that has been applied for a regional climate model (RCM) (Bellprat et al., 2012a and 2012b). This calibration methodology relies on a meta-model (MM) that approximates the parameter space, using a multi-variate quadratic regression in an N-dimensional model (Neelin et al., 2010 and 2010a; Box and Behnken, 1960; Mayers et al., 2009) where the dimension N of the model is the number of the parameters that are chosen to be optimized. The number of simulations required to create the quadratic polynomial necessary to construct the MM for calibrating N parameters varies from a minimum of 2N+N(N-1)/2 to a maximum of 2N+2N(N-1) plus a simulation standing for the default parameter values combination. In principle, the first step is to perform the runs of COSMO model with the default parameter values for the time period and

domain under consideration and then repeat the process, first by changing one parameter at a time to its maximum and minimum limits values and then changing two parameters at a time to account for the interaction between these parameters. Although the approach is rather straightforward, its computational cost rises practically in analogy to N^2 providing significant constraints in its realization if the number of the parameters rises, especially when relatively large domains are considered along with fine grid spacing.

In the present approach, a strategy is developed on how to decrease the computational cost of the above process by providing realistic options towards the truncation both of the number N of the parameters chosen as well as the choice of the interaction terms. The key concept of this mechanism is the relative sensitivity of the minimum and maximum parameter values with respect to their default values in reference to certain meteorological fields that are considered as the most important ones from the operational perspective of the user (e.g. cloud cover, precipitation, 2m temperature etc.). In this work and in analogy to the work of Dierer et al (Dierer et al., 2009), this sensitivity is defined as the ratio of the difference of the average area values of the considered meteorological fields between their limit parameter values and their default ones over the total period of the model runs. A direct insight regarding the relative sensitivity among the parameters is visualized in the form of spider-graphs. Another feature of the methodology is the possibility to use the parameter sensitivities to relate meteorological similarities among internal domains in reference to the wider area of the model run and potentially attribute criteria for their optimum position and extent in case of the application of nesting techniques to further increase the local model performance. Towards this direction, the relative sensitivities of domains over the areas of Greece, Italy, Israel and Switzerland are presented in reference to the domain of the Mediterranean.

3 Model setup

3.1 Configuration

In this work. Version 5.0 of COSMO model was used that forms the reference version of the current operational applications of the model. Extensive physical parametrizations, as well as refined numerical schemes are induced in the model making it particularly applicable for the current study, since it is mainly designed to be applied operationally in the Meso-β and Meso-γ scales (Steppeler et al., 2003; Baldauf et al., 2011; Gebhardt et al., 2011; Schättler et al., 2013; Collaud Coen, 2014). The model runs were performed for 48hr periods starting at 00 UTC over the wider Mediterranean area (Fig. 1), the domain used operationally by the Hellenic National Meteorological Service (HNMS), on a 0.0625° ($\sim 7\,Km$) horizontal grid spacing, 649x393 grid points with 60 vertical levels and a 30 second integration time step.

This configuration has also been used for research purposes that highlight the value of the model towards the further understanding of storm surges (Calafat et al., 2014), cloud schemes (Avgoustoglou and Tzeferi, 2015), tornadoes (Avgoustoglou et al., 2018) and non-adiabatic atmospheric processes (Kouroutzoglou et al., 2018). The model was initialized from 6-hour analysis of the ECMWF operational model (www.ecmwf.int/en/forecasts/datasets/set-i) over a 0.150° ($\sim 15\,Km$) horizontal grid, while the outputs were produced in 3-hour time intervals. The model runs were performed at ECMWF's High Performance Computing Facility (www.ecmwf.int/en/computing/our-facilities/supercomputer) and are equivalent of approximately 6 years of model runs.

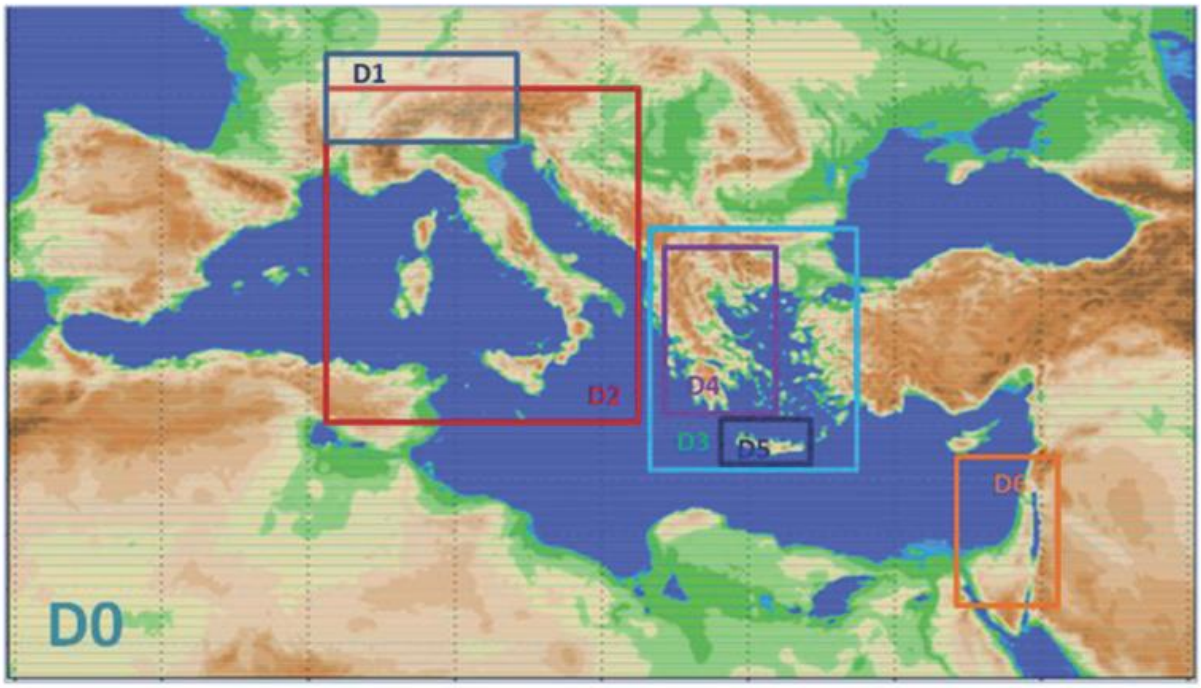

Figure 1: Domain of model runs over the wider Mediterranean area (D0) along with specific test domain for areas around: Switzerland (D1), Italy (D2), Greece (D3), Continental Greece (mainly) (D4), Crete (D5), and Israel (D6).

3.2 Parameter selection and model tests

A set of twelve parameters was selected (Table 1) that practically envelops the most significant physical processes of COSMO model over a general domain selection (Schättler et al 2013).

PARAMETER	INTERPRETATION	TEST VALUES
a_stab	stability correction factor of horizontal length scale	**0.0** , 0.5, 1.0
crsmin	minimum stomatal resistance	50, **150**, 300
c_soil	surface area index of evaporative soil	0, **1**, 2
entr_sc	mean entrainment rate for shallow convection	$5 \cdot 10^{-5}$, $\mathbf{3 \cdot 10^{-4}}$, $2 \cdot 10^{-3}$
mu_rain	shape parameter of the rain drop size distribution	0, **1**, 2
q_crit	critical value for normalized oversaturation	1.6, 2.8, **4.0**
rain_n0_factor	factor to reduce the evaporation of raindrops	0.02, **1.0**, 5.0
rat_sea	ratio of laminar scaling factors for heat over sea	1, **20**, 100
rlam_heat	scaling factor of the laminar boundary layer for heat	0.1, **1.0**, 2.0
tkmmin tkhmax	minimal value of diffusion coefficients for heat and momentum (kept equal)	0.1,**0.4**, 1.0
tur_len	asymptotic maximal turbulent length scale (m)	100, **150**, 1000
v0snow	factor in the terminal velocity for snow	10, **20**, 30

Table 1: List of the 12 parameters of tested sensitivity based on their code names (first column), interpretation (second column) and test values range (third column). The default values are denoted with bold italic characters.

However, the application of a MM for the calibration of COSMO model over such a large number of parameters is prohibitive, especially when a domain with the complexities and

size of the Mediterranean should be considered. In our previous works (Voudouri et al., 2017 and 2018), the reduction of the parameters was decided mainly on heuristic arguments based on the works of Bellprat et al (Bellprat et al. 2012a, Bellprat et al. 2012b) as well as the climatological and meteorological characteristics of the considered domain of Switzerland and Northern Italy. The choice of the parameters to be tuned was an essential task and a considerable effort was given regarding their selection since there are numerous parameters in COSMO model specifically related to sub-grid scale turbulence, surface layer parametrization, grid-scale clouds, precipitation, moist and shallow convection, radiation, the soil scheme etc. (Doms et al., 2011, Gebhardt et al., 2011).

Therefore, the consensus regarding the selection of parameters turns out to be the most crucial task to control the number of the model simulations and the consequent computational cost. In the present work and under this motivation, the domain parameter sensitivity (DPS) is introduced as the key term. DPS is considered that leads to the desired most convenient parameter choice in an objective manner via a consequent imposed hierarchy over the resulting DPS of the considered parameters.

For a model field F the domain parameter sensitivity DPS_F is defined as ,

$$DPS_F = \frac{< F >_{TEST} - < F >_{DEFAULT}}{< F >_{DEFAULT}} \cdot 100 \tag{1}$$

where $< F >_{DEFAULT}$ stands for the temporal domain areal average of F for the default parameter values, while $< F >_{TEST}$ stands for the test run where one of the parameters has been set equal to its limit values given in Table 1, while the other parameters are kept with their default values (Avgoustoglou et al., 2016). Although, there is no constraint on the model fields attributed for consideration, the applicability of the method is presented upon the choice of rather common meteorological features related with cloud cover,precipitation and temperature (Table 2).

0-24 hr period accumulated precipitation (kg m^{-2})	TOTPREC
0-24 hr periods accumulated grid-scale snow (kg m^{-2})	SNOW_GSP
Low cloud cover (%) average of 3hr time steps 03-24 hs	CLCL
Medium cloud cover (%) average of 3hr time steps 03-24 hs	CLCM
High cloud cover (%) average of 3hr time steps 03-24 hs	CLCH
Total cloud cover (%) average of 3hr time steps 03-24 hs	CLCT
Maximum 2m temperature (^oC) for 0-24 hr periods	TMAX2m
Minimum 2m (^oC) temperature 0-24 hr periods	TMIN2

Table 2: List of the examined meteorological fields. Their encoded names in COSMO model are given in the second column.

Regarding TMAX2m and TMIN2m the denominator of (1) changes very little relative to the absolute temperature and it was considered more convenient to define DPS simply as,

$$DPS_{\left[\begin{smallmatrix} TMIN2m \\ TMAX2m \end{smallmatrix}\right]} = \begin{bmatrix} TMIN2m \\ TMAX2m \end{bmatrix}_{TEST} - \begin{bmatrix} TMIN2m \\ TMAX2m \end{bmatrix}_{DEFAULT} \tag{2}$$

For the sake of seasonal coverage, the model tests were performed over a total of 62 days in continuous periods of 20, 20 and 22 days over February, June and December 2013 respectively. Periods from spring and autumn were not included in order to avoid any complexities due to the transitional nature of these seasons.

4 Methodology

4.1 Elemental application over one meteorological field

In order to present the essence of the method, we focus on a single meteorological field, the precipitation (TOTPREC) for the domain of the Mediterranean (D0). After completion of the tests, the resulting DPSs are presented in a standard column graph at the upper part of Fig. 2, from which it is obvious that for D0 the parameters are divided practically in three groups with respect to their sensitivities. According to the magnitude of the DPSs, the first group includes the two most sensitive parameters rat_sea and rlam_heat, the second group includes the five less sensitive parameters c_soil, entr_sc, v0_snow, rain_n0_factor and crsmin while in the third group the five least sensitive remaining parameters are included. Although this preponderance regarding the sensitivities of rat_sea and rlam_heat is directly visible from this graph, it has also been supported by previous works especially regarding rat_sea and rlam_heat parameters (Dierer et al., 2009; Kouroutzoglou et al., 2018) directly from physical arguments regarding mainly non adiabatic atmospheric processes. Of particular importance to our approach is the presentation of DPSs in the form of a spider-graph as given in the lower part of Fig. 2. In this graph the DPSs are given as bullets, the positive ones over and the negative ones under the red polygon of "no sensitivity". The line that connects the dots defines the domain parameter sensitivity polygon (DPSP). It is drawn to address visually a geometrical morphology to the DPSs that is considered to be important over the next stages of the procedure. The limit parameter values are given as the extensions of the parameter names addressed in the tables and figures of the present work. In case the goal is to optimize the model performance with respect to TOTPREC using a MM, there is also the demand to consider tests with pair parameter combinations (Voudouri et al., 2017 and 2018), an essential task that becomes more and more complicated as the number of sensitive parameters is rising. This requirement is accounted by the creation of the domain parameter sensitivity priority board (DPSPB) presented in Table 3 where the absolute differences of the different parameter pair limit values are given in descending order. It can be easily shown that for N parameters, the number of pairs is 2N(N-1). So in the present case (12 parameters) the number of pairs is 264. Due to the large number of parameter pairs, only the first 20 are given in Table 3. As also shown in Fig. 2, the largest differences correspond to the most sensitive parameters (shaded rows) while there are also large differences between these parameters and those of very low sensitivity. Additionally, in the third column of Table 3, the relative sensitivity of the pairs of the DPSs is addressed by attributing the value -1 if the sensitivities have opposite signs and 1 if the signs are the same. In principle, the couples of the parameters with the highest DPS differences and with opposite sign sensitivities should be considered as the most appropriate choices in the optimization process via the use of a MM (highlighted rows in Table 3). According to the above analysis, upon the application of a model optimization technique, the initial choice of 12 parameters regarding D0 can be truncated from two to seven most sensitive ones and in case of the use of a MM the dominant parameter pairs are the ones addressed with the highlighted rows in Table 3.

4.2 Extension of the methodology over several meteorological fields

Although the precipitation has a standalone value regarding the optimization of model performance (Dierer et al., 2009), in principle, it is necessary to account for the model calibration with respect to more meteorological fields. In that case the parameter selection method can be readily generalized. Under this requirement, the meteorological fields of gridpoint snow (SNOWGSP), minimum 2m temperature (TMIN2m), maximum 2m temperature

(TMAX2m), high, medium and low cloud cover (CLCH, CLCM, CLCL respectively) are also included modifying the method accordingly.

TOTPREC		
rat_sea_ 1 - rlam_ heat_0.1	28.389	-1
rat_sea_100 - rlam_heat_2.0	25.164	-1
c_soil_0 - rat_sea_100	25.023	-1

crsmin_300 - rlam_heat_0.1	18.858	-1
rat_sea_100 - tkhmin_tkmmin_0.1	18.792	1
q_crit_2.8 - rat_sea_100	18.463	1
...	...	...

Table 3: DPSPB for TOTPREC, i.e. the absolute values, in descending order, of DPS differences of temporal area 24-hour means for pairs of different parameter combinations for precipitation (TOTPREC) over the wider Mediterranean area D0 and over the 62-day period. The highest 20 values of the total of 264 combinations are displayed (second column) along with the corresponding parameter pair (first) column and their relative sensitivity signs (third column) denoted with -1 if they are opposite and 1 they are the same.

The corresponding DPSs are given in Table 4 and are shown in Fig. 3 where the spider graphs are referenced with respect to TOTPREC as it is given in the lower part graph of Fig. 2 and placed again in the head of Fig. 3. From the DPSs given in Table 4, it can be noticed that the most sensitive parameters (in gray shade) are essentially the same with those assessed from Table 3 with the inclusion of the minimal value of diffusion coefficients for heat and momentum (tkhmin & tkmmin) which have a significant impact in middle and low cloud cover, a feature that was the central point of a previous work (Avgoustoglou and Tzeferi, 2015). Moreover, towards the selection of the dominant interaction terms, a compiled DPSPB for all the meteorological fields is given in Table 5 as an extension to Table 3 and in reference to Fig. 3. Although the content of this table is considerably broad, the hierarchical display of the DPSs differences for several meteorological fields in adjacent places provides the framework to place consistent quantitative criteria on the interaction terms that should be considered.

5 Discussion of the relative sensitivity of different domains

As a sequel to the previous analysis regarding the establishment of a parameter ranking for model tuning of a particular domain, there is the possibility to use the DPSs for inducing similarities among different internal areas of the wider domain. These similarities may provide a valuable insight regarding the application of nesting techniques. In Figs. 4-10 the

spider graphs for domains D0 to D6 are presented for the meteorological fields of precipitation (TOTPREC) (Fig. 4), grid-point snow (SNOWGSP) (Fig. 5), high, medium, low cloud cover (CLCH, CLCM, CLCL respectively) (Figs. 6, 7, 8), minimum (TMIN2m) (Fig. 9) and maximum 2m temperature (TMAX2m) (Fig. 10).

PARAM	TOTPREC	SNOW_GSP	CLCH	CLCM	CLCL	TMAX2m	TMIN2m

Table 4: DPSs for min and max parameter values for precipitation (TOTPREC), grid-point snow (SNOWGSP), minimum 2m temperature (TMIN2m), maximum 2m temperature (TMAX2m), high, medium and low cloud cover (CLCH, CLCM, CLCL respectively) over the wider Mediterranean area D0 and over the 62-day period.

In addition to the wider area of the Mediterranean D0 where the corresponding spidergraph is placed on the top of the figures, D1 refers to an area around Switzerland; D2 refers to an area around Italy, D3 to an area around Greece, D4 to an area constrained mainly to continental Greece, D5 to the area of Crete and D6 to an area around Israel as shown in Fig. 1. All graphs are scaled with respect to the most sensitive parameter of the specific meteorological field and particular domain to provide a better perspective of the analogies and similarities of the DPSs among the domains. For TOTPREC all domains show comparable DPSs and similar corresponding polygons (DPDPs) with the exception of D1 that exhibits considerably lower DPSs from the other areas. In addition, the areas of Italy (D2) and Greece (D3, D4) are very close in DPSs. An interesting aspect with this analysis are the close similarities between D5 (Crete) and D6 (Israel) which most probably addresses climatic characteristics between the two areas directly from the model parameters. This is also highlighted in Fig. 5 regarding SNOWGSP although this parameter might have certain spurious features due to the small number of events for the particular time sampling of 62 days including 20 days in summer. The situation is similar with the rest of the meteorological fields although for low cloud-cover (CLCL) the domains associated with the areas of Greece (D3, D4, D5) and Israel D5 denote sensitivity for several parameters however in good analogy with the reference domain D0.

Table 5: Three-column groups of the DPS differences absolute values for different parameter pair combinations regarding precipitation (TOTPREC), grid-point snow (SNOWGSP), minimum 2m temperature (TMIN2m), maximum 2m temperature (TMAX2m), high, medium and low cloud cover (CLCH, CLCM, CLCL respectively) over the wider Mediterranean area D0. The highest 20 values of the total of the 264 combinations are displayed (second) column along with the corresponding parameter pair (first) column and their relative sensitivities (third column) denoted with -1 if it is of the opposite and 1 if it is of the same sign. Due to space constraints, we correspond, P01 → a_stab, P02 → crssmin, P03 → c_soil, P04 → entr_sc, P05 → mu_rain, P06 → q_crit, P07 → rain_n0_factor, P08 → rat_sea, P09 → rlam_heat, P10 → tkhmin (together with tkmmin), P11 → tur_len , P12 → v0snow.

6 Conclusions

In the present study, a method was given aimed to restrict consistently the number of parameters chosen for COSMO model optimization especially via the use of a MM. The criteria were based on parameter sensitivities with additional insight of their relative values via spider-graphs. The method was developed analytically for the meteorological field of precipitation and was generalized to more meteorological fields where an internal consistency regarding the parameter choice was displayed. A decision process with respect to the interaction terms was also provided based on the differences of parameter sensitivities as well as their relative sign via the domain sensitivity priority boards. Finally, it was shown that the domain sensitivity spider graphs provide an important direct visual insight to certain similarities among them. These similarities might turn out to be important on the domain choice for the application of nesting techniques. This methodology is currently utilized in the development of CALMO-MAX project of COSMO (http://www.cosmo-model.org/content/tasks/priorityProjects/calmoMax/).

7 Acknowledgments

The current study was realized using computational resources provided gratis by the Hellenic National Meteorological Service (HNMS) taken from the available allocation billing units at the European Center for Medium-Range Forecasts (ECMWF) supercomputer resources.

9 Appendix for Figs. 2 to 10

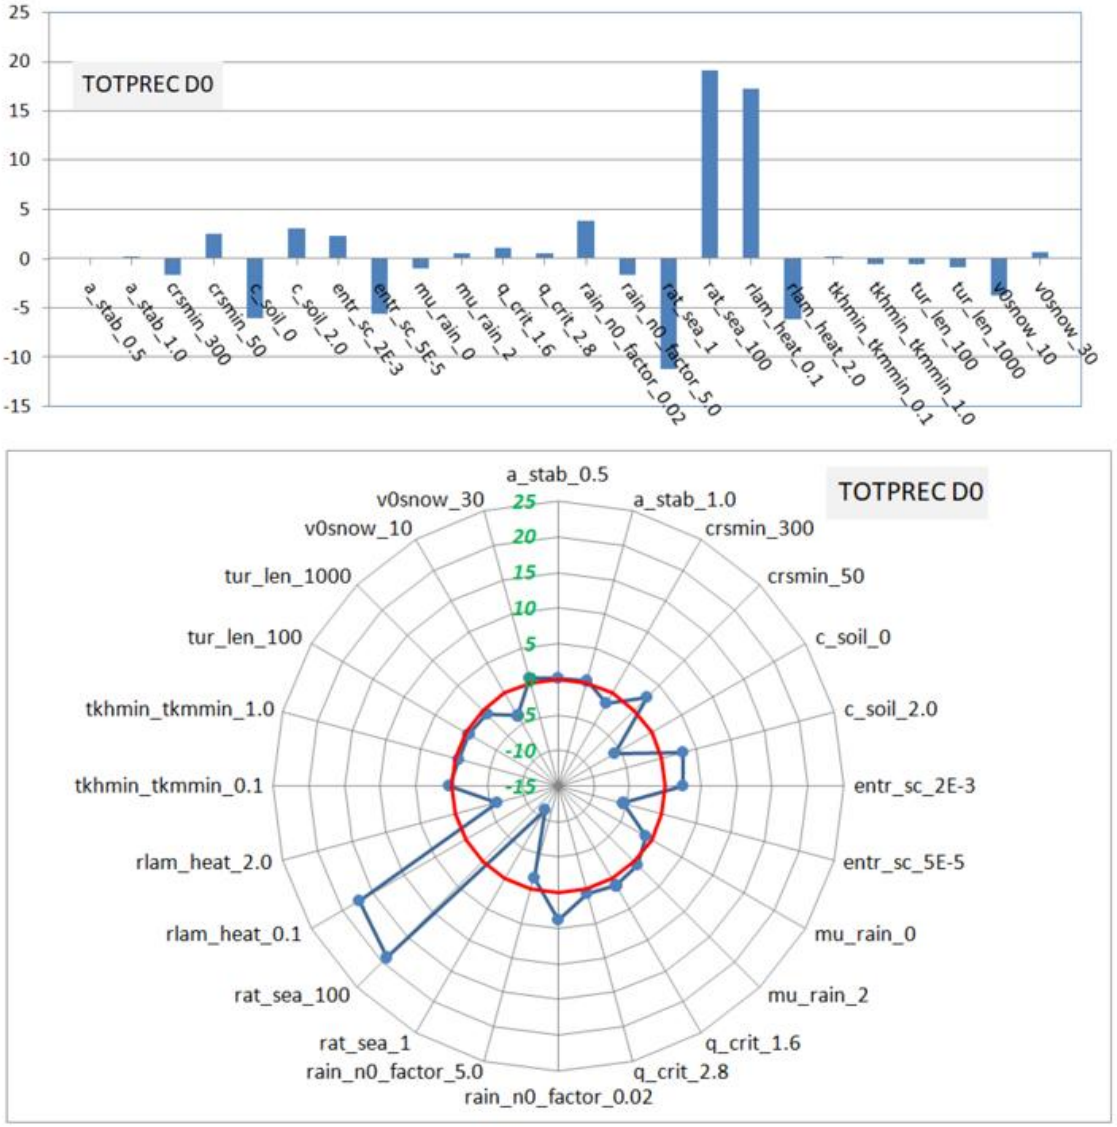

Figure 2: : DPSs for 24-hour precipitation (TOTPREC) over the wider Mediterranean area D0 in standard column form and in the form of spider-graph.

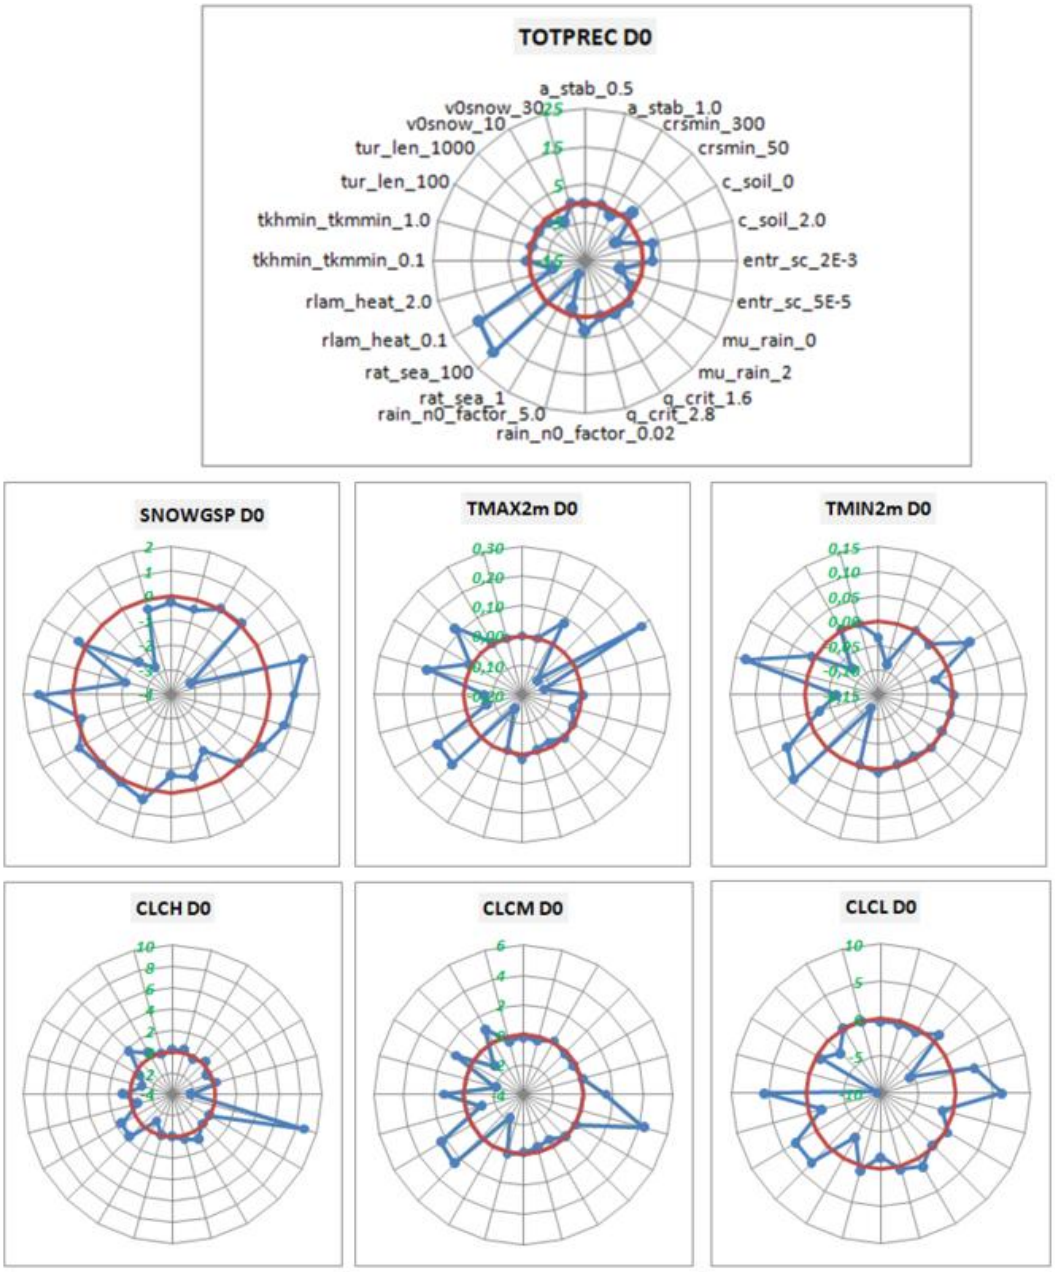

Figure 3: : DPS spider-graphs for temporal area 24-hour means of precipitation (TOTPREC), grid-point snow (SNOWGSP), minimum 2m temperature (TMIN2m), maximum 2m temperature (TMAX2m), high, medium and low cloud cover (CLCH, CLCM, CLCL respectively) over the wider Mediterranean area D0 and over the 62-day period.

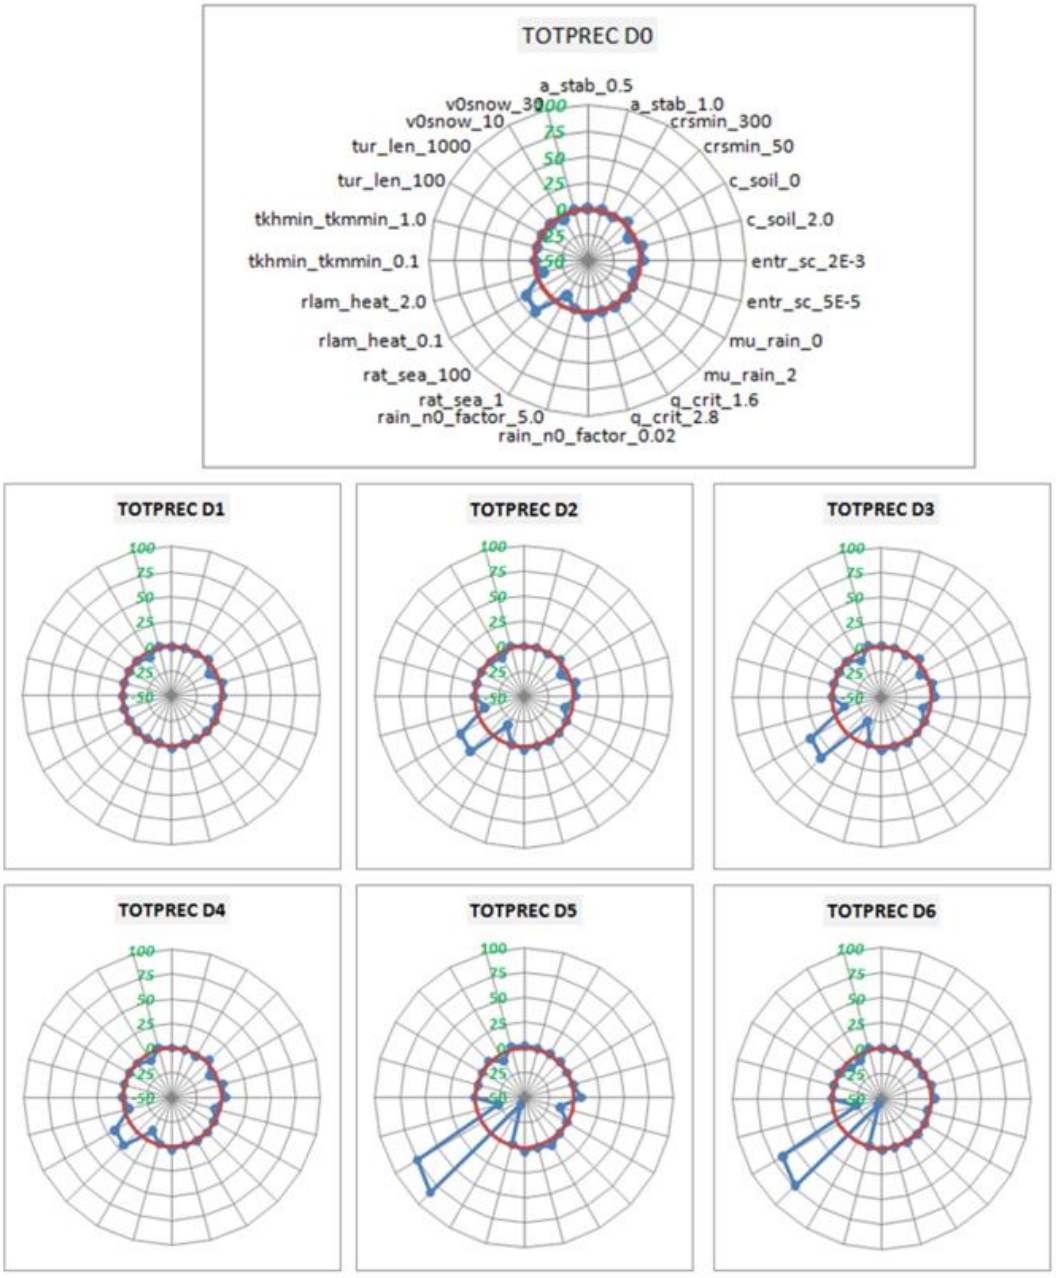

Figure 4: : DPS spider-graphs for temporal area 24-hour means of precipitation (TOTPREC), over the wider Mediterranean area D0, Switzerland (D1), Italy (D2), Greece (D3), Continental Greece (D4), Crete (D5) and Israel (D6) over the 62-day period.

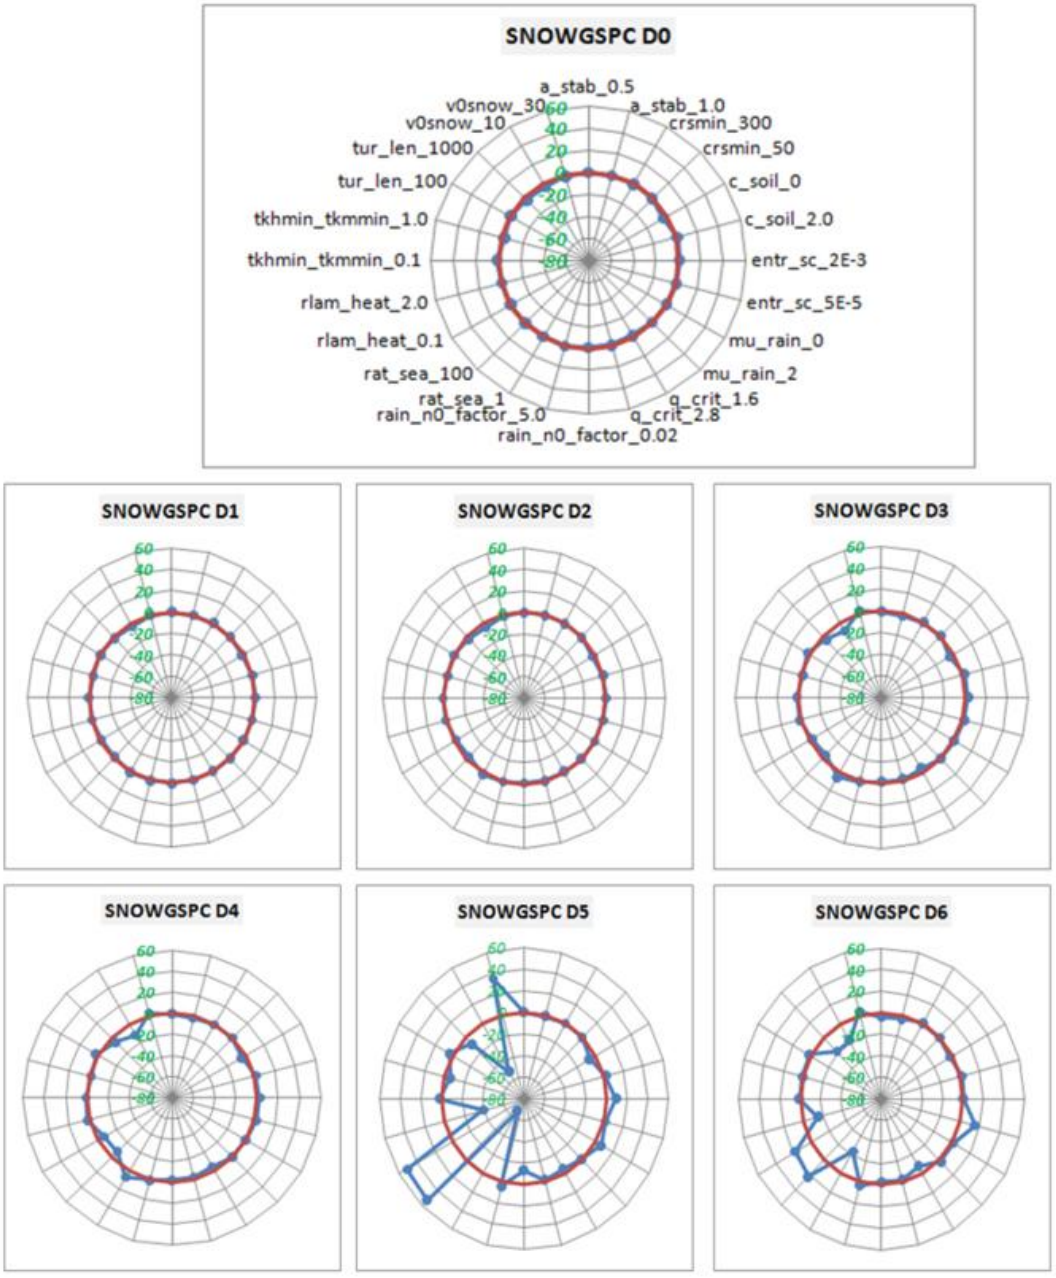

Figure 5: : DPS spider-graphs for temporal area 24-hour means of grid point snow(SNOWGSP), over the wider Mediterranean area (D0), Switzerland (D1), Italy (D2), Greece (D3), Continental Greece (D4), Crete (D5) and Israel (D6) over the 62-day period.

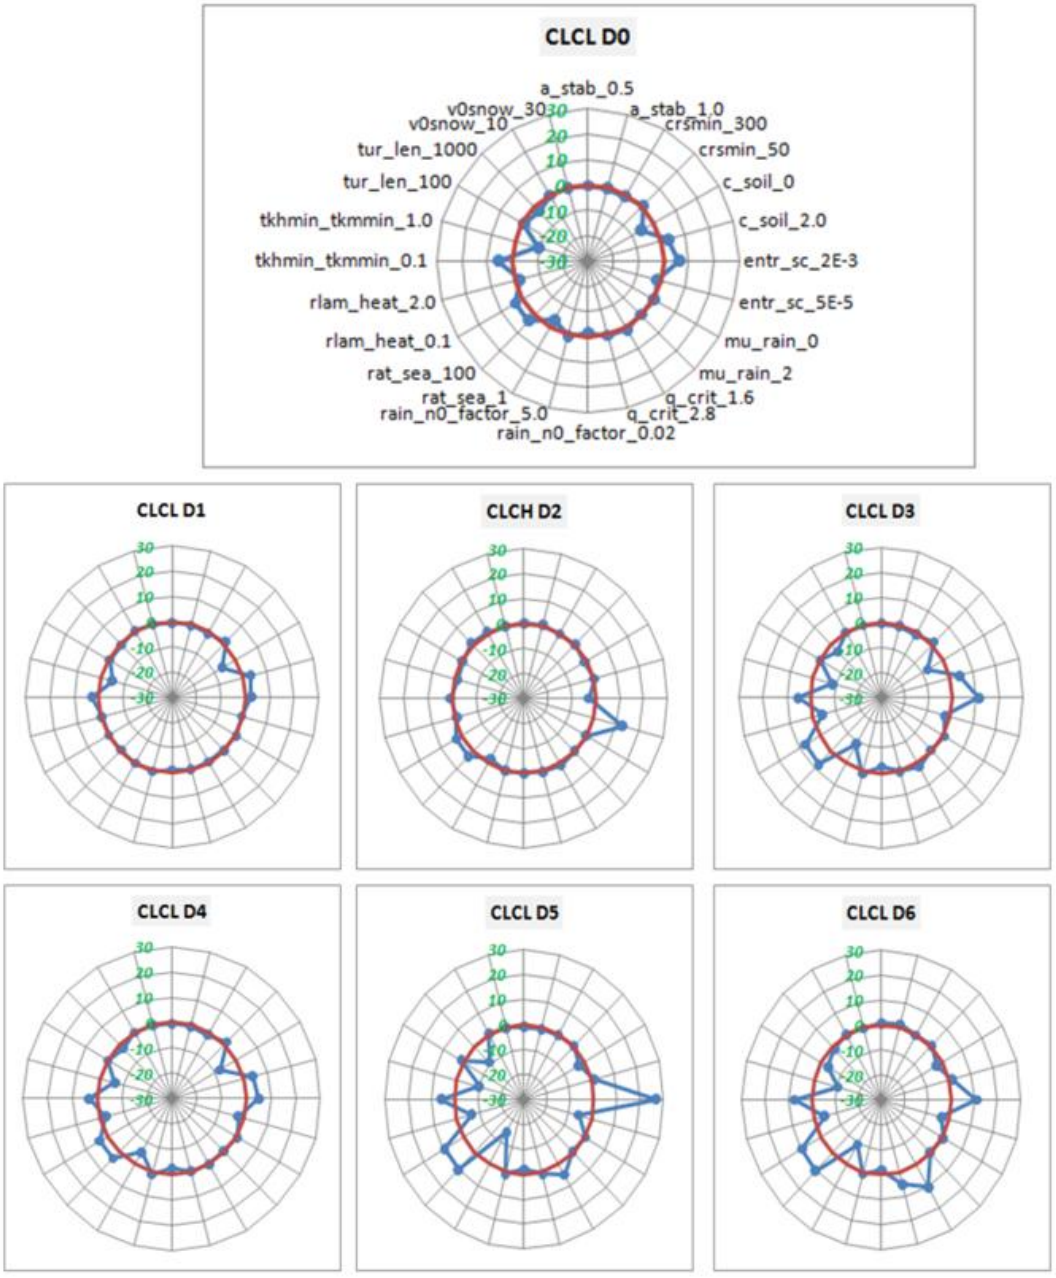

Figure 6: : DPS spider-graphs for temporal area 24-hour means, in 3-hour intervals, for low cloud cover (CLCL), over the wider Mediterranean area (D0), Switzerland (D1), Italy (D2), Greece (D3), Continental Greece (D4), Crete (D5) and Israel (D6) over the 62-day period.

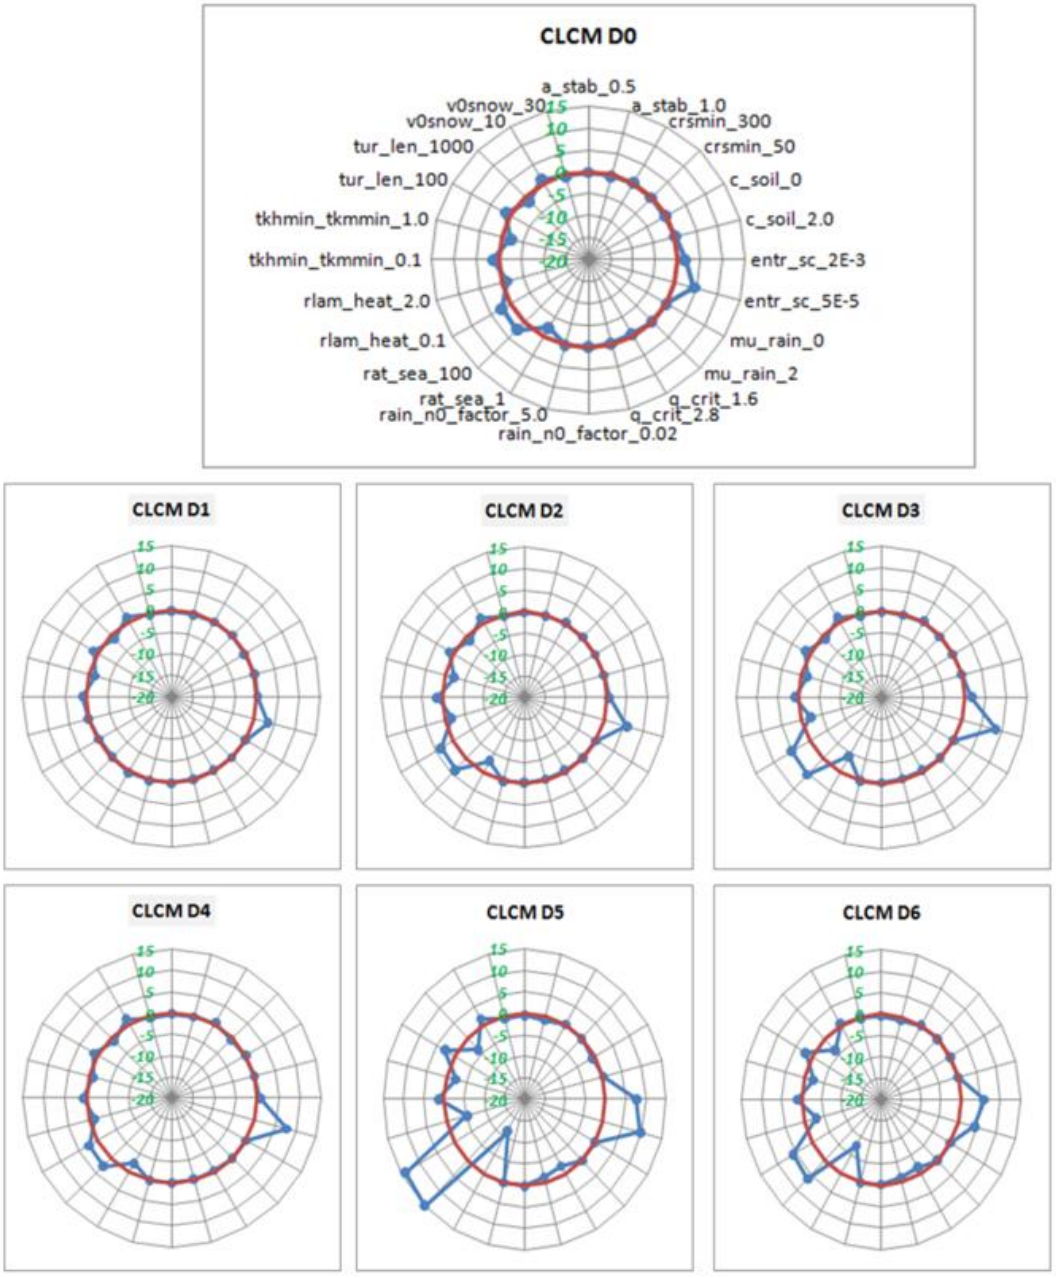

Figure 7: :DPS spider-graphs for temporal area 24-hour means, in 3-hour intervals, for medium cloud cover (CLCM), over the wider Mediterranean area (D0), Switzerland (D1), Italy (D2), Greece (D3), Continental Greece (D4), Crete (D5) and Israel (D6) over the 62-day period.

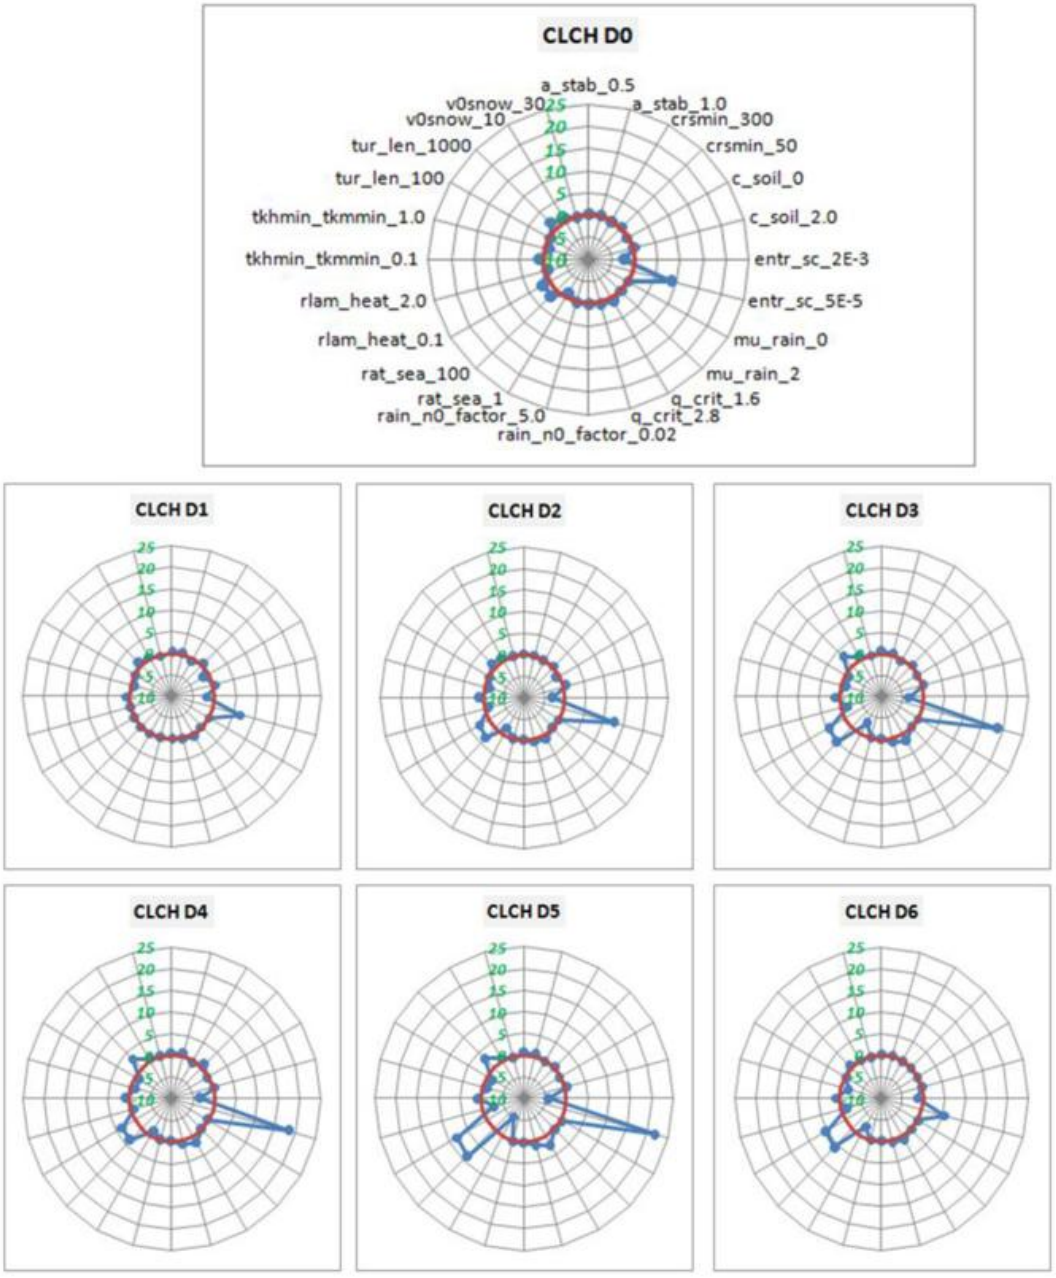

Figure 8: : DPS spider-graphs for temporal area 24-hour means, in 3-hour intervals, for high cloud cover (CLCM), over the wider Mediterranean area (D0), Switzerland (D1), Italy (D2), Greece (D3), Continental Greece (D4), Crete (D5) and Israel (D6) over the 62-day period.

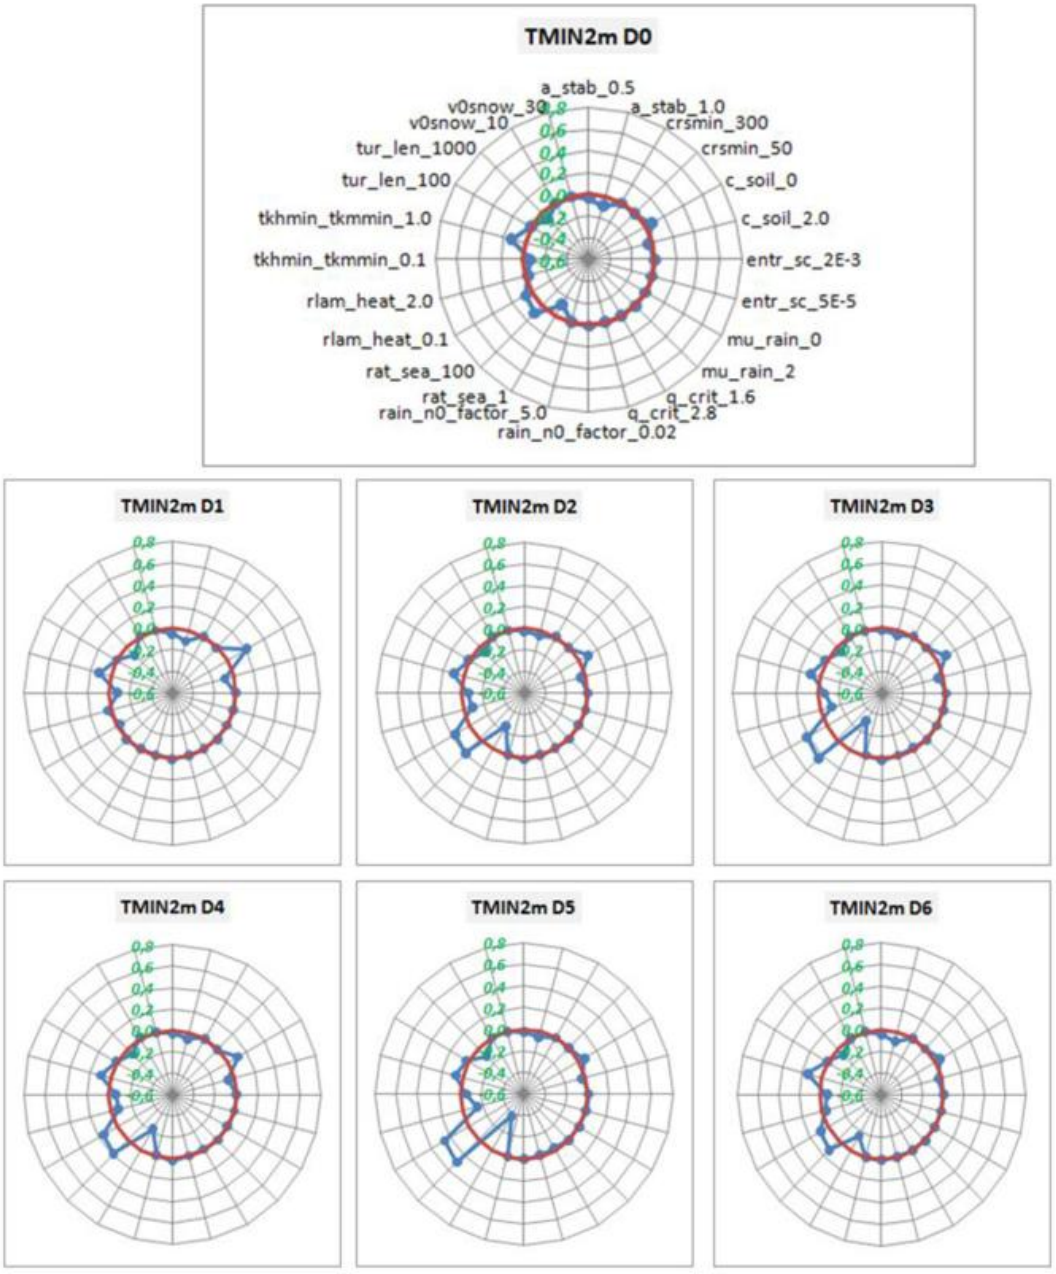

Figure 9: : DPS spider-graphs for temporal area 24-hour means, for minimum 2m-Temperature (Tmin2m), over the wider Mediterranean area (D0), Switzerland (D1), Italy (D2), Greece (D3), Continental Greece (D4), Crete (D5) and Israel (D6) over the 62-day period.

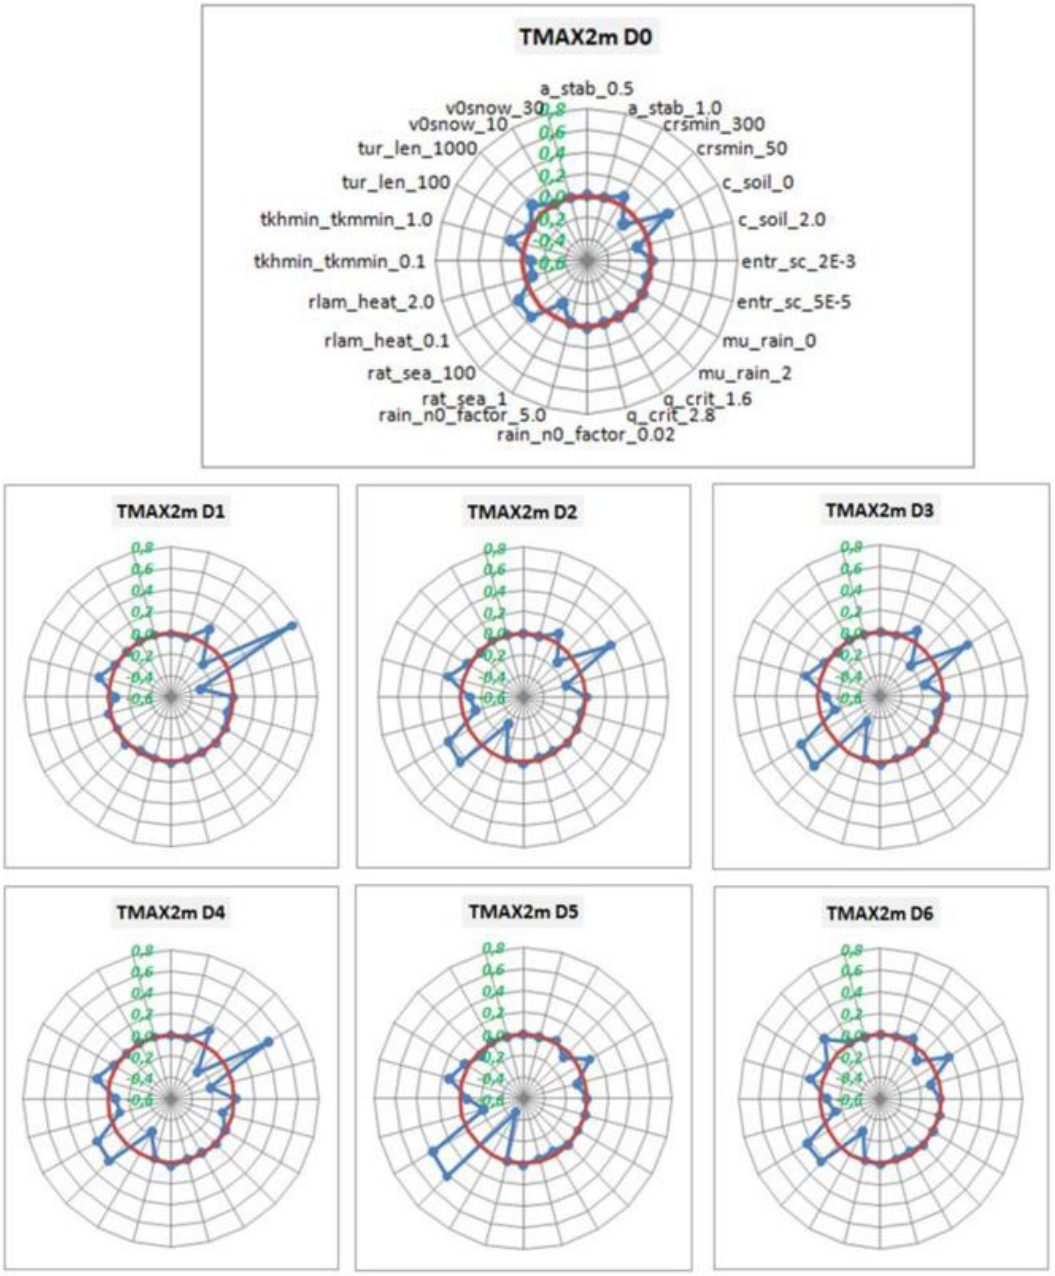

Figure 10: :DPS spider-graphs for temporal area 24-hour means, for minimum 2m-Temperature (Tmin2m), over the wider Mediterranean area (D0), Switzerland (D1), Italy (D2), Greece (D3), Continental Greece (D4), Crete (D5) and Israel (D6) over the 62-day period.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (ITAF-ReMet, ARPAE, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA), Russia (RHM) and Israel (IMS). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

For any comments and questions, please contact the editor:

1 Abstract

An essential part of the COSMO dynamical core is the fast waves solver. Here, the processes sound wave and gravity wave expansion are integrated and a stabilization of the whole time-splitting procedure by divergence damping is done. Sound and long gravity waves have high velocities and therefore are solved with a smaller time step (small compared to the larger time step of the advection process) and vertically implicit, to prevent from the strong time step reduction by flat grid elements in the vicinity of the ground.
This report describes a complete revision of the previously existing fast waves solver and incorporates several new aspects. First, all vertical discretizations are done with the proper distance weightings in the vertically stretched grid. Second, the so called strong conservation form of the divergence operator is used. Third, the possibility to use a fully 3D divergence damping should be possible. Fourth, the option to use a discretization of the horizontal pressure gradient, which promises to be more stable in steep terrain, should be implemented. Beyond these broader development goals several smaller improvements concerning e.g. the formulation of boundary conditions, the use of the reference state, more accurate formulation of the buoyancy term, or several other numerical operations have been done.
The report at first describes the discretization of the new fast waves solver to enable the model developer or user to understand the code structure. The second part motivates the chosen discretization by a truncation error analysis. Finally the third part assess the properties of the new solver against idealized test setups, where partially exact solutions are known.
This development is available since COSMO version 4.24 (together with INT2LM 1.20).

2 Introduction

This technical report describes a complete revision of the fast waves solver and thus the development of its new version. This new development is available since COSMO version 4.24 (available since July 2012).

The COSMO model was developed during the 1990's and at first went into operations at the end of 1999 at DWD (at this time named LM). Due to the planned usage of the COSMO model for convection-permitting resolutions, the decision to abandon the hydrostatic approximation was made from the beginning. The rising of massively parallel computers at this time further led to the decision not to use any anelastic approximation, but to use the fully compressible equation system. The latter equation system leads to a fast waves solver which is relatively easy to parallelize. G. Doms (?) developed the first fast waves solver for the LM, which mainly based on the solver of the MM5 (?, ?), and further using ideas of the leapfrog based split explicit solver by ? and ?. A. Gassmann abandoned the 3-time level leapfrog scheme and implemented a 2-time level Runge-Kutta scheme (? and ?). Additionally, she introduced e.g. the dynamical bottom boundary condition (?) in the fast waves solver. This at this time improved a lot the model behavior at the lower boundaries. J. Förstner implemented the Runge-Kutta scheme of ? into the COSMO model and introduced T' instead of T into the fast waves solver. This resulted in a reduced noise in the vertical velocity field, mainly due to the better behavior of the temperature advection. Later on, G. Zängl has demonstrated that the introduction of vertical weightings in some of the explicit terms of the fast waves solver largely improves the pressure bias. This was one of the prerequisites to be able to use the Runge-Kutta dynamical core for the 7 km COSMO applications at the different COSMO services (e.g. COSMO-EU at DWD).

The main goals of this development project are the following:

- The consideration of the vertical grid stretching by introduction of appropriate weightings in *all* vertical discretizations of the fast waves solver. In particular their use in the *implicit* terms in the discretization of the Euler equations requires a complete re-derivation of the tridiagonal equation system.

- The usage of the 'strong conservation form' for the divergence operator. Though mainly developed for finite volume schemes with conservation properties, there was the hope to gain advantages by a more direct discretization of the metric terms and by a better formulation of the lower boundary conditions.

- The option for a fully 3-dimensional (3D) isotropic divergence damping instead of the 'traditional' quasi-3D version should be available. ? have derived the dispersion relation of sound and gravity waves and have found a larger deviation from the correct one in the case of the quasi-3D version compared to the isotropic version.

- A further option should be the alternative discretization of the horizontal pressure gradients by the methodology of ?. This z-plane treatment should result in a more stable behavior in steep terrain.

These new features did not only require changes at almost every place in the fast waves code, but partially required a restructuring of the code logic, too. Together with the aim to introduce a bit more descriptive variable names, the decision was made, to reprogram the whole fast waves solver from scratch; a work which started at the end of 2010. This approach resulted in additional smaller improvements at other places, too, concerning e.g. the formulation of boundary conditions, the use of the reference state, a more accurate formulation of the buoyancy term, and others.

This report is subdivided into three parts. In the first part, sections 3-7, the discretization of the Euler equations, the setup and the solution of the vertically implicit tridiagonal equation for w is explained. To offer the reader an as much as possible consistent description, several repetitions of material presented in ? (or the revised version ?) have been unavoidable. But with this, the model developer (and model user) should be able to understand the code structure of the module `fast_waves_sc`.
To understand the embedding of the fast waves solver in the whole Runge-Kutta time integration framework, the reader should consult chapter 8 in ?. Also not contained here is the stability analysis of the COSMO dynamical core. For this we refer to ?. There, the reader will find reasons why the time integration scheme is done in the current manner.
In the second part (section 8), a motivation is given for one of the main development goals, namely the improved vertical discretization, by a truncation error analysis.
In the third part (9 and 10) a broad investigation of the properties of the new fast waves solver by idealized tests is performed. A few statements about model performance in real cases closes this part.

3 The Euler equations

The Euler equations in spherical, terrain following coordinates (λ, ϕ, ζ) with $\zeta = \zeta(\lambda, \phi, z)$, $r = r_{earth} + z$, can be written as

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho}\frac{1}{r\cos\phi}\left(\frac{\partial p'}{\partial \lambda} + \frac{\partial \zeta}{\partial \lambda}\frac{\partial p'}{\partial \zeta}\right) + \frac{1}{\rho}\frac{1}{r\cos\phi}\left(\frac{\partial\, \alpha^h_{div}\,\rho\, D}{\partial \lambda} + \frac{\partial \zeta}{\partial \lambda}\frac{\partial\, \alpha^h_{div}\,\rho\, D}{\partial \zeta}\right) + \left.\frac{\partial u}{\partial t}\right|_{slow} \quad (1)$$

$$\frac{\partial v}{\partial t} = -\frac{1}{\rho}\frac{1}{r}\left(\frac{\partial p'}{\partial \phi} + \frac{\partial \zeta}{\partial \phi}\frac{\partial p'}{\partial \zeta}\right) + \frac{1}{\rho}\frac{1}{r}\left(\frac{\partial\, \alpha^h_{div}\,\rho\, D}{\partial \phi} + \frac{\partial \zeta}{\partial \phi}\frac{\partial\, \alpha^h_{div}\,\rho\, D}{\partial \zeta}\right) + \left.\frac{\partial v}{\partial t}\right|_{slow} \quad (2)$$

$$\frac{\partial w}{\partial t} = -\frac{1}{\rho}\frac{\partial \zeta}{\partial z}\frac{\partial p'}{\partial \zeta} + g\left(\frac{p_0}{p}\frac{T'}{T_0} - \frac{p'}{p} + \frac{p_0}{p}\frac{T}{T_0}q_x\right) + \frac{1}{\rho}\frac{\partial \zeta}{\partial z}\frac{\partial\, \alpha^v_{div}\,\rho\, D}{\partial \zeta} + \left.\frac{\partial w}{\partial t}\right|_{slow} \quad (3)$$

$$\frac{\partial p'}{\partial t} = -\frac{c_p}{c_V} p\, D + g\rho_0 w + \left.\frac{\partial p'}{\partial t}\right|_{slow} \quad (4)$$

$$\frac{\partial T'}{\partial t} = -\frac{R}{c_V} T\, D - \frac{\partial T_0}{\partial z} w + \left.\frac{\partial T'}{\partial t}\right|_{slow} \quad (5)$$

The denotations are the same as in **?**, in particular $T = T_0 + T'$ and $p = p_0 + p'$ are split into the stationary reference state and deviations. Here only the 'fast' processes are written down and grouped into sound (left group of terms on the rhs), buoyancy (middle group of terms in the w, p', and T'-equations) and artificial divergence damping (right group in the three momentum equations). $\left.\frac{\partial u}{\partial t}\right|_{slow}$, ..., $\left.\frac{\partial T'}{\partial t}\right|_{slow}$ denote the remaining ('slow') processes advection, Coriolis force and all physical parameterizations.

The occurring coordinate derivatives may be understood as

$$\frac{\partial \zeta}{\partial \lambda} \equiv \left.\frac{\partial \zeta}{\partial \lambda}\right|_z \equiv \frac{\partial \zeta(\lambda,\phi,z)}{\partial \lambda}, \quad \frac{\partial \zeta}{\partial \phi} \equiv \left.\frac{\partial \zeta}{\partial \phi}\right|_z \equiv \frac{\partial \zeta(\lambda,\phi,z)}{\partial \phi}, \quad \frac{\partial \zeta}{\partial z} \equiv \left.\frac{\partial \zeta}{\partial z}\right|_z \equiv \frac{\partial \zeta(\lambda,\phi,z)}{\partial z}.$$

We remind the abbreviations and relations valid for the COSMO coordinate transformation

$$\sqrt{g} := -\frac{\partial z}{\partial \zeta} = -\frac{1}{\frac{\partial \zeta}{\partial z}} \quad \Leftrightarrow \quad \frac{\partial \zeta}{\partial z} = -\frac{1}{\sqrt{g}}, \quad (6)$$

$$\left.\frac{\partial z}{\partial \lambda}\right|_\zeta = -\frac{\partial z}{\partial \zeta}\frac{\partial \zeta}{\partial \lambda} \quad \Leftrightarrow \quad \frac{\partial \zeta}{\partial \lambda} = \frac{1}{\sqrt{g}}\left.\frac{\partial z}{\partial \lambda}\right|_\zeta, \quad (7)$$

$$\left.\frac{\partial z}{\partial \phi}\right|_\zeta = -\frac{\partial z}{\partial \zeta}\frac{\partial \zeta}{\partial \phi} \quad \Leftrightarrow \quad \frac{\partial \zeta}{\partial \phi} = \frac{1}{\sqrt{g}}\left.\frac{\partial z}{\partial \phi}\right|_\zeta. \quad (8)$$

The divergence is denoted by $D = \operatorname{div}\mathbf{v}$. One difference to the former version of the fast-waves solver is the use of its so-called strong conservation form (**?**, eq. (3.122))

$$D \equiv \operatorname{div}\mathbf{v} = \frac{1}{r^2\cos\phi}\frac{1}{\sqrt{g}}\left[\frac{\partial}{\partial \lambda}(r\sqrt{g}\,u) + \frac{\partial}{\partial \phi}(r\cos\phi\sqrt{g}\,v) + \frac{\partial rZ}{\partial \zeta}\right] \quad (9)$$

with the definition

$$Z := r\cos\phi\,\sqrt{g}\,\dot{\zeta} = \frac{\partial z}{\partial \lambda}u + \frac{\partial z}{\partial \phi}\cos\phi\,v - r\cos\phi\,w. \quad (10)$$

Obviously, the divergence is expressed on one hand by derivatives in *terrain following* coordinates but on the other hand of the physical components u, v, w in *spherical* coordinates. Here one can cancel one factor r due to the shallow atmosphere approximation $r \approx r_{earth} = const.$, which is used throughout in the COSMO model

$$D = \frac{1}{r\cos\phi}\frac{1}{\sqrt{g}}\left[\frac{\partial}{\partial \lambda}(\sqrt{g}\,u) + \frac{\partial}{\partial \phi}(\cos\phi\sqrt{g}\,v) + \frac{\partial Z}{\partial \zeta}\right]. \quad (11)$$

It is advisable to introduce some other abbreviations

$$\tilde{d}_{hor} := \frac{\partial}{\partial\lambda}(\sqrt{g}\,u) + \frac{\partial}{\partial\phi}(\cos\phi\,\sqrt{g}\,v), \tag{12}$$

$$\tilde{d}_{vert} := \frac{\partial Z}{\partial\zeta}, \tag{13}$$

so we can write the divergence as

$$D = \frac{1}{r\cos\phi}\frac{1}{\sqrt{g}}\left[\tilde{d}_{hor} + \tilde{d}_{vert}\right]. \tag{14}$$

Furthermore we define

$$Z = Z_{hor} + Z_{vert} \tag{15}$$

with

$$Z_{hor} := Z_x + Z_y, \tag{16}$$

$$Z_x := \frac{\partial z}{\partial\lambda}\,u, \tag{17}$$

$$Z_y := \frac{\partial z}{\partial\phi}\cos\phi\,v, \tag{18}$$

$$Z_{vert} := -r\cos\phi\,w. \tag{19}$$

The artificial divergence damping has been written in a more efficient form - compared to the original idea of having a damping of the divergence[1] - analogous to ?. This form allows a common discretization of $\tilde{p} = p' - \alpha^h_{div}\rho D$ in the horizontal momentum equations. To indicate the optional divergence damping in the w-equation, the diffusion coefficient α^v_{div} carries an upper index 'v'.

The buoyancy term in the w-equation has a slightly different form than in the former COSMO versions. To derive it we use the ideal gas equation for moist air

$$p = \rho\,R_d\,(1 + q_x)\,T, \tag{23}$$

where

$$q_x := \left(\frac{R_v}{R_d} - 1\right)q_v - q_{cond}, \tag{24}$$

describes the so-called 'water loading' in the buoyancy term. From this we can derive the

[1] A more self-evident form of the divergence damping leads to the three momentum equations

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho}\frac{1}{r\cos\phi}\left(\frac{\partial p'}{\partial\lambda} + \frac{\partial\zeta}{\partial\lambda}\frac{\partial p'}{\partial\zeta}\right) + \alpha^h_{div}\frac{1}{r\cos\phi}\left(\frac{\partial D}{\partial\lambda} + \frac{\partial\zeta}{\partial\lambda}\frac{\partial D}{\partial\zeta}\right) + \left.\frac{\partial u}{\partial t}\right|_{slow}, \tag{20}$$

$$\frac{\partial v}{\partial t} = -\frac{1}{\rho}\frac{1}{r}\left(\frac{\partial p'}{\partial\phi} + \frac{\partial\zeta}{\partial\phi}\frac{\partial p'}{\partial\zeta}\right) + \alpha^h_{div}\frac{1}{r}\left(\frac{\partial D}{\partial\phi} + \frac{\partial\zeta}{\partial\phi}\frac{\partial D}{\partial\zeta}\right) + \left.\frac{\partial v}{\partial t}\right|_{slow}, \tag{21}$$

$$\frac{\partial w}{\partial t} = -\frac{1}{\rho}\left(\frac{\partial\zeta}{\partial z}\frac{\partial p'}{\partial\zeta}\right) + g\left(\frac{p_0}{p}\frac{T'}{T_0} - \frac{p'}{p} + \frac{p_0}{p}\frac{T}{T_0}q_x\right) + \alpha^v_{div}\frac{\partial\zeta}{\partial z}\frac{\partial D}{\partial\zeta} + \left.\frac{\partial w}{\partial t}\right|_{slow}. \tag{22}$$

However the discretization of this form leads to much more inefficient code, because - in contrast to the above form - the divergence terms cannot be treated together with the pressure terms. Beyond this, both forms have the same slight tendency to instability in a Bretherton-transformed equation system (see (?, Appendix B)). Hence, there is no advantage in using this form.

buoyancy term, expressed by p' and T', without any approximation

$$\begin{aligned}
-g\frac{\rho'}{\rho} = -g\frac{1}{\rho}(\rho-\rho_0) &= -g\frac{1}{\rho}\left(\frac{p}{R_d(1+q_x)T}-\frac{p_0}{R_dT_0}\right)\\
&= -g\frac{\rho_0}{\rho}\left(\frac{T_0}{p_0}\frac{p}{(1+q_x)T}-1\right)\\
&= -g\frac{\rho_0}{\rho(1+q_x)}\left(\frac{T_0}{p_0}\frac{p'+p_0}{T}-(1+q_x)\right)\\
&= -g\frac{\rho_0}{\rho(1+q_x)}\left(\frac{T_0}{T}\frac{p'}{p_0}+\frac{T_0-T}{T}-q_x\right)\\
&= +g\frac{\rho_0}{\rho(1+q_x)}\left(-\frac{T_0}{T}\frac{p'}{p_0}+\frac{T'}{T}+q_x\right)
\end{aligned}$$

In former versions of the fast waves solver, $(1+q_x)$ was neglected in the denominator because q_x is at most about 1%. Nevertheless one can avoid this neglect by

$$-g\frac{\rho'}{\rho} = +g\frac{p_0}{T_0}\frac{T}{p}\left(-\frac{T_0}{T}\frac{p'}{p_0}+\frac{T'}{T}+q_x\right) = +g\left(-\frac{p'}{p}+\frac{p_0}{p}\frac{T'}{T_0}+\frac{p_0}{p}\frac{T}{T_0}q_x\right), \tag{25}$$

i.e. densities are expressed by pressure and temperature in an efficient manner. By the way, inserting $T' = T - T_0$ results in

$$-g\frac{\rho'}{\rho} = +g\left(-1+\frac{p_0}{p}\frac{T}{T_0}(1+q_x)\right). \tag{26}$$

This form is used for the 'dynamical bottom boundary condition' (section 5.2.1). The reason is, that for parallelization no boundary exchange of T' is needed; instead an estimation of T by the starting value is used.

4 Discretization

4.1 Numerical operators for the spatial discretization

To define the numerical operators for the *spatial* discretizations we have to remember the distinct grid positions, where the different variables are located in the COSMO model. The main grid positions with integer indices (i, j, k) are those, where the scalars p, T, ρ, p_0, T_0, ρ_0, p', T', q_v, q_c, ... and the divergence D are located. The velocity components u are defined at the staggered grid position $(i+\frac{1}{2}, j, k)$, v at $(i, j+\frac{1}{2}, k)$, and w at $(i, j, k-\frac{1}{2})$. In the following, we will keep the half indices for the staggered velocity positions for clarification. One should notice that in the *COSMO code* the staggered grid positions $(i+\frac{1}{2}, j, k)$, $(i, j+\frac{1}{2}, k)$, and $(i, j, k-\frac{1}{2})$ (minus sign!) are denoted as `(i,j,k)` (this is indicated by the gray connection lines in Figure 1).

For the grid position definition of the metric terms one has to notice that the half level positions $z^{(h)}$ (or 'hhl'), i.e. with the 'w'-position indices $(i, j, k-\frac{1}{2})$ are prescribed. Therefore, $\frac{\partial z}{\partial \zeta}$ and $\frac{\partial \zeta}{\partial z}$ or $\sqrt{g}$ and $1/\sqrt{g}$ are defined most naturally at the scalar ('s') position (i, j, k) (in this context it might by denoted equally as the 'ww'-position), $\frac{\partial z}{\partial \lambda}$ is defined most naturally at the 'uw'-position $(i+\frac{1}{2}, j, k-\frac{1}{2})$, and $\frac{\partial z}{\partial \phi}$ most naturally at the 'vw'-position $(i, j+\frac{1}{2}, k-\frac{1}{2})$.

For the spatial discretization we introduce the following 2-point operators, leading to at most second order formulas. The limitation to two point operators in the vertical stems from the fact, that only a tridiagonal implicit equation system should occur. For the horizontal

operations in principle higher order discretizations may be used (this is currently under investigation by A. Will and J. Ogaja at the University in Cottbus), but here only 2-point formulas are used, too.

We start with the spatial *averaging* operators. Horizontal averaging is done by

$$\overline{\psi}^{\lambda}\Big|_{i,j,k} \equiv A_\lambda \psi|_{i,j,k} := \frac{1}{2}(\psi_{i-\frac{1}{2},j,k} + \psi_{i+\frac{1}{2},j,k}), \tag{27}$$

$$\overline{\psi}^{\phi}\Big|_{i,j,k} \equiv A_\phi \psi|_{i,j,k} := \frac{1}{2}(\psi_{i,j-\frac{1}{2},k} + \psi_{i,j+\frac{1}{2},k}). \tag{28}$$

These are second order discretizations. In the following, the notation with an over-bar '$\overline{\psi}$' is mostly used for prefactors, whereas the operator notation '$A\psi$' is mostly used for the prognostic variables, for which an implicit equation system will be derived.

For the vertical averaging we have to keep in mind the special definition of the so called main levels (index k) and the half levels (index $k+\frac{1}{2}$). As stated above, in the COSMO model, the user can prescribe the grid positions of the half levels $z^{(h)}_{i,j,k-\frac{1}{2}}$. The height of the main levels is a simple arithmetic average

$$z^{(m)}_{i,j,k} := \frac{1}{2}\left(z^{(h)}_{i,j,k-\frac{1}{2}} + z^{(h)}_{i,j,k+\frac{1}{2}}\right). \tag{29}$$

Accordingly an averaging from half level variables (e.g. w) to the main level is done by arithmetic averaging:

$$\overline{\psi}^{\zeta}\Big|_{i,j,k} \equiv A_\zeta \psi|_{i,j,k} := \frac{1}{2}(\psi_{i,j,k-\frac{1}{2}} + \psi_{i,j,k+\frac{1}{2}}). \tag{30}$$

But averaging from main level variables (e.g. p', T', ...) to the half level position is done by a weighting

$$\overline{\psi}^{\zeta,N}\Big|_{i,j,k-\frac{1}{2}} \equiv A^N_\zeta \psi\big|_{i,j,k-\frac{1}{2}} := g_{i,j,k-\frac{1}{2}}\psi_{i,j,k} + (1 - g_{i,j,k-\frac{1}{2}})\psi_{i,j,k-1} \tag{31}$$

with

$$g_{i,j,k-\frac{1}{2}} := \frac{z^{(h)}_{i,j,k-\frac{1}{2}} - z^{(h)}_{i,j,k-\frac{3}{2}}}{z^{(h)}_{i,j,k+\frac{1}{2}} - z^{(h)}_{i,j,k-\frac{3}{2}}}. \tag{32}$$

To be complete, we also note the extrapolation formula

$$\psi_{i,j,k+\frac{1}{2}} = -(1 - g_{i,j,k-\frac{1}{2}})\ \psi_{i,j,k-1} + (2 - g_{i,j,k-\frac{1}{2}})\ \psi_{i,j,k}. \tag{33}$$

For vertical averages for u and v one has to use appropriate weights $g_{i+\frac{1}{2},j,k-\frac{1}{2}}$ or $g_{i,j+\frac{1}{2},k-\frac{1}{2}}$, respectively. The appropriate averaging operators are denoted by a bar above the N: $A^{\bar{N}}_\zeta$ (of course one should even distinguish between the u or v position; but this can be easily seen from the context).

In the program code the denotations $g_{i,j,k-\frac{1}{2}}$ = `wgtfac(i,j,k)` , $g_{i+\frac{1}{2},j,k-\frac{1}{2}}$ = `wgtfac_u(i,j,k)` and $g_{i,j+\frac{1}{2},k-\frac{1}{2}}$ = `wgtfac_v(i,j,k)` (introduced by G. Zängl) are used.

Now we turn to spatial *derivatives*. For horizontal derivatives we can simply use the standard centered difference formulas

$$\delta_\lambda \psi|_{i,j,k} := \frac{\psi_{i+\frac{1}{2},j,k} - \psi_{i-\frac{1}{2},j,k}}{\Delta\lambda}, \tag{34}$$

$$\delta_\phi \psi|_{i,j,k} := \frac{\psi_{i,j+\frac{1}{2},k} - \psi_{i,j-\frac{1}{2},k}}{\Delta\phi}, \tag{35}$$

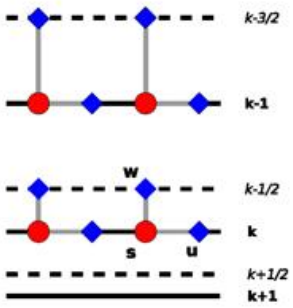

Figure 1: Denotation of the levels and the position of variables in the COSMO-model. Grey connection lines indicate staggered grid positions with the same indices in the COSMO program code.

and analogous for staggered variables.

In the case of vertical derivatives things become a little bit more complicated. Here one has to distinguish if the variable is defined on the half or the main level and if the target point is on a half or a main level.

The derivative of a half level variable at the position of the main level is obviously done by

$$\delta_\zeta \psi|_{i,j,k} := \frac{\psi_{i,j,k+\frac{1}{2}} - \psi_{i,j,k-\frac{1}{2}}}{\Delta\zeta}. \tag{36}$$

The derivative of a main level variable to the half level position could be done in the same way

$$\delta_\zeta^N \psi\big|_{i,j,k-\frac{1}{2}} := \frac{\psi_{i,j,k} - \psi_{i,j,k-1}}{\Delta\zeta} \tag{37}$$

with the argumentation, that from two points one can calculate a derivative only in one manner, independently from the position of the target point. But a second order formula can only be achieved if the target point is exactly in between the two main level points. For a decentered target point, the formula is only of first order accurate. Therefore, one should avoid this type of derivation operator, if possible.

Vertical derivative of a 'scalar variable to the u-Position':

$$\delta_\zeta^{(s,u)} \psi := A_\lambda \delta_\zeta A_\zeta^N \psi \tag{38}$$

An equally accurate discretization is

$$\delta_\zeta^{(s,u)} \psi := \delta_\zeta A_\zeta^{\bar{N}} A_\lambda \psi \tag{39}$$

For the vertical derivative 'u-Position to a scalar point' one can use

$$\delta_\zeta^{(u,s)} u := A_\lambda \delta_\zeta A_\zeta^{\bar{N}} u \tag{40}$$

analogous to eq. (38) or alternatively

$$\delta_\zeta^{(u,s)} u := \delta_\zeta A_\zeta^N A_\lambda u. \tag{41}$$

Vertical derivatives 'scalar to v-position' or 'v-position to scalar' are discretized analogously.

Now we define operators for combinations or products of vertical derivatives. Such larger stencils occur in particular in the metric correction terms.

- The following metric term occurring in the 'strong conservation'-form of the divergence is best discretized as

$$discr.^{(s)}\left[\frac{\partial z}{\partial \lambda}u\right] = \delta_\zeta\left(A_\lambda\left(\frac{\partial z}{\partial \lambda}A_\zeta^{\bar{N}}u\right)\right). \tag{42}$$

  Analogous for the y-direction.

- Metric terms of ∇p and ∇D

$$discr.^{(u)}\left[\frac{\partial \zeta}{\partial \lambda}\ \frac{\partial \psi}{\partial \zeta}\right] \tag{43}$$

  occur in the explicit integration of the horizontal momentum equations (hence, at the u- or v-position). The calculation of the metrical prefactor is done in any case by the partitioning

$$\frac{\partial \zeta}{\partial \lambda} = -\frac{\partial \zeta}{\partial z}\ \frac{\partial z}{\partial \lambda}. \tag{44}$$

  Here $\frac{\partial \zeta}{\partial z}$ is defined most naturally at the 's'-position and $\frac{\partial z}{\partial \lambda}$ most naturally at the 'uw'-position. Therefore

$$discr.\left[\frac{\partial \zeta}{\partial \lambda}\right] = -\left(A_\lambda\frac{\partial \zeta}{\partial z}\right)\cdot\left(A_\zeta\frac{\partial z}{\partial \lambda}\right). \tag{45}$$

  This results in

$$discr.^{(u)}\left[\frac{\partial \zeta}{\partial \lambda}\ \frac{\partial \psi}{\partial \zeta}\right] = -\left(A_\zeta\frac{\partial z}{\partial \lambda}\right)\cdot\left(A_\lambda\underbrace{\left(\frac{\partial \zeta}{\partial z}\delta_\zeta A_\zeta^N\psi\right)}_{=discr.^{(s)}\left[\frac{\partial \psi}{\partial z}\right]}\right). \tag{46}$$

  This means that a ζ-derivative can be expressed most naturally by a z-derivative. Analogous:

$$discr.^{(v)}\left[\frac{\partial \zeta}{\partial \phi}\ \frac{\partial \psi}{\partial \zeta}\right] = -\left(A_\zeta\frac{\partial z}{\partial \phi}\right)\cdot\left(A_\phi\underbrace{\left(\frac{\partial \zeta}{\partial z}\delta_\zeta A_\zeta^N\psi\right)}_{=discr.^{(s)}\left[\frac{\partial \psi}{\partial z}\right]}\right). \tag{47}$$

- For the z-derivative of a scalar variable at the s-position we use in the following

$$discr.^{(s)}\left[\frac{\partial \psi}{\partial z}\right] \equiv \delta_z^{(s,s)}\psi := \frac{\partial \zeta}{\partial z}\delta_\zeta A_\zeta^N\psi. \tag{48}$$

- We further remark that $\sqrt{g}$ at the 'w'-position can be better calculated directly by

$$\left.\frac{\partial z}{\partial \zeta}\right|_{k-\frac{1}{2}} = \frac{z_k^{(m)} - z_{k-1}^{(m)}}{1} = \frac{\frac{1}{2}\left(z_{k+\frac{1}{2}}^{(h)} + z_{k-\frac{1}{2}}^{(h)}\right) - \frac{1}{2}\left(z_{k-\frac{1}{2}}^{(h)} + z_{k-\frac{3}{2}}^{(h)}\right)}{1} = \frac{z_{k+\frac{1}{2}}^{(h)} - z_{k-\frac{3}{2}}^{(h)}}{2} \tag{49}$$

  instead of a weighted averaging, due to the special definition of the position of the main levels (hint by A. Will (personal communication)).

Some definitions of these operators may seem a bit ad hoc for the reader. A deeper reasoning for them is given in section 8, where truncation errors are calculated and those operators with the smallest error are chosen.

4.2 Discretization of the Euler equations

In the last section, spatial discretization operators have been defined, which are necessary for the numerical treatment of the Euler equations. The basic time integration idea behind the fast waves solver is the horizontally explicit-vertically implicit (HE-VI) scheme, where the horizontal integration is further done by a forward-backward scheme and the vertical implicit step is a general Crank-Nicholson scheme (?). It is therefore reasonable to define a general time averaging operator, here called a 'Crank-Nicholson time averaging operator', by

$$\hat{\beta}_i^{(a)}\phi := \beta_i^{(a)}\phi^{n+1} + \left(1-\beta_i^{(a)}\right)\phi^n. \tag{50}$$

The upper index (a) denotes a process, e.g. the terms for sound expansion (s), the lower index i simply enumerates terms. This nomenclature for the Crank-Nicholson weights is adopted from ?. To limit the number of weights $\beta_i^{(a)}$, not for every term an own Crank-Nicholson weighting parameter is introduced. u- and v-terms, which are analogous in a process, get the same weighting parameter, because the both horizontal directions have often quite equal rights in real model applications and their appropriate grid stretching in a limited area model are not so different.

Now, the discretized Euler equations are expressed by the formerly defined operators:

$$\begin{aligned}
\frac{u^{n+1}-u^n}{\Delta t} &= -\overline{\frac{1}{\rho}}^{\lambda}\,\overline{\frac{1}{r\cos\phi}}^{\lambda}\left(\hat{\beta}_1^s\delta_\lambda p' - \hat{\beta}_7^s\overline{\frac{\partial z}{\partial\lambda}}^{\zeta}\,A_\lambda\left(\delta_z^{(s,s)}p'\right)\right) + \\
&\quad +\overline{\frac{1}{\rho}}^{\lambda}\,\overline{\frac{1}{r\cos\phi}}^{\lambda}\left(\delta_\lambda(\alpha_{div}^h\rho D_{(uv)}) - \overline{\frac{\partial z}{\partial\lambda}}^{\zeta}\,A_\lambda\left(\delta_z^{(s,s)}(\alpha_{div}^h\rho D_{(uv)})\right)\right) + \left.\frac{\partial u}{\partial t}\right|_{slow} \qquad (51)\\
\frac{v^{n+1}-v^n}{\Delta t} &= -\overline{\frac{1}{\rho}}^{\phi}\,\overline{\frac{1}{r}}^{\phi}\left(\hat{\beta}_1^s\delta_\phi p' - \hat{\beta}_7^s\overline{\frac{\partial z}{\partial\phi}}^{\zeta}\,A_\phi\left(\delta_z^{(s,s)}p'\right)\right) + \\
&\quad +\overline{\frac{1}{\rho}}^{\phi}\,\overline{\frac{1}{r}}^{\phi}\left(\delta_\phi(\alpha_{div}^h\rho D_{(uv)}) - \overline{\frac{\partial z}{\partial\phi}}^{\zeta}\,A_\phi\left(\delta_z^{(s,s)}(\alpha_{div}^h\rho D_{(uv)})\right)\right) + \left.\frac{\partial v}{\partial t}\right|_{slow} \qquad (52)\\
\frac{w^{n+1}-w^n}{\Delta t} &= -\overline{\frac{1}{\rho}}^{\zeta,N}\left(\hat{\beta}_2^s\overline{\frac{\partial\zeta}{\partial z}}^{\zeta,N}\,\delta_\zeta^N p'\right) + \\
&\quad +g\left(\hat{\beta}_1^b\overline{\frac{p_0}{p}}^{\zeta,N}\,\overline{\frac{1}{T_0}}^{\zeta,N}\,A_\zeta^N T' - \hat{\beta}_2^b\overline{\frac{1}{p}}^{\zeta,N}\,A_\zeta^N p' + \overline{\frac{p_0}{p}}^{\zeta,N}\,\overline{\frac{T'}{T_0}}^{\zeta,N}\,\overline{q_x}^{\zeta,N}\right) + \\
&\quad +\overline{\frac{1}{\rho}}^{\zeta,N}\,\overline{\frac{\partial\zeta}{\partial z}}^{\zeta,N}\,\delta_\zeta^N(\alpha_{div}^v\rho D_{(w)}) + \left.\frac{\partial w}{\partial t}\right|_{slow} \qquad (53)\\
\frac{p'^{n+1}-p'^n}{\Delta t} &= -\frac{c_p}{c_V}pD_{(p)} + \hat{\beta}_3^b g\rho_0\,A_\zeta w + \left.\frac{\partial p'}{\partial t}\right|_{slow} \qquad (54)\\
\frac{T'^{n+1}-T'^n}{\Delta t} &= -\frac{R}{c_V}TD_{(T)} - \hat{\beta}_4^b\frac{\partial T_0}{\partial z}\,A_\zeta w + \left.\frac{\partial T'}{\partial t}\right|_{slow} \qquad (55)
\end{aligned}$$

Here, different divergences $D_{(p)}$, $D_{(T)}$, $D_{(uv)}$, $D_{(w)}$ have been introduced, because they can carry different Crank-Nicholson weights (see sections 4.2.1).

Be aware, that each variable has a distinct time index, too, by the Crank-Nicholson operators $\hat{\beta}$. Only the additional slow processes $\left.\frac{\partial u}{\partial t}\right|_{slow}, \ldots, \left.\frac{\partial T'}{\partial t}\right|_{slow}$ don't carry any time index: they are assumed to be constant during the small time step integration.

In deviation from the above defined operators, the following coefficient functions occurring

in the buoyancy terms are calculated by

$$\overline{\frac{1}{p}}^{\zeta,N} = \frac{1}{p_0(z_{k+1/2}) + A_\zeta^N p'}, \qquad \overline{\frac{p_0}{p}}^{\zeta,N} = \frac{1}{1 + \frac{A_\zeta^N p'}{p_0(z_{k+1/2})}}, \tag{56}$$

$$\overline{\frac{1}{T_0}}^{\zeta,N} = \frac{1}{T_0(z_{k+1/2})}, \qquad \overline{\frac{T}{T_0}}^{\zeta,N} = 1 + \frac{A_\zeta^N T'}{T_0(z_{k+1/2})}. \tag{57}$$

The writing for the reference state variables T_0 and p_0 indicates that they can be calculated *exactly* at their grid position[2] (proposal by A. Will (personal communication)). Analogous to that, $\overline{\frac{1}{\rho}}^{\zeta,N}$ in eq. (53) is calculated with the aid of the ideal gas equation by the values of $T_0(z_{k+1/2}) + A_\zeta^N T'$ and $p_0(z_{k+1/2}) + A_\zeta^N p'$. In particular $\overline{\frac{\partial \zeta}{\partial z}}^{\zeta,N}$ is calculated by (49).

4.2.1 Discretization of the divergence

The horizontal contributions of the divergence can be discretized by

$$\tilde{d}_{hor} := \delta_\lambda(\overline{\sqrt{g}}^{\lambda}\, u) + \delta_\phi(\overline{\cos\phi}^{\phi}\, \overline{\sqrt{g}}^{\phi}\, v). \tag{58}$$

For the vertical contribution

$$\tilde{d}_{vert} := \delta_\zeta Z, \tag{59}$$

Z, Z_x, Z_y, Z_{hor} and Z_{vert} are needed. They are most naturally defined at the w-position $(i, j, k - \frac{1}{2})$. However, one cannot directly use $\tilde{d}_{vert}$, because the implicit weighting must be considered.

Z_{hor} is calculated in the subroutine `calc_Z_horiz`, and discretized by

$$Z_{hor} = Z_x + Z_y, \tag{60}$$

$$Z_x = A_\lambda \left(\frac{\partial z}{\partial \lambda}\, A_\zeta^{\bar{N}}\, u \right), \tag{61}$$

$$Z_y = A_\phi \left(\frac{\partial z}{\partial \phi}\, \cos\phi\, A_\zeta^{\bar{N}}\, v \right). \tag{62}$$

In this manner Z_{hor} can be calculated for $k = 2, 3, ..., ke$. At $k = 1$ (upper boundary) one immediately gets $Z_{hor} = 0$ (due to $\frac{\partial z}{\partial \lambda} = 0$, ...). At $k = ke + 1$ (lower boundary) u and v must be extrapolated. In contrast

$$Z_{vert} := -r \cos\phi\, w \tag{63}$$

can be calculated at the boundaries, too.

The different divergence terms are:

$$D_{(p)} = \frac{1}{r\cos\phi}\, \frac{1}{\sqrt{g}} \left[\hat{\beta}_3^s\, \tilde{d}_{hor} + \hat{\beta}_8^s\, \delta_\zeta Z_{hor} + \hat{\beta}_4^s\, \delta_\zeta Z_{vert} \right]. \tag{64}$$

$$D_{(T)} = \frac{1}{r\cos\phi}\, \frac{1}{\sqrt{g}} \left[\hat{\beta}_5^s\, \tilde{d}_{hor} + \hat{\beta}_9^s\, \delta_\zeta Z_{hor} + \hat{\beta}_6^s\, \delta_\zeta Z_{vert} \right]. \tag{65}$$

[2]Therefore the reference state variables have to be calculated not only on the main levels but on the half level positions, too. This must be done in all modules, which calculate them. In particular in the interpolation program `int2lm` one has to set the namelist switch `lanalyt_calc_p0T0=.TRUE.`, if `irefatm=1` is still used.

$$D_{(uv)} = \frac{1}{r\cos\phi}\frac{1}{\sqrt{g}}\left[\hat{\beta}_1^d\,\tilde{d}_{hor} + \hat{\beta}_5^d\,\delta_\zeta Z_{hor} + \hat{\beta}_2^d\,\delta_\zeta Z_{vert}\right]. \tag{66}$$

$$D_{(w)} = \frac{1}{r\cos\phi}\frac{1}{\sqrt{g}}\left[\hat{\beta}_3^d\,\tilde{d}_{hor} + \hat{\beta}_6^d\,\delta_\zeta Z_{hor} + \hat{\beta}_4^d\,\delta_\zeta Z_{vert}\right]. \tag{67}$$

4.2.2 Mahrer discretization of the horizontal pressure gradients

The basic idea behind the discretization of the horizontal pressure gradient by ? consists in using the gradient $\frac{\partial p'(\lambda,z)}{\partial\lambda}$ on z-planes instead of the conventional form $\frac{\partial p'(\lambda,\zeta)}{\partial\lambda} + \frac{\partial\zeta}{\partial\lambda}\frac{\partial p'(\lambda,\zeta)}{\partial\zeta}$ (equivalently for the ϕ-direction). To this purpose p' is interpolated vertically on the left- and right hand side of the target u-position. This means, at both columns (i,j) and $(i+1,j)$ p' is interpolated at the height $z_{i+\frac{1}{2},j,k}$ from the vertically nearest p'-values (analogous to the λ-direction). In this manner, the nearest values of p' are used in steep terrain. In contrast, in the above mentioned 'conventional' discretization, it can happen, that $\frac{\partial p'(\lambda,\zeta)}{\partial\zeta}$ is estimated from p'-values, which are (vertically) quite far away. This bears the risk of an instability, which does not occur in the Mahrer-approach.

A crucial point in the Mahrer discretization lies in the fact, that in the vicinity of steep terrain, interpolation is not longer possible, when $z_{i+\frac{1}{2},j,k}$ lies under the orography at least on one side of the u-position. As pointed out by ?, the then required *extrapolation* of p' often leads to similar instabilities as the conventional discretization. ? describes a way, how to estimate the extrapolation by the hydrostatic approximation in the ICON dynamical core. Unfortunately, the need for a (quasi-)3-dimensional divergence damping necessary in the time-splitting approach (?, ?) does not allow to transfer this idea to the COSMO fast waves solver (there is no hydrostatic approximation for the divergence).

However, in the new fast waves solver, an also linear extrapolation is used if $z_{i,j,ke} > z_{i+\frac{1}{2},j,k}$ (similar for the other neighboring orography heights). This indeed can help to increase stability in steep terrain in idealized test scenarios (see sections 9.4 and 9.5). But in real case applications, this approach is not entirely satisfying. One reason could be the occurring of a mixed term in the Taylor expansion (section 8.2). Therefore, though the Mahrer discretization has proven as a stable method in several real case runs (mainly for COSMO-DE), the conventional discretization is still recommended.

5 Boundary conditions

5.1 The free slip condition

At the upper and lower boundaries the pure Euler equations (i.e. without friction/diffusion) possess only one physical boundary condition: the free slip condition, i.e. the velocity component perpendicular to the boundary must be zero

$$\dot{\zeta} = 0, \tag{68}$$

which is equivalent to

$$w = \frac{1}{r\cos\phi}\frac{\partial z}{\partial\lambda}u + \frac{1}{r}\frac{\partial z}{\partial\phi}v. \tag{69}$$

As mentioned above, the vertically implicit solver needs this boundary condition at time level $n+1$. This is not a problem, because u^{n+1} and v^{n+1} are already known by the forward step of the horizontal momentum equations.

At the top boundary we can simply prescribe

$$\dot{\zeta}_{i,j,k=\frac{1}{2}} = 0 \quad \Rightarrow \quad w^{n+1}_{i,j,\frac{1}{2}} = 0. \tag{70}$$

At the lower boundary the free slip condition reduces to

$$w^{n+1}_{i,j,ke+\frac{1}{2}} = \frac{1}{r\cos\phi}\left[A_\lambda\left(\frac{\partial z}{\partial \lambda}\, u^{n+1}_{(sfc)}\right) + A_\phi\left(\frac{\partial z}{\partial \phi}\cos\phi\, v^{n+1}_{(sfc)}\right)\right], \tag{71}$$

where the $\cos\phi$-terms are arranged analogous to the strong conservation form of the divergence. $u^{n+1}_{(sfc)}$ and $v^{n+1}_{(sfc)}$ must be known at $k = ke + \frac{1}{2}$, therefore they must be extrapolated.

5.2 Boundary treatments

The following considerations does not concern true physical boundary conditions, but *boundary treatments* in the sense that the appropriate terms cannot longer be calculated by centered differences but need a different numerical treatment.

5.2.1 The vertical pressure gradient in the horizontal equations of motion

In the both horizontal momentum equations there is a need to have a different discretization of $\partial p'/\partial z$ or alternatively of $\partial\left(p' - \alpha^h_{div}\rho D\right)/\partial z$.

At the bottom boundary there exist two options. Th first option is to use a one sided formula. Günther Zängl proposed to use a one sided derivative of *2nd order accuracy* (a first order formula is not accurate enough!) instead of the boundary treatment described in[3] (?, section 5.4).

For three arbitrarily prescribed points

$$z_1, \quad z_2 = z_1 + h_1, \quad z_3 = z_1 + h_2, \tag{72}$$

one can derive a one-sided derivative formula of 2nd order for a function $f(z)$ in z_1 by

$$af(z_1) + bf(z_2) + cf(z_3) = (a+b+c)f + (bh_1 + ch_2)f' + \left(b\frac{h_1^2}{2} + c\frac{h_2^2}{2}\right)f'' + \ldots. \tag{73}$$

This results in the weights

$$a = -(b+c), \tag{74}$$

$$b = \frac{1 - ch_2}{h_1}, \tag{75}$$

$$c = \frac{h_1}{h_2(h_1 - h_2)}. \tag{76}$$

This is active if the switch `ldyn_bbc=.FALSE.` is set. If it is set to `.TRUE.`, then the other possibility is used, the so called 'dynamical bottom boundary boundary' (?), described in the next section 5.2.1.

At the top boundary a one sided derivative formula of first order is sufficient.

[3]Therefore the switch `ldyn_bbc=.FALSE.` has a different meaning in the two fast waves solver versions.

Dynamic bottom boundary condition for the pressure In section 5.4 of ? the strong influence of the formulation of the lower boundary condition for the pressure p' was mentioned. Instead of a pressure extrapolation, ? proposed a so called 'dynamic bottom (or lower) boundary condition' for p'. The goal is to determine $\partial p'/\partial\zeta$ in a manner *consistent* to the free-slip condition $\dot{\zeta} = 0$. The starting point for the derivation is the bottom boundary condition $\dot{\zeta} = 0$ at the surface $z = h_s(\lambda, \phi)$, explicitly written

$$\dot{\zeta} = \frac{u}{r\cos\phi}\left.\frac{\partial\zeta}{\partial\lambda}\right|_z + \frac{v}{r}\left.\frac{\partial\zeta}{\partial\phi}\right|_z + w\frac{\partial\zeta}{\partial z} = 0. \tag{77}$$

The vertical pressure gradient occurs in the three momentum equations, therefore we differentiate by time to obtain

$$\frac{\partial\dot{\zeta}}{\partial t} = \frac{1}{r\cos\phi}\left.\frac{\partial\zeta}{\partial\lambda}\right|_z \frac{\partial u}{\partial t} + \frac{1}{r}\left.\frac{\partial\zeta}{\partial\phi}\right|_z \frac{\partial v}{\partial t} + \frac{\partial\zeta}{\partial z}\frac{\partial w}{\partial t} = 0. \tag{78}$$

Here we insert the momentum equations (1)-(3) in the form

$$\begin{aligned}
\frac{\partial u}{\partial t} &= F_u - \frac{1}{\rho}\frac{1}{r\cos\phi}\frac{\partial z}{\partial\lambda}\left(-\frac{\partial\zeta}{\partial z}\frac{\partial\tilde{p}}{\partial\zeta}\right), \\
\frac{\partial v}{\partial t} &= F_v - \frac{1}{\rho}\frac{1}{r}\frac{\partial z}{\partial\phi}\left(-\frac{\partial\zeta}{\partial z}\frac{\partial\tilde{p}}{\partial\zeta}\right), \\
\frac{\partial w}{\partial t} &= F_w - \frac{1}{\rho}\frac{\partial\zeta}{\partial z}\frac{\partial\tilde{p}}{\partial\zeta},
\end{aligned}$$

with $\tilde{p} = p' - \alpha^h_{div}\rho D$ and

$$F_u := -\frac{1}{\rho}\frac{1}{r\cos\phi}\frac{\partial\tilde{p}}{\partial\lambda} + \left.\frac{\partial u}{\partial t}\right|_{slow} \tag{79}$$

$$F_v := -\frac{1}{\rho}\frac{1}{r}\frac{\partial\tilde{p}}{\partial\phi} + \left.\frac{\partial v}{\partial t}\right|_{slow} \tag{80}$$

$$F_w := +g\left(-1 + \frac{p_0}{p}\frac{T}{T_0}(1+q_x)\right) + \frac{1}{\rho}\frac{\partial\zeta}{\partial z}\frac{\partial(\alpha^v_{div} - \alpha^h_{div})\rho D}{\partial\zeta} + \left.\frac{\partial w}{\partial t}\right|_{slow}. \tag{81}$$

In F_w the form (26) of the buoyancy term was used. Sorting by $\frac{\partial\zeta}{\partial z}\frac{\partial p'}{\partial\zeta}$ finally results in

$$\frac{\partial\zeta}{\partial z}\frac{\partial p'}{\partial\zeta}\frac{1}{\rho}\left[\left(\frac{1}{r\cos\phi}\frac{\partial z}{\partial\lambda}\right)^2 + \left(\frac{1}{r}\frac{\partial z}{\partial\phi}\right)^2 + 1\right] = -\frac{1}{r\cos\phi}\frac{\partial z}{\partial\lambda}F_u - \frac{1}{r}\frac{\partial z}{\partial\phi}F_v + F_w. \tag{82}$$

This delivers the needed value of $\frac{\partial\zeta}{\partial z}\frac{\partial p'}{\partial\zeta}$ at the lower boundary (for $k = ke$) in the u- and v-equation. The discretization of this expression and the averaging to the u and v position is straightforward. Nevertheless, several spatial interpolations with 4-point or even 8-point formulas are needed.

5.2.2 Boundary treatment of the divergence

In the 'strong conservation form' the horizontal derivatives may be calculated in every grid point by centered differences, even at the boundary points (see eq. (10)).

For the remaining vertical derivative $\frac{\partial Z}{\partial\zeta}$ one needs Z at the boundary, i.e. at $k = ke + 1/2$ and $k = 1/2$. For this two variants are possible. First it can be calculated by extrapolation; this is currently implemented.

Second, through the use of the *exact* boundary condition $Z = 0$. This is a theoretical advantage of the 'strong conservation form'. An important requirement for this is that the implicit weightings are chosen as

$$\beta_8^s = \beta_4^s, \quad \text{and} \quad \beta_9^s = \beta_6^s. \tag{83}$$

But nevertheless, there remains the problem that Z must be subdivided into horizontal and vertical parts, due to the vertically implicit solver. Therefore one cannot pose this exact boundary condition for the divergence itself. This probably is the reason, why this second boundary treatment does not work until now.

6 The linear equation system for the vertical velocity

6.1 Setup of the equation system

To get rid of the sound speed limitation, the Euler equations are solved vertically implicit. To derive the equation system we write the Euler equations in the following linear form

$$\mathbf{A} \begin{pmatrix} u^{n+1} \\ v^{n+1} \\ w^{n+1} \\ p'^{n+1} \\ T'^{n+1} \end{pmatrix} = \mathbf{b}^n$$

with

$$\mathbf{A} = \begin{pmatrix} \frac{1}{\Delta t}\mathbf{1} & 0 & 0 & \mathbf{A}_{up} & 0 \\ 0 & \frac{1}{\Delta t}\mathbf{1} & 0 & \mathbf{A}_{vp} & 0 \\ \mathbf{A}_{wu} & \mathbf{A}_{wv} & \mathbf{A}_{ww} & \mathbf{A}_{wp} & \mathbf{A}_{wT} \\ \mathbf{A}_{pu} & \mathbf{A}_{pv} & \mathbf{A}_{pw} & \frac{1}{\Delta t}\mathbf{1} & 0 \\ \mathbf{A}_{Tu} & \mathbf{A}_{Tv} & \mathbf{A}_{Tw} & 0 & \frac{1}{\Delta t}\mathbf{1} \end{pmatrix}, \tag{84}$$

and

$$\mathbf{b}^n = (b_u, b_v, b_w, b_p, b_T)^T. \tag{85}$$

Of course, nearly all the terms arising in the Euler equations are non-linear. But this non-linearity in the sound and buoyancy terms is small enough, that in every small time step, the coefficients can be considered as quasi constant. They can even be considered as constant through the whole fast waves integration procedure[4].

Here the following operators have been used for the horizontal momentum equations

$$\mathbf{A}_{up} = \overline{\frac{1}{\rho}}^{\lambda} \overline{\frac{1}{r\cos\phi}}^{\lambda} \left(\beta_1^s \, \delta_\lambda - \beta_7^s \overline{\frac{\partial z}{\partial \lambda}}^{\zeta} A_\lambda \delta_z^{(s,s)} \right), \tag{86}$$

$$\mathbf{A}_{vp} = \overline{\frac{1}{\rho}}^{\phi} \overline{\frac{1}{r}}^{\phi} \left(\beta_1^s \, \delta_\phi - \beta_7^s \overline{\frac{\partial z}{\partial \phi}}^{\zeta} A_\phi \delta_z^{(s,s)} \right), \tag{87}$$

In $\mathbf{A}$ we have already used the fact, that the artificial divergence damping in the u- and v-equation must be treated explicitly, i.e. $\beta_1^d = \beta_2^d = \beta_5^d = 0$, otherwise no tridiagonal

[4]There is an internal switch `l_small_pert_in_pT`. If it is set to `.TRUE.`, then the coefficients (i.e. the lhs) of this equation system is calculated only once per *large* time step. If it is set to `.FALSE.`, then they are set in every small time step. The latter setting may be an interesting, although efficiency reducing, option in heavy weather conditions, e.g. in the simulation of tornadoes.

system can be achieved. We will see below that the horizontal pressure gradient terms must be treated fully explicit, too; therefore, $\mathbf{A}_{up} = 0$ and $\mathbf{A}_{vp} = 0$.

For the vertical momentum equation we get

$$\mathbf{A}_{wu} = -\overline{\left(\frac{1}{\rho}\right)}^{\zeta,N} \overline{\frac{\partial\zeta}{\partial z}}^{\zeta,N} \delta_\zeta^N \left[\alpha_{div}^v \rho \frac{1}{r\cos\phi} \frac{1}{\sqrt{g}} \left(\beta_3^d \, \delta_\lambda(\overline{\sqrt{g}}^\lambda \cdot ...) + \beta_6^d \, \mathbf{B}_x\right)\right], \tag{88}$$

$$\mathbf{A}_{wv} = -\overline{\left(\frac{1}{\rho}\right)}^{\zeta,N} \overline{\frac{\partial\zeta}{\partial z}}^{\zeta,N} \delta_\zeta^N \left[\alpha_{div}^v \rho \frac{1}{r\cos\phi} \frac{1}{\sqrt{g}} \left(\beta_3^d \, \delta_\phi(\overline{\cos\phi\sqrt{g}}^\phi \cdot ...) + \beta_6^d \, \mathbf{B}_y\right)\right], \tag{89}$$

$$\mathbf{A}_{ww} = \frac{1}{\Delta t}\mathbf{1} + \overline{\left(\frac{1}{\rho}\right)}^{\zeta,N} \overline{\frac{\partial\zeta}{\partial z}}^{\zeta,N} \delta_\zeta^N \left[\alpha_{div}^v \rho \frac{1}{r\cos\phi} \frac{1}{\sqrt{g}} \beta_4^d \, \delta_\zeta(r\cos\phi \cdot ...)\right], \tag{90}$$

$$\mathbf{A}_{wp} = \overline{\left(\frac{1}{\rho}\right)}^{\zeta,N} \overline{\frac{\partial\zeta}{\partial z}}^{\zeta,N} \beta_2^s \, \delta_\zeta^N + g\beta_2^b \overline{\frac{1}{p}}^{\zeta,N} A_\zeta^N, \tag{91}$$

$$\mathbf{A}_{wT} = -g\beta_1^b \overline{\frac{p_0}{p}}^{\zeta,N} \overline{\frac{1}{T_0}}^{\zeta,N} A_\zeta^N, \tag{92}$$

for the pressure equation

$$\mathbf{A}_{pu} = +\frac{c_p}{c_v} p \frac{1}{r\cos\phi} \frac{1}{\sqrt{g}} \left[\beta_3^s \, \delta_\lambda \left(\overline{\sqrt{g}}^\lambda \cdot ...\right) + \beta_8^s \, \mathbf{B}_x,\right] \tag{93}$$

$$\mathbf{A}_{pv} = +\frac{c_p}{c_v} p \frac{1}{r\cos\phi} \frac{1}{\sqrt{g}} \left[\beta_3^s \, \delta_\phi \left(\overline{\cos\phi\sqrt{g}}^\phi \cdot ...\right) + \beta_8^s \, \mathbf{B}_y\right], \tag{94}$$

$$\mathbf{A}_{pw} = -\frac{c_p}{c_v} p \frac{1}{r\cos\phi} \frac{1}{\sqrt{g}} \beta_4^s \, \delta_\zeta(r\cos\phi \cdot ...) - \beta_3^b g\rho_0 A_\zeta, \tag{95}$$

and for the temperature equation

$$\mathbf{A}_{Tu} = +\frac{R}{c_v} T \frac{1}{r\cos\phi} \frac{1}{\sqrt{g}} \left[\beta_5^s \, \delta_\lambda \left(\overline{\sqrt{g}}^\lambda \cdot ...\right) + \beta_9^s \, \mathbf{B}_x\right], \tag{96}$$

$$\mathbf{A}_{Tv} = +\frac{R}{c_v} T \frac{1}{r\cos\phi} \frac{1}{\sqrt{g}} \left[\beta_5^s \, \delta_\phi \left(\overline{\cos\phi\sqrt{g}}^\phi \cdot ...\right) + \beta_9^s \, \mathbf{B}_y\right], \tag{97}$$

$$\mathbf{A}_{Tw} = -\frac{R}{c_v} T \frac{1}{r\cos\phi} \frac{1}{\sqrt{g}} \beta_6^s \, \delta_\zeta(r\cos\phi \cdot ...) + \beta_4^b \frac{\partial T_0}{\partial z} A_\zeta, \tag{98}$$

where operators for the calculation of $\delta_\zeta Z_{hor}$ have been introduced:

$$\mathbf{B}_x := \delta_\zeta \left(A_\lambda \left(\frac{\partial z}{\partial\lambda} \, A_\zeta^{\bar{N}} \, \ldots\right)\right), \tag{99}$$

$$\mathbf{B}_y := \delta_\zeta \left(A_\phi \left(\frac{\partial z}{\partial\phi} \, \cos\phi \, A_\zeta^{\bar{N}} \, \ldots\right)\right). \tag{100}$$

Using again the shallow atmosphere approximation ($r \approx r_{earth}$ in all the prefactors) we can cancel $r\cos\phi$ in $\mathbf{A}_{pw}$, $\mathbf{A}_{Tw}$, and $\mathbf{A}_{ww}$.

The right hand sides are

$$b^n_{(u)} = \frac{1}{\Delta t}u^n - \overline{\frac{1}{\rho}}^{\lambda}\overline{\frac{1}{r\cos\phi}}^{\lambda}\left((1-\beta^s_1)\delta_\lambda p'^n - (1-\beta^s_7)\overline{\frac{\partial z}{\partial\lambda}}^{\zeta} A_\lambda\left(\delta^{(s,s)}_z p'^n\right)\right) + \\ + \overline{\frac{1}{\rho}}^{\lambda}\overline{\frac{1}{r\cos\phi}}^{\lambda}\left(\delta_\lambda(\alpha^h_{div}\,\rho\,D^n_{(uv)}) - \overline{\frac{\partial z}{\partial\lambda}}^{\zeta} A_\lambda\left(\delta^{(s,s)}_z(\alpha^h_{div}\,\rho\,D^n_{(uv)})\right)\right) + \left.\frac{\partial u}{\partial t}\right|_{slow}, \quad (101)$$

$$b^n_{(v)} = \frac{1}{\Delta t}v^n - \overline{\frac{1}{\rho}}^{\phi}\overline{\frac{1}{r}}^{\phi}\left((1-\beta^s_1)\delta_\phi p'^n - (1-\beta^s_7)\overline{\frac{\partial z}{\partial\phi}}^{\zeta} A_\phi\left(\delta^{(s,s)}_z p'^n\right)\right) + \\ + \overline{\frac{1}{\rho}}^{\phi}\overline{\frac{1}{r}}^{\phi}\left(\delta_\phi(\alpha^h_{div}\,\rho\,D^n_{(uv)}) - \overline{\frac{\partial z}{\partial\phi}}^{\zeta} A_\phi\left(\delta^{(s,s)}_z(\alpha^h_{div}\,\rho\,D^n_{(uv)})\right)\right) + \left.\frac{\partial v}{\partial t}\right|_{slow}, \quad (102)$$

$$b^n_{(w)} = \frac{1}{\Delta t}w^n - \overline{\frac{1}{\rho}}^{\zeta,N}(1-\beta^s_2)\overline{\frac{\partial\zeta}{\partial z}}^{\zeta,N}\delta^N_\zeta p'^n + \\ + g\left((1-\beta^b_1)\overline{\frac{p_0}{p}}^{\zeta,N}\overline{\frac{1}{T_0}}^{\zeta,N} A^N_\zeta T' - (1-\beta^b_2)\overline{\frac{1}{p}}^{\zeta,N} A^N_\zeta p' + \overline{\frac{p_0}{p}}^{\zeta,N}\overline{\frac{T}{T_0}}^{\zeta,N}\overline{q_x}^{\zeta,N}\right) + \\ + \overline{\frac{1}{\rho}}^{\zeta,N}\overline{\frac{\partial\zeta}{\partial z}}^{\zeta,N}\delta^N_\zeta(\alpha^v_{div}\,\rho\,D^n_{(w)}) + \left.\frac{\partial w}{\partial t}\right|_{slow}, \quad (103)$$

$$b^n_{(p)} = \frac{1}{\Delta t}p'^n - \frac{c_p}{c_V}pD^n_{(p)} + (1-\beta^b_3)g\rho_0\,A_\zeta w^n + \left.\frac{\partial p'}{\partial t}\right|_{slow}, \quad (104)$$

$$b^n_{(T)} = \frac{1}{\Delta t}T'^n - \frac{R}{c_V}TD^n_{(T)} - (1-\beta^b_4)\frac{\partial T_0}{\partial z}A_\zeta w^n + \left.\frac{\partial T'}{\partial t}\right|_{slow}, \quad (105)$$

with the explicit divergence terms

$$D^n_{(p)} = \frac{1}{r\cos\phi}\frac{1}{\sqrt{g}}\left[(1-\beta^s_3)\,\tilde{d}^n_{hor} + (1-\beta^s_8)\,\delta_\zeta Z^n_{hor} + (1-\beta^s_4)\,\delta_\zeta Z^n_{vert}\right], \quad (106)$$

$$D^n_{(T)} = \frac{1}{r\cos\phi}\frac{1}{\sqrt{g}}\left[(1-\beta^s_5)\,\tilde{d}^n_{hor} + (1-\beta^s_9)\,\delta_\zeta Z^n_{hor} + (1-\beta^s_6)\,\delta_\zeta Z^n_{vert}\right], \quad (107)$$

$$D^n_{(uv)} = \frac{1}{r\cos\phi}\frac{1}{\sqrt{g}}\left[(1-\beta^d_1)\,\tilde{d}^n_{hor} + (1-\beta^d_5)\,\delta_\zeta Z^n_{hor} + (1-\beta^d_2)\,\delta_\zeta Z^n_{vert}\right], \quad (108)$$

$$D^n_{(w)} = \frac{1}{r\cos\phi}\frac{1}{\sqrt{g}}\left[(1-\beta^d_3)\,\tilde{d}^n_{hor} + (1-\beta^d_6)\,\delta_\zeta Z^n_{hor} + (1-\beta^d_4)\,\delta_\zeta Z^n_{vert}\right]. \quad (109)$$

Here $\tilde{d}^n_{hor}$ is calculated by eq. (58) and Z^n_{hor} by eq. (60)-(62) (in both cases with u^n and v^n, Z^n_{vert} analogous to eq. (63) with w^n).

6.2 Solution of the tridiagonal equation system

The solution of the tridiagonal equation system is a tedious, but straightforward work. First, one only ends up with a tridiagonal equation system, if the following requirements for the implicit weightings are fulfilled:

$$\beta^{(s)}_1 = 0, \quad \beta^{(s)}_7 = 0, \quad (110)$$

and

$$\beta^{(d)}_1 = 0, \quad \beta^{(d)}_2 = 0, \quad \beta^{(d)}_5 = 0, \quad \beta^{(d)}_7 = 0. \quad (111)$$

This simply means, that the equations for u and v must be solved explicitly, i.e. in a pure forward sense:

$$u^{n+1} = \Delta t\, b^n_{(u)}, \tag{112}$$
$$v^{n+1} = \Delta t\, b^n_{(v)}. \tag{113}$$

This can be done at the beginning of the small time step. As said above, the updated values u^{n+1}, v^{n+1} are already available to formulate the boundary condition for the implicit equation system for w^{n+1}. ? determines optimal values of the remaining off-centering weights by a stability analysis to

$$\beta_3^{(s)} = \beta_5^{(s)} = 1, \quad \beta_2^{(s)} = \beta_4^{(s)} = \beta_6^{(s)} = 0.7, \tag{114}$$
$$\beta_1^{(b)} = \beta_2^{(b)} = \beta_3^{(b)} = \beta_4^{(b)} = 0.7, \tag{115}$$
$$\beta_3^{(d)} = \beta_4^{(d)} = 1.0. \tag{116}$$

Further we use for the metric correction terms $\beta_8^{(s)} = \beta_4^{(s)}$, $\beta_9^{(s)} = \beta_6^{(s)}$, and $\beta_6^{(d)} = \beta_4^{(d)}$.

Finally the equation system can be formulated as a linear system of equations for w

$$A_{k-\frac{1}{2}} w_{k-\frac{3}{2}} + B_{k-\frac{1}{2}} w_{k-\frac{1}{2}} + C_{k-\frac{1}{2}} w_{k+\frac{1}{2}} = rhs_{k-\frac{1}{2}} \tag{117}$$

(A, B, C, rhs and w are further defined at (i, j)) with the coefficients

$$\begin{aligned}
A_{k-\frac{1}{2}} = \; & -a_{wp1\,|\,k-\frac{1}{2}} \cdot a_{pw1\,|\,k-1} \cdot r_c \\
& +a_{wp1\,|\,k-\frac{1}{2}} \cdot a_{pw2\,|\,k-1} \cdot \frac{1}{2} \\
& +a_{wp2\,|\,k-\frac{1}{2}} \cdot (1-g_{k-\frac{1}{2}}) \cdot a_{pw1\,|\,k-1} \cdot r_c \\
& -a_{wp2\,|\,k-\frac{1}{2}} \cdot (1-g_{k-\frac{1}{2}}) \cdot a_{pw2\,|\,k-1} \cdot \frac{1}{2} \\
& +a_{wT\,|\,k-\frac{1}{2}} \cdot (1-g_{k-\frac{1}{2}}) \cdot a_{Tw1\,|\,k-1} \cdot r_c \\
& -a_{wT\,|\,k-\frac{1}{2}} \cdot (1-g_{k-\frac{1}{2}}) \cdot a_{Tw2\,|\,k-1} \cdot \frac{1}{2} \\
& +\frac{1}{\Delta t}\, a_{ww1\,|\,k-\frac{1}{2}} \cdot a_{ww2\,|\,k-1} \cdot r_c
\end{aligned}$$

$$\begin{aligned}
B_{k-\frac{1}{2}} = \; & +a_{wp1\,|\,k-\frac{1}{2}} \cdot \left[a_{pw1\,|\,k} + a_{pw1\,|\,k-1}\right] \cdot r_c \\
& -a_{wp1\,|\,k-\frac{1}{2}} \cdot \left[a_{pw2\,|\,k} - a_{pw2\,|\,k-1}\right] \cdot \frac{1}{2} \\
& -a_{wp2\,|\,k-\frac{1}{2}} \cdot \left[-g_{k-\frac{1}{2}} \cdot a_{pw1\,|\,k} + (1-g_{k-\frac{1}{2}}) \cdot a_{pw1\,|\,k-1}\right] \cdot r_c \\
& -a_{wp2\,|\,k-\frac{1}{2}} \cdot \left[+g_{k-\frac{1}{2}} \cdot a_{pw2\,|\,k} + (1-g_{k-\frac{1}{2}}) \cdot a_{pw2\,|\,k-1}\right] \cdot \frac{1}{2} \\
& -a_{wT\,|\,k-\frac{1}{2}} \cdot \left[-g_{k-\frac{1}{2}} \cdot a_{Tw1\,|\,k} + (1-g_{k-\frac{1}{2}}) \cdot a_{Tw1\,|\,k-1}\right] \cdot r_c \\
& -a_{wT\,|\,k-\frac{1}{2}} \cdot \left[+g_{k-\frac{1}{2}} \cdot a_{Tw2\,|\,k} + (1-g_{k-\frac{1}{2}}) \cdot a_{Tw2\,|\,k-1}\right] \cdot \frac{1}{2} \\
& -\frac{1}{\Delta t}\, a_{ww1\,|\,k-\frac{1}{2}} \cdot \left[a_{ww2\,|\,k} + a_{ww2\,|\,k-1}\right] \cdot r_c \\
& +\frac{1}{\Delta t^2}
\end{aligned}$$

$$
\begin{aligned}
C_{k-\frac{1}{2}} \;=\; & -a_{wp1\,|\,k-\frac{1}{2}} \cdot a_{pw1\,|\,k} \cdot r_c \\
& -a_{wp1\,|\,k-\frac{1}{2}} \cdot a_{pw2\,|\,k} \cdot \frac{1}{2} \\
& -a_{wp2\,|\,k-\frac{1}{2}} \cdot g_{k-\frac{1}{2}} \cdot a_{pw1\,|\,k} \cdot r_c \\
& -a_{wp2\,|\,k-\frac{1}{2}} \cdot g_{k-\frac{1}{2}} \cdot a_{pw2\,|\,k} \cdot \frac{1}{2} \\
& -a_{wT\,|\,k-\frac{1}{2}} \cdot g_{k-\frac{1}{2}} \cdot a_{Tw1\,|\,k} \cdot r_c \\
& -a_{wT\,|\,k-\frac{1}{2}} \cdot g_{k-\frac{1}{2}} \cdot a_{Tw2\,|\,k} \cdot \frac{1}{2} \\
& +\frac{1}{\Delta t}\, a_{ww1\,|\,k-\frac{1}{2}} \cdot a_{ww2\,|\,k} \cdot r_c
\end{aligned}
$$

using the denotations

$$
a_{wp1} := \overline{\left(\frac{1}{\rho}\right)}^{\zeta,N} \overline{\frac{\partial\zeta}{\partial z}}^{\zeta,N} \beta_2^s, \qquad a_{wp2} := g\,\beta_2^b \overline{\left(\frac{1}{p}\right)}^{\zeta,N}, \tag{118}
$$

$$
a_{ww1} := \overline{\left(\frac{1}{\rho}\right)}^{\zeta,N} \overline{\frac{\partial\zeta}{\partial z}}^{\zeta,N}, \qquad a_{ww2} := \alpha_{div}^v\,\rho\,\frac{1}{r\cos\phi}\,\frac{1}{\sqrt{g}}\,\beta_4^d, \tag{119}
$$

$$
a_{wT} := -g\,\overline{\left(\frac{p_0}{p}\right)}^{\zeta,N} \overline{\left(\frac{1}{T_0}\right)}^{\zeta,N} \beta_1^b, \tag{120}
$$

$$
a_{pw1} := -\frac{c_p}{c_v}\,p\,\frac{1}{r\cos\phi}\,\frac{1}{\sqrt{g}}\,\beta_4^s, \qquad a_{pw2} := -\beta_3^b g\rho_0, \tag{121}
$$

$$
a_{Tw1} := -\frac{R}{c_v}\,T\,\frac{1}{r\cos\phi}\,\frac{1}{\sqrt{g}}\,\beta_6^s, \qquad a_{Tw2} := \beta_4^b \frac{\partial T_0}{\partial z}, \tag{122}
$$

and

$$
r_c := \overline{r\,\cos\phi}^{\zeta}. \tag{123}
$$

In a_{pw1}, a_{Tw1}, and a_{ww2} one can cancel $r\cos\phi$ terms by the shallow atmosphere approximation and may set $r_c = 1$. (By efficiency reasons the averaging factor $1/2$ is defined into a_{pw2} and a_{Tw2} in the program code.)

The right hand side of eq. (117) reads

$$
\begin{aligned}
rhs \;:=\; & -\mathbf{A}_{wp} \underbrace{\left[b_p^{(n)} - (\mathbf{A}_{pu}u^{n+1} + \mathbf{A}_{pv}v^{n+1})\right]}_{=:b_{4,p}} \\
& -\mathbf{A}_{wT}\left[b_T^{(n)} - (\mathbf{A}_{Tu}u^{n+1} + \mathbf{A}_{Tv}v^{n+1})\right] \\
& +\frac{1}{\Delta t}\left[b_w^{(n)} - (\mathbf{A}_{wu}u^{n+1} + \mathbf{A}_{wv}v^{n+1})\right].
\end{aligned} \tag{124}
$$

We express some of the needed terms more explicitly by

$$
\mathbf{A}_{pu}u^{n+1} + \mathbf{A}_{pv}v^{n+1} = \frac{c_p}{c_v}\,p\,\frac{1}{r\cos\phi}\,\frac{1}{\sqrt{g}}\left[\beta_3^s\,\tilde{d}_{hor}^{n+1} + \beta_8^s\,\delta_\zeta Z_{hor}^{n+1}\right], \tag{125}
$$

$$
\mathbf{A}_{Tu}u^{n+1} + \mathbf{A}_{Tv}v^{n+1} = \frac{R}{c_v}\,T\,\frac{1}{r\cos\phi}\,\frac{1}{\sqrt{g}}\left[\beta_5^s\,\tilde{d}_{hor}^{n+1} + \beta_9^s\,\delta_\zeta Z_{hor}^{n+1}\right], \tag{126}
$$

$$
\mathbf{A}_{wu}u^{n+1} + \mathbf{A}_{wv}v^{n+1} = -\overline{\left(\frac{1}{\rho}\right)}^{\zeta,N} \overline{\frac{\partial\zeta}{\partial z}}^{\zeta,N} \delta_\zeta^N \left[\frac{\alpha_{div}^v\,\rho}{r\cos\phi}\,\frac{1}{\sqrt{g}}\left(\beta_3^d\,\tilde{d}_{hor}^{n+1} + \beta_6^d\,\delta_\zeta Z_{hor}^{n+1}\right)\right] \tag{127}
$$

where $\tilde{d}_{hor}^{n+1}$ is calculated via (58) and Z_{hor}^{n+1} via (60) (both with u^{n+1} and v^{n+1}).

The explicit solution for p'^{n+1} reads

$$p'^{n+1} = \Delta t \left(b_{4,p} - \mathbf{A}_{pw} w^{n+1} \right) \tag{128}$$

(this can be calculated without any further boundary conditions/treatments).

The explicit equation for T'^{n+1} directly follows from eq. (55) using p'^{n+1} from eq. (128).

7 Stability of the divergence damping in tilted terrain

Though the divergence damping is in general necessary to stabilize the whole split-explicit time integration scheme, it can itself become unstable. Beyond the stability limitation $\alpha_{div}\Delta t/\Delta x^2 \leq 1/2$ (?), there is an additional constraint in tilted terrain.

To derive this constraint, one can start from the following 2D equations for the quasi-2D-divergence damping alone in terrain following coordinates

$$\frac{\partial u}{\partial t} = \alpha_{div}^h \left(\frac{\partial D}{\partial x} + \frac{\partial \zeta}{\partial x}\frac{\partial D}{\partial \zeta} \right), \tag{129}$$

$$\frac{\partial v}{\partial t} = \alpha_{div}^h \left(\frac{\partial D}{\partial y} + \frac{\partial \zeta}{\partial y}\frac{\partial D}{\partial \zeta} \right), \tag{130}$$

$$\frac{\partial w}{\partial t} = 0, \tag{131}$$

$$D = \frac{\partial u}{\partial x} + \frac{\partial \zeta}{\partial x}\frac{\partial u}{\partial \zeta} + \frac{\partial v}{\partial y} + \frac{\partial \zeta}{\partial y}\frac{\partial v}{\partial \zeta} + \frac{\partial \zeta}{\partial z}\frac{\partial w}{\partial \zeta}. \tag{132}$$

For an explicit discretization of these equations analogous to (51), a von-Neumann stability analysis is relatively straightforward and results in the sufficient condition

$$\alpha_{div}^h \, \Delta t \left\{ \frac{1}{\Delta x^2} \left(2 + \frac{\Delta x}{\Delta \zeta} \left| \frac{\partial \zeta}{\partial x} \right| \right)^2 + \frac{1}{\Delta y^2} \left(2 + \frac{\Delta y}{\Delta \zeta} \left| \frac{\partial \zeta}{\partial y} \right| \right)^2 \right\} \leq 2. \tag{133}$$

This can be reformulated by prescribing $\frac{\partial z}{\partial x}$ (at constant ζ). Due to the relations similar to (7) and (8) and the estimation $\Delta\zeta \approx \frac{\partial \zeta}{\partial z}\,\Delta z$, this can be written as

$$\alpha_{div}^h \, \Delta t \left\{ \frac{1}{\Delta x^2} \left(2 + \frac{\Delta x}{\Delta z} \left| \frac{\partial z}{\partial x} \right| \right)^2 + \frac{1}{\Delta y^2} \left(2 + \frac{\Delta y}{\Delta z} \left| \frac{\partial z}{\partial y} \right| \right)^2 \right\} \leq 2. \tag{134}$$

This is a quite general stability condition not only for the divergence damping but for explicit discretizations of the diffusion equation in general. Because $\Delta h := \frac{\partial z}{\partial x}\,\Delta x$ is just the height jump along a ζ-coordinate line, the expression

$$\frac{\Delta h}{\Delta z} \equiv \frac{\Delta x}{\Delta z}\frac{\partial z}{\partial x} \tag{135}$$

describes the ratio between the height change Δh of a coordinate plane over one grid mesh size Δx and the vertical thickness Δz of the grid box.

Near the ground, where small $\Delta z \sim 20$ m are common, the ratio $\Delta h/\Delta z$ can be quite large even for rather gentle slopes. Therefore, in steep terrain the dimensionless value $xkd := \alpha_{div}/(c_s^2 \Delta t)$ must be chosen much smaller than the recommended value of 0.1 by ? or even as the recommendation of 0.3 by ?. It is interesting that $\Delta h/\Delta z$ often achieves higher values for coarser resolutions, where the jumps from one grid box to another are larger than for

finer resolutions. Hence, the steeper slopes occurring in fine scale model applications are not the limiting factor in this case.

The good news is that in practice, the limitation (134) must not be strictly fulfilled. One reason is, that the forward-backward scheme of the fast waves solver rather adds the tendencies of sound, buoyancy and divergence damping instead of doing an operator splitting. Therefore, in the COSMO code a namelist variable `divdamp_slope` was introduced to weaken up the condition (134). The true value of α_{div}^h is determined by

$$\alpha_{div}^h = \min\left(\texttt{xkd} \cdot c_s^2\,\Delta t,\ \texttt{divdamp_slope} \cdot \alpha_{div,slope}\right),$$

where `xkd` is the namelist variable for divergence damping, and $\alpha_{div,slope}$ is the value determined by (134). Consequently, the divergence damping coefficient never exceeds the value given by `xkd`.

8 Discretization errors in a stretched grid

8.1 General analysis procedure

Now, in a certain sense we go back to section 4.1 and answer the question, why the vertical weighting is advantageous and why the chosen operators are to favor compared to other choices. To this purpose, a truncation error analysis is carried out. But first, we have to consider the following question: how can we determine the convergence order or the truncation error for discretizations on a *stretched* grid?

Hence, we consider a (vertical) interval $[0, L]$ which is discretized by $N+1$ grid points

$$z_{\frac{1}{2}}^{(h)} = L, \quad z_{1+\frac{1}{2}}^{(h)}, \quad \ldots, \quad z_{N-\frac{1}{2}}^{(h)}, \quad z_{N+\frac{1}{2}}^{(h)} = 0. \tag{136}$$

In COSMO the position of the half levels is prescribed, therefore we write half indices and add an upper index (h). The grid mesh size in a grid box is $\Delta z_k := z_{k-\frac{1}{2}}^{(h)} - z_{k+\frac{1}{2}}^{(h)}$, $k = 1, .., N$.

In contrast to an equidistant grid there exist arbitrary many different possibilities to perform a grid refinement. In the following, two variants of grid refinements are analyzed, that lead to different orders of the truncation error.

8.1.1 Discretization error analysis - variant A

In this first variant, the grid stretching is described by a *coordinate transformation* $z(\zeta)$. The transformed coordinate ζ generates an equidistant grid:

$$\zeta_{k+\frac{1}{2}} = \left(k + \frac{1}{2}\right) \cdot \Delta\zeta, \quad k = 0, \ldots, N. \tag{137}$$

With increasing grid refinement $\Delta\zeta \to 0$ all the grid mesh sizes $\Delta z_k \approx \left.\frac{\partial z}{\partial \zeta}\right|_{k+\frac{1}{2}} \cdot \Delta\zeta$ converge to 0, too. Hence, the convergence inspection takes place for $\Delta\zeta \to 0$.

With decreasing $\Delta\zeta$ the stretching function *locally* becomes increasingly linear. Consequently, with this approach to refine the grid one gets formally 2nd order truncation errors for all two-point discretizations.

In the following analysis one has to distinguish carefully between main and half levels; otherwise a restriction to 2-dimensional fields in (λ, z) is sufficient. The grid is horizontally defined by

$$\lambda_i = i \cdot \Delta\lambda \tag{138}$$

with $i = 0, 1, 2, \ldots$ (for scalar- or w-positions) or $i = 1/2, 3/2, 5/2, \ldots$ (for u-position), and vertically by the z-coordinates of the half levels

$$z^{(h)}_{i,k+\frac{1}{2}} = z\left(\lambda_i, \zeta_{k+\frac{1}{2}}\right) \tag{139}$$

(with the above mentioned stretching function) and the main levels

$$z^{(m)}_{i,k} = \frac{z^{(h)}_{i,k+\frac{1}{2}} + z^{(h)}_{i,k-\frac{1}{2}}}{2}. \tag{140}$$

Hence, the w-positions are in $(\lambda_i, z^{(h)}_{i,k+\frac{1}{2}})$, the scalars T, p are in $(\lambda_i, z^{(m)}_{i,k})$, and so on. In the following truncation error analysis these coordinates have to be inserted into the discretizations according to the grid positions of the variables. Then a Taylor expansion for $\Delta\lambda \to 0$ and $\Delta\zeta \to 0$ *around the position of the target point* (which itself can be a function of $\Delta\lambda$ and $\Delta\zeta$, too) must be carried out.

8.1.2 Discretization error analysis - variant B

To avoid the circumstance, that for increasing resolution $\Delta z_k \to 0$ the grid stretching becomes *locally* more and more linear, one can prescribe a constant grid stretching

$$\frac{\Delta z_k}{\Delta z_{k-1}} = s$$

instead. Without any loss of generality we can assume that $s > 1$, i.e. the grid becomes finer in the vicinity of $z^{(h)}_0 = 0$.

To this purpose we choose the grid points in

$$\begin{aligned}
z^{(h)}_{i,-1-\frac{1}{2}} &= h(\lambda_i) - \frac{1}{2}\Delta\zeta - \frac{1}{s}\Delta\zeta, \\
z^{(h)}_{i,-\frac{1}{2}} &= h(\lambda_i) - \frac{1}{2}\Delta\zeta, \\
z^{(h)}_{i,\frac{1}{2}} &= h(\lambda_i) + \frac{1}{2}\Delta\zeta, \\
z^{(h)}_{i,1+\frac{1}{2}} &= h(\lambda_i) + \frac{1}{2}\Delta\zeta + s\Delta\zeta,
\end{aligned} \tag{141}$$

Here the prescription of a slope by $h(x)$ is possible. The flattening of coordinate surfaces with increasing height is neglected. The position of the main levels again is defined by Eq. (140). The Taylor expansion is performed in analogy to variant A.

One has to note, that such a grid refinement does not converge *globally*! For the grid mesh size it follows by the geometric summation formula

$$\Delta z_k = \Delta z_1 \cdot s^{k-1} = \frac{L}{\sum_{l=0}^{N-1} s^l} \cdot s^{k-1} = \frac{L}{\frac{s^N-1}{s-1}} \cdot s^{k-1}. \tag{142}$$

In particular for the coarsest grid mesh size it follows

$$\Delta z_N = L\frac{s-1}{s-s^{1-N}} \overset{N\to\infty}{\to} L\frac{s-1}{s} \neq 0!$$

By this kind of grid refinement one inserts smaller and smaller grid boxes only on one end of the interval (at $z = 0$), without a significant refinement at the other end (at $z = L$) for the coarse grid boxes. This, of cause, is a bit odd situation for this variant of grid refinement.

8.2 Horizontal pressure gradient term in the u-equation

We inspect the discretization of the horizontal pressure gradient

$$\frac{\partial p(\lambda, z)}{\partial \lambda} = \frac{\partial p(\lambda, \zeta)}{\partial \lambda} + \frac{\partial \zeta}{\partial \lambda}\frac{\partial p}{\partial \zeta} = \frac{\partial p(\lambda, \zeta)}{\partial \lambda} - \frac{\partial z}{\partial \lambda}\frac{\partial p}{\partial z}.$$

Discretization error analysis - variant A

1. The discretization with weighted vertical interpolation delivers

$$\begin{aligned}\delta_\lambda p - \left(A_\zeta \frac{\partial z}{\partial \lambda}\right)\left(A_\lambda\left(\frac{\partial \zeta}{\partial z}\delta_\zeta A_\zeta^N p\right)\right) = \left.\frac{\partial p}{\partial \lambda}\right|_z + \\ + d\zeta^2\left[-\frac{1}{6}\frac{\partial z}{\partial \lambda}\left(\frac{\partial z}{\partial \zeta}\right)^2\frac{\partial^3 p}{\partial z^3} - \frac{1}{4}\frac{\partial z}{\partial \lambda}\frac{\partial^2 z}{\partial \zeta^2}\frac{\partial^2 p}{\partial z^2}\right] + \\ + d\lambda^2[\ldots] + d\zeta\, d\lambda \cdot 0 + O(d\zeta^4, d\zeta^2 d\lambda^2, d\lambda^4). \qquad (143)\end{aligned}$$

   The discretization operators are defined in section 4.1. For the 2nd order term $\sim \Delta\zeta^2$ one has either a contribution from the curvature of $p(z)$ (first term) or a stretching (=curvature) in the grid $z(\zeta)$ (second term).

2. The same discretization, but without weighted averages delivers

$$\begin{aligned}\delta_\lambda p - \left(A_\zeta \frac{\partial z}{\partial \lambda}\right)\left(A_\lambda\left(\frac{\partial \zeta}{\partial z}\delta_\zeta A_\zeta p\right)\right) = \left.\frac{\partial p}{\partial \lambda}\right|_z + \\ + d\zeta^2\left[-\frac{1}{6}\frac{\partial z}{\partial \lambda}\left(\frac{\partial z}{\partial \zeta}\right)^2\frac{\partial^3 p}{\partial z^3} - \frac{1}{2}\frac{\partial z}{\partial \lambda}\frac{\partial^2 z}{\partial \zeta^2}\frac{\partial^2 p}{\partial z^2}\right] + \\ + d\lambda^2[\ldots] + d\zeta\, d\lambda \cdot 0 + O(d\zeta^4, d\zeta^2 d\lambda^2, d\lambda^4). \qquad (144)\end{aligned}$$

   In the term $\sim \Delta\zeta^2$ the second term has a twice as large prefactor compared to the discretization above. The prefactor of the term $\sim d\lambda^2$ is the same as above, as expected.

3. One can think about a lot of other discretizations for the horizontal pressure gradient, for example with

$$\begin{aligned}\delta_\lambda p - \left(A_\lambda \frac{\partial \zeta}{\partial z}\right)\left(A_\zeta\left(\frac{\partial z}{\partial \lambda}A_\lambda \delta_\zeta p\right)\right) = \left.\frac{\partial p}{\partial \lambda}\right|_z + \\ + d\zeta^2\left[-\frac{1}{6}\frac{\partial z}{\partial \lambda}\left(\frac{\partial z}{\partial \zeta}\right)^2\frac{\partial^3 p}{\partial z^3} - \frac{1}{2}\frac{\partial z}{\partial \lambda}\frac{\partial^2 z}{\partial \zeta^2}\frac{\partial^2 p}{\partial z^2} - \frac{1}{4}\frac{\partial z}{\partial \zeta}\frac{\partial^2 z}{\partial \lambda \partial \zeta}\frac{\partial^2 p}{\partial z^2}\right. \\ \left. - \frac{1}{4}\frac{\frac{\partial^2 z}{\partial \lambda \partial \zeta}\frac{\partial^2 z}{\partial \zeta^2}}{\frac{\partial z}{\partial \zeta}}\frac{\partial p}{\partial z} - \frac{1}{4}\frac{\frac{\partial^3 z}{\partial \zeta^3}\frac{\partial z}{\partial \lambda}}{\frac{\partial z}{\partial \zeta}}\frac{\partial p}{\partial z}\right] + \\ + d\lambda^2[\ldots] + d\zeta\, d\lambda \cdot 0 + O(d\zeta^4, d\zeta^2 d\lambda^2, d\lambda^4). \qquad (145)\end{aligned}$$

   Obviously this is discretization generates larger errors.

4. The Mahrer (1984)-discretization can only be inspected for gentle slopes. In this case it follows

$$\frac{\partial p}{\partial \lambda} = \left.\frac{\partial p}{\partial \lambda}\right|_z + d\zeta^2 \left[-\frac{1}{24}\frac{\partial z}{\partial \lambda}\left(\frac{\partial z}{\partial \zeta}\right)^2 \frac{\partial^3 p}{\partial z^3}\right] + \\ + d\zeta\, d\lambda \left[\frac{1}{16}\frac{\partial^2 z}{\partial \lambda^2}\frac{\partial z}{\partial \zeta}\frac{\partial^2 p}{\partial z^2} + \ldots\right] + d\lambda^2 [\ldots] + \ldots \quad (146)$$

Though the term $\sim d\zeta^2$ is much smaller than in the above discretizations, another second order term arises which is proportional to $d\zeta\, d\lambda$. This could explain the slightly worse discretization properties in the vertical.

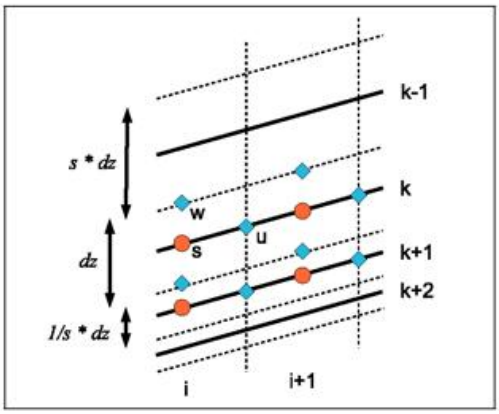

Figure 2: Grid positions and stretching in the 'discretization error analysis - variant B' for the horizontal pressure gradient $\partial p/\partial \lambda$.

Discretization error analysis - variant B

1. The discretization with weighted vertical interpolation delivers

$$\delta_\lambda p - \left(A_\zeta \frac{\partial z}{\partial \lambda}\right)\left(A_\lambda\left(\frac{\partial \zeta}{\partial z}\delta_\zeta A_\zeta^N p\right)\right) = \left.\frac{\partial p}{\partial \lambda}\right|_z + \\ + dz\left[\frac{1}{8}\frac{\partial h}{\partial \lambda}\left(\frac{1}{s} - s\right)\frac{\partial^2 p}{\partial z^2}\right] + \\ + d\lambda^2 [\ldots] + dz^2 [..] + O(dz^3, d\lambda^2\, dz, \ldots) \quad (147)$$

Now the leading truncation error is indeed of *first order* in dz.

2. The same discretization but without weighted averaging

$$\delta_\lambda p - \left(A_\zeta \frac{\partial z}{\partial \lambda}\right)\left(A_\lambda\left(\frac{\partial \zeta}{\partial z}\delta_\zeta A_\zeta p\right)\right) = \left.\frac{\partial p}{\partial \lambda}\right|_z + \\ + dz\left[\frac{1}{4}\frac{\partial h}{\partial \lambda}\left(\frac{1}{s} - s\right)\frac{\partial^2 p}{\partial z^2}\right] + \\ + d\lambda^2 [\ldots] + dz^2 [..] + \ldots \quad (148)$$

Again the truncation error structure is the same as above but now the prefactor is twice as large.

3. The inappropriate discretization from above delivers

$$\delta_\lambda p - \left(A_\lambda \frac{\partial \zeta}{\partial z}\right)\left(A_\zeta\left(\frac{\partial z}{\partial \lambda} A_\lambda \delta_\zeta p\right)\right) = \left.\frac{\partial p}{\partial \lambda}\right|_z + \frac{\partial p}{\partial \zeta}\frac{\partial h}{\partial \lambda}\left(\frac{1}{2} - \frac{1}{4}\left(\frac{1}{s} + s\right)\right) + \\ + dz\,[...] + d\lambda^2\,[...] + dz^2\,[..] + ... \tag{149}$$

   For $s \neq 1$ this don't even is a consistent discretization!

4. For the Mahrer (1984) discretization one gets:

$$\begin{aligned} \frac{\partial p}{\partial \lambda} &= \left.\frac{\partial p}{\partial \lambda}\right|_z + \\ &+ dz^2\left[-\frac{1}{24}\frac{\partial h}{\partial \lambda}\frac{\partial^3 p}{\partial z^3}\right] + \\ &+ d\lambda dz\,[...] + d\lambda^2\,[...] + dz^2\,[..] + ... \end{aligned} \tag{150}$$

   The interesting result is, that no terms $\sim dz$ or $\sim dz\ d\lambda$ occur. So it is indeed a second order discretization!

Summarizing the results, it is clear, that the discretization with vertical weightings (option 1) is the best one. Further one can see, that discretizations with slightly wider stencils (option 3) in general lead to worse truncation errors. For the Mahrer discretization, the decision is a bit more difficult. Whereas in analysis variant A there occurs a mixed second order term, which is probably detrimental, in analysis variant B this is the only discretization which is really of second order.

8.3 Buoyancy term in the w-equation

Terms of the form T'/T_0 (or $p'/p0$) occuring in the buoyancy term of the w-equation.

Discretization error analysis - variant A

1. The discretization in the new fast waves solver uses weighted vertical interpolations for T' and calculates T_0 exactly at the w-position.

$$\frac{1}{T_0} A_\zeta^N T' = \frac{T'}{T_0} + d\zeta^2 \frac{1}{T_0}\left[\frac{1}{8}\left(\frac{\partial z}{\partial \zeta}\right)^2 \frac{\partial^2 T'}{\partial z^2}\right] + O(d\zeta^4). \tag{151}$$

2. use no weighting for the vertical averaging and calculate T_0 exactly at the w-position

$$\frac{1}{T_0} A_\zeta T' = \frac{T'}{T_0} + d\zeta^2 \frac{1}{T_0}\left[\frac{1}{8}\left(\frac{\partial z}{\partial \zeta}\right)^2 \frac{\partial^2 T'}{\partial z^2} + \frac{1}{4}\frac{\partial^2 z}{\partial \zeta^2}\frac{\partial T'}{\partial z}\right] + O(d\zeta^4). \tag{152}$$

   Compared to the above truncation error an additional term occurs, which stems from the curvature of the coordinate transformation. Therefore the weighted average is the better discretization.

3. use weighted averages both for T_0 and T':

$$\frac{1}{A_\zeta^N T_0} A_\zeta^N T' = \frac{T'}{T_0} + d\zeta^2 \frac{1}{T_0}\left[\frac{1}{8}\left(\frac{\partial z}{\partial \zeta}\right)^2 \frac{\partial^2 T'}{\partial z^2} - \frac{1}{8}\frac{1}{T_0}\frac{\partial^2 T_0}{\partial z^2}\left(\frac{\partial z}{\partial \zeta}\right)^2 T'\right] + O(d\zeta^4) \tag{153}$$

As expected, an additional term occurs when the reference state temperature exhibits a curvature. Since no statement about the sign of this term can be made, it is in general better to have no such term at all, i.e. the direct calculation of T_0 at this position is the better solution here.

4. Previous version without weighted averages

$$A_\zeta^N \left(\frac{T'}{T_0}\right) = \frac{T'}{T_0} + d\zeta^2 \frac{1}{T_0}\left[\frac{1}{8}\left(\frac{\partial z}{\partial \zeta}\right)^2 \frac{\partial^2 T'}{\partial z^2} + \ldots\right] + O(d\zeta^4). \tag{154}$$

There arise several additional terms compared to the first version above.

Discretization error analysis - variant B Instead of (141) we use the following z-positions of the grid

$$\begin{aligned} z^{(h)}_{i,-1-\frac{1}{2}} &:= h(\lambda) - 2\frac{1}{s+1}dz, \\ z^{(h)}_{i,-\frac{1}{2}} &:= h(\lambda), \\ z^{(h)}_{i,+\frac{1}{2}} &:= h(\lambda) + 2\frac{s}{s+1}dz, \end{aligned} \tag{155}$$

with the (dimensionless) stretching factor s; this simply leads to more symmetric formula in s if applied to the w equation terms.

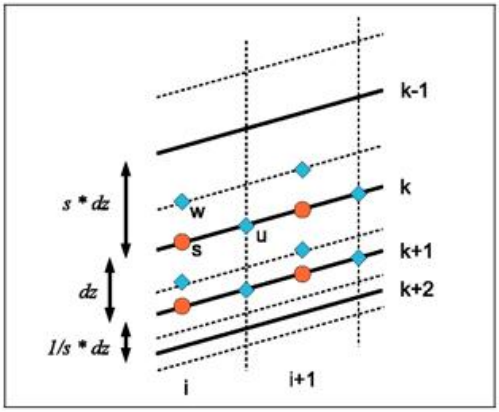

Figure 3: Grid positions and stretching in the 'discretization error analysis - variant B' for the buoyancy term in the w-equation.

1. use weighted vertical interpolations for T' and calculates T_0 exactly at the w-position

$$\frac{1}{T_0} A_\zeta^N T' = \frac{T'}{T_0} + dz \cdot 0 + dz^2 \left[\frac{1}{2}\frac{s}{(s+1)^2}\frac{1}{T_0}\frac{\partial^2 T'}{\partial z^2}\right] + O(dz^3). \tag{156}$$

Through the weighting this discretization is indeed of 2nd order in dz.

2. use no weighting for the vertical averaging and calculate T_0 exactly at the w-position

$$\frac{1}{T_0} A_\zeta T' = \frac{T'}{T_0} + dz\left[\frac{1}{2}\frac{s-1}{s+1}\frac{1}{T_0}\frac{\partial T'}{\partial z}\right] + dz^2\left[\frac{1}{4}\frac{s^2+1}{(s+1)^2}\frac{1}{T_0}\frac{\partial^2 T'}{\partial z^2}\right] + O(dz^3) \tag{157}$$

This is only of first order for all $s \neq 1$..

3. use weighted averages both for T_0 and T'

$$\frac{1}{A_\zeta^N T_0} A_\zeta^N T' = \frac{T'}{T_0} + dz^2 \frac{1}{2} \frac{s}{(s+1)^2} \left[\frac{1}{T_0} \frac{\partial^2 T'}{\partial z^2} - \frac{1}{T_0^2} \frac{\partial^2 T_0}{\partial z^2} T' \right] + O(dz^3). \quad (158)$$

   There arise additional terms.

4. Old version:

$$A_\zeta^N \left(\frac{T'}{T_0} \right) = \frac{T'}{T_0} + dz^2 \frac{1}{T_0} \left[\frac{1}{2} \frac{\partial^2 T'}{\partial z^2} \frac{s}{(s+1)^2} + \ldots \right] + O(dz^3). \quad (159)$$

   There arise additional terms.

As in the section before, both analysis variants qualitatively deliver the same picture: the use of vertical weightings delivers discretizations with the smallest errors. In particular for variant B, there is a difference between a true second order discretization (option 1 with weightings) and an only first order discretization (option 2, without weightings). Further, the use of the exact values of the reference atmosphere is favorable.

8.4 The divergence term

$$\operatorname{div} \mathbf{v} = \frac{1}{g} \left[\frac{\partial g u(x,\zeta)}{\partial x} + \frac{\partial}{\partial \zeta} \left(\frac{\partial z}{\partial x} u - w \right) \right] \quad (160)$$

Discretization error analysis - variant A

1. $\frac{\partial Z_x}{\partial \zeta}$ is discretized by a weighted vertical average

$$\begin{aligned} \operatorname{div} \mathbf{v} = \frac{\partial u(x,z)}{\partial x} + \frac{\partial w(x,z)}{\partial z} + d\zeta^2 \Bigg(& -\frac{1}{4} \frac{\partial^2 z}{\partial x \partial \zeta} \frac{\partial z}{\partial \zeta} \frac{\partial^2 u}{\partial z^2} - \frac{1}{4} \frac{\partial^2 z}{\partial \zeta^2} \frac{\partial z}{\partial x} \frac{\partial^2 u}{\partial z^2} \\ & - \frac{1}{6} \left(\frac{\partial z}{\partial \zeta} \right)^2 \frac{\partial z}{\partial x} \frac{\partial^3 u}{\partial z^3} + \frac{1}{24} \left(\frac{\partial z}{\partial \zeta} \right)^2 \frac{\partial^3 w}{\partial z^3} \Bigg) + dx^2 () + \ldots \end{aligned} \quad (161)$$

2. $\frac{\partial Z_x}{\partial \zeta}$ is averaged without weights:

$$\begin{aligned} \operatorname{div} \mathbf{v} = \frac{\partial u(x,z)}{\partial x} + \frac{\partial w(x,z)}{\partial z} + d\zeta^2 \Bigg(& -\frac{1}{4} \frac{\partial^2 z}{\partial x \partial \zeta} \frac{\partial z}{\partial \zeta} \frac{\partial^2 u}{\partial z^2} - \frac{1}{2} \frac{\partial^2 z}{\partial \zeta^2} \frac{\partial z}{\partial x} \frac{\partial^2 u}{\partial z^2} \\ & - \frac{1}{6} \left(\frac{\partial z}{\partial \zeta} \right)^2 \frac{\partial z}{\partial x} \frac{\partial^3 u}{\partial z^3} + \frac{1}{24} \left(\frac{\partial z}{\partial \zeta} \right)^2 \frac{\partial^3 w}{\partial z^3} \\ & - \frac{1}{4} \frac{\partial \zeta}{\partial z} \frac{\partial^2 z}{\partial x \partial \zeta} \frac{\partial^2 z}{\partial \zeta^2} \frac{\partial u}{\partial z} - \frac{1}{4} \frac{\partial \zeta}{\partial z} \frac{\partial^3 z}{\partial \zeta^3} \frac{\partial z}{\partial x} \frac{\partial u}{\partial z} \Bigg) + dx^2 () + \ldots \end{aligned} \quad (162)$$

   One of the terms has a twice as large prefactor and two additional terms occur.

Discretization error analysis - variant B

1. $\frac{\partial Z_x}{\partial \zeta}$ is discretized by a weighted vertical average

$$\operatorname{div} \mathbf{v} = \frac{\partial u(x,z)}{\partial x} + \frac{\partial w(x,z)}{\partial z} + dz \left(\frac{1}{8} \frac{\partial h}{\partial x} \frac{\partial^2 u}{\partial \zeta^2} \left(\frac{1}{s} - s \right) \right) + O(dz^2, dx^2) \quad (163)$$

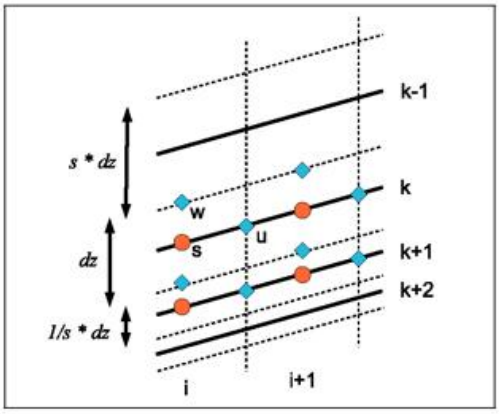

Figure 4: Grid positions and stretching in the 'discretization error analysis - variant B' for the divergence term in the scalar p'- or T'-equations.

2. $\frac{\partial Z_x}{\partial \zeta}$ is discretized without weightings

$$\begin{aligned} \operatorname{div} \mathbf{v} &= \frac{\partial u(x,z)}{\partial x} + \frac{\partial h}{\partial x}\frac{\partial u(x,z)}{\partial z}\left(\frac{1}{2} - \frac{1}{4}\left(s + \frac{1}{s}\right)\right) + \frac{\partial w(x,z)}{\partial z} + \\ &+ dz\left(\frac{1}{8}\frac{\partial h}{\partial x}\frac{\partial^2 u}{\partial \zeta^2}\left(\left(\frac{1}{s} - s\right) + \frac{1}{2}\left(\frac{1}{s^2} - s^2\right)\right)\right) + O(dz^2, dx^2) \end{aligned} \tag{164}$$

For a stretched grid ($s \neq 1$) this is not a consistent discretization at all!

9 Idealized tests

In this section, the properties of the new fast waves solver are inspected using several idealized test setups. All the following simulations are performed with COSMO version 4.26.2 (concerning the dynamics this is similar to the more official version 4.27). If not otherwise stated, the switches for the new fast waves solver are `itype_fast_waves=2`, `ldyn_bbc=.FALSE.`, and `itype_bbc_w=114`. These settings will be denoted as 'FW2' in the following. The namelist values for the simulations with the old fast waves solver are `1`, `.TRUE.`, and `2`, respectively. The old fast waves solver settings are denoted by 'FW1'.

9.1 Linear gravity and sound wave expansion

In ? (in the following abbreviated by BB13) an exact analytic solution for the expansion of linear gravity and sound waves for the compressible, non-hydrostatic Euler equations in an isothermal atmosphere was derived. This test case inspects almost all terms of the fast waves solver (with the exception of the 'horizontal' metric terms) together with the time integration scheme and the coupling with the advection process.

In the following simulations, the same setup as proposed for the small-scale test in BB13 is used. A weak warm bubble is set into a 10 km high and 300 km wide channel with periodic boundary conditions in the horizontal. The only difference is the definition of the grid. To demonstrate the benefit of the vertical weightings in the new fast waves solver a vertical grid stretching is introduced, with a grid stretching ratio of 1:10 between the finest vertical mesh size around $z = 5$ km and the coarsest mesh size around $z = 0$ and $z = 10$ km. Figures 5 show the grid for the first three chosen (horizontal) resolutions $\Delta x = 1000$ m, 500 m,

and 250 m with 300×20, 600×40, and 1200×80 grid points, respectively, and the initial temperature perturbation T' of the weak warm bubble at $t = 0$. The time steps for these simulations are 20 s, 10 s, and 5 s, respectively, and analogous for the finer resolutions. During the expansion of the waves a background velocity field with $u_0 = 20$ m/s advects the waves to the right. Figure 6 shows the solution for T' and w of FW2 after 30 min. together with the analytic solution.

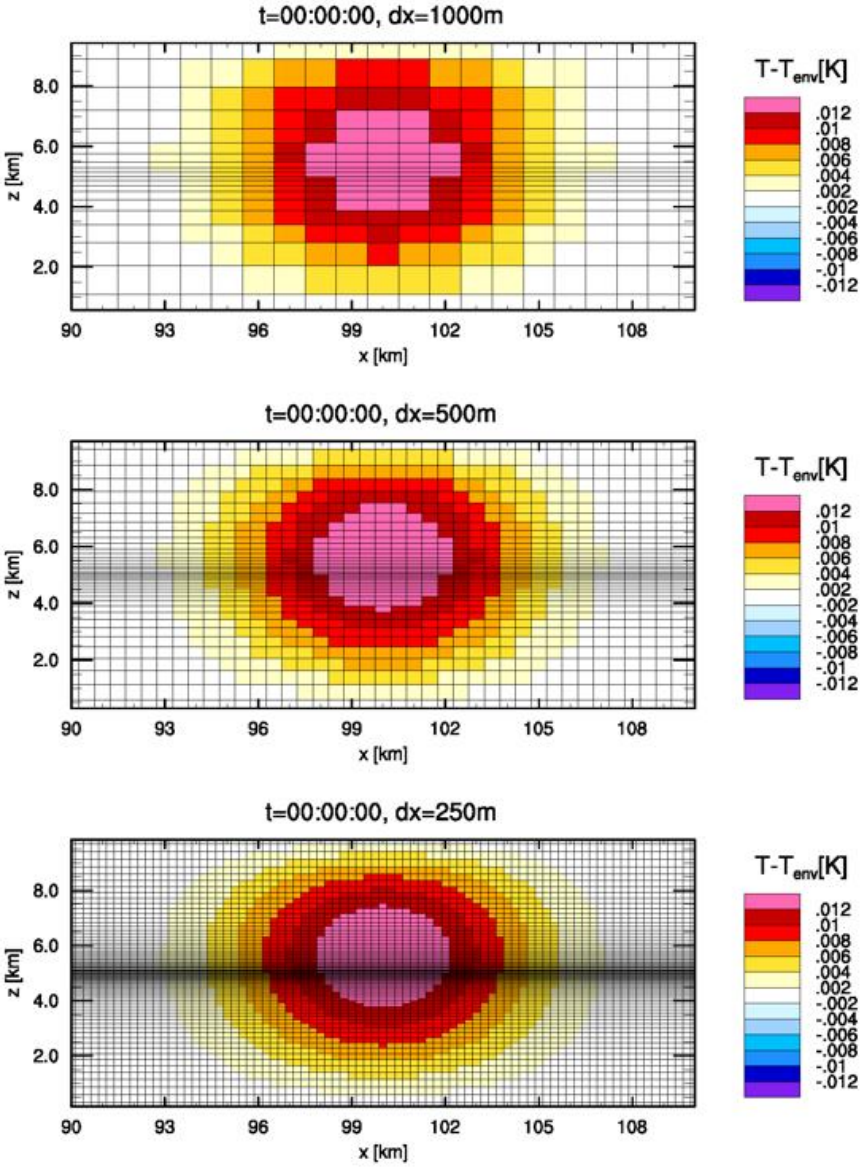

Figure 5: Grid and initial temperature perturbation $T'(t = 0)$ for the first three resolutions $\Delta x = 1000$ m, 500 m, and 250 m for the linear gravity/sound wave test.

The following results are obtained by COSMO 4.26.2 (with the additional implementation of the grid stretching in `src_artifdata.f90`). Figures 7 and 8 show the error norms of the simulated solution against the analytic solution after 30 min. The error norms

$$L_m(\psi) = \left(\frac{1}{N_x N_z} \sum_{i=1}^{N_x} \sum_{k=1}^{N_z} |\psi(x_i, z_k) - \psi_{\text{lin}}(x_i, z_k)|^m \right)^{1/m}, \quad m = 1, 2, \infty \tag{165}$$

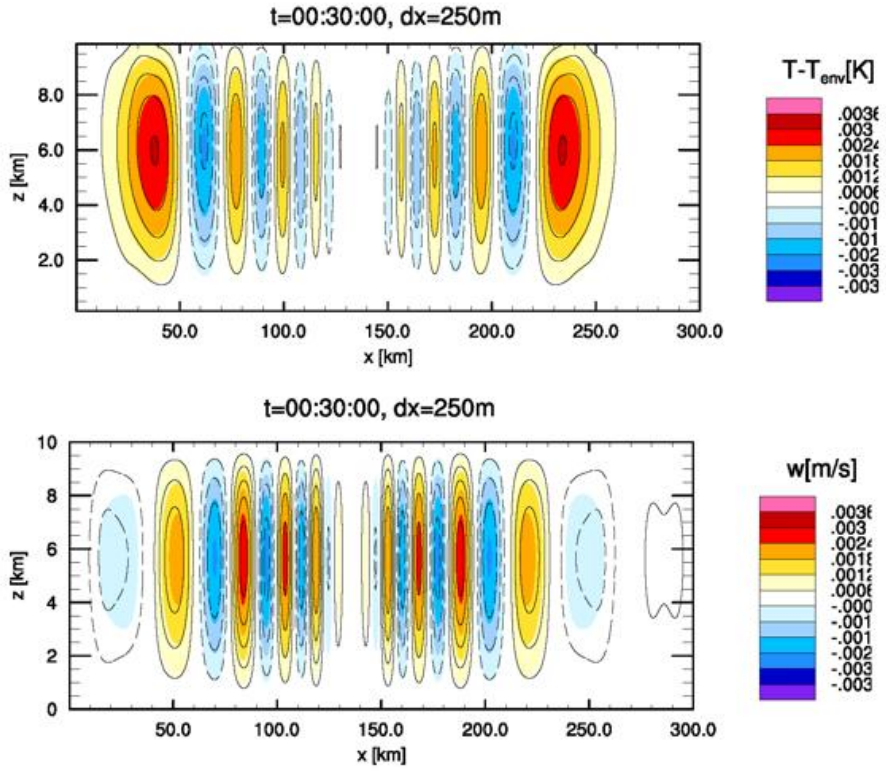

Figure 6: Temperature perturbation T' and vertical velocity w after 30 min. for $\Delta x = 250$ m horizontal resolution. Comparison between FW2-simulation (shaded) and analytic solution (lines).

for any field $\psi(x, z, t)$ are calculated as described in BB13 for the COSMO model; in particular the L_∞ norm is the usual maximum norm. In all cases, the errors of the new fast waves solver (FW2) are smaller compared to those of the old one (FW1). For the coarsest resolution the error of FW1 is nearly twice as large compared to FW2. One should notice that the more gentle slope for FW2 does not mean a smaller convergence rate. As one can see from the curvature of the lines, the simulation for the coarser resolutions is not yet in the convergence range. In contrast, these error norms show that the errors for not completely resolved structures are better with the vertical weightings in the new FW2. For very fine resolutions, at least for the L_∞-error of w, the error norms of FW1 and FW2 are nearly the same and result in a convergence rate of about 0.7 for T' and slightly higher for w. The reason for this behavior is, that for an increasing number of vertical grid points, the local grid stretching becomes increasingly linear. This can be seen in figures 5, too. Consequently, the importance of the weightings in the averages decreases.

9.2 2D linear flow over a series of hills

To test the proper inclusion of metric terms, 2-dimensional flow over a couple of hills is inspected. The test setup is chosen as in (?, section 5.b), but with a reduced mountain height of $h_{max} = 1$ m. This test combines hydrostatic and non-hydrostatic features of flow over mountains. An analytic solution for linear flow over hills for exactly the compressible, non-hydrostatic Euler equation system used in the COSMO model and in particular for this test setup is given in ?.

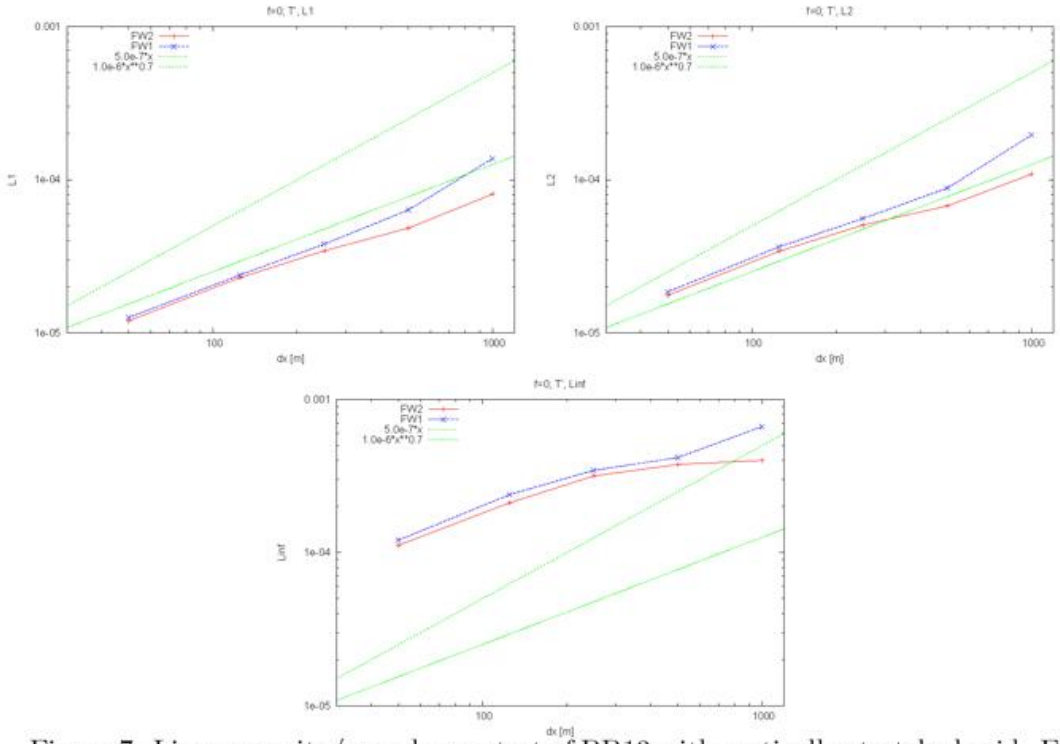

Figure 7: Linear gravity/sound wave test of BB13 with vertically stretched grid. Error norms of T' for the new fast waves solver (FW2, red) and the old one (FW1, blue) for different resolutions.

The vertical grid is stretched by a quadratic stretching function, i.e

$$z_k^{(h)} = H_{top} \cdot (\beta\eta^2 + (1-\beta)\eta), \qquad \eta = 1 - \frac{k-1}{ke}, \qquad k = 1, 2, \ldots, ke+1. \tag{166}$$

$(1+\beta)/(1-\beta)$ is roughly the ratio $\Delta z_{top}/\Delta z_{bottom}$. We choose $H_{top} = 25$ km and $\beta = 0.95$ and the following two resolutions:
1.) $\Delta x = 1000$ m and $ke = 50$ vertical levels,
2.) $\Delta x = 500$ m and $ke = 100$ vertical levels.
The tables 1 give an impression about the resulting vertical levels. All physical parameterizations, in particular the turbulence scheme, are switched off. Otherwise boundary layer effects would prevent from a correct comparison with the analytic solution.

The comparison for these two resolutions with the analytic solution is quite good (see figure 9). Both the hydrostatic pattern (higher above the hills) and the non-hydrostatic pattern (in the vicinity of the hills) is well represented by the simulation. The convergence to the correct solution can be seen also in the error measures between the simulations for the two different resolutions and the analytic solution (table 2). The integration area for the determination of the errors is chosen as far as possible away from the boundaries, therefore it was chosen horizontally in the range $[80, 120]$ km and vertically approximately in the range $[0.5, 7]$ km. The errors for the new fast waves solver are smaller compared to the old one. Again, as for the linear wave expansion in the section before, the differences become smaller, when the local grid stretching ratio becomes smaller. It is interesting, that the version with the isotropic 3D divergence damping is even better than with the quasi-3D version.

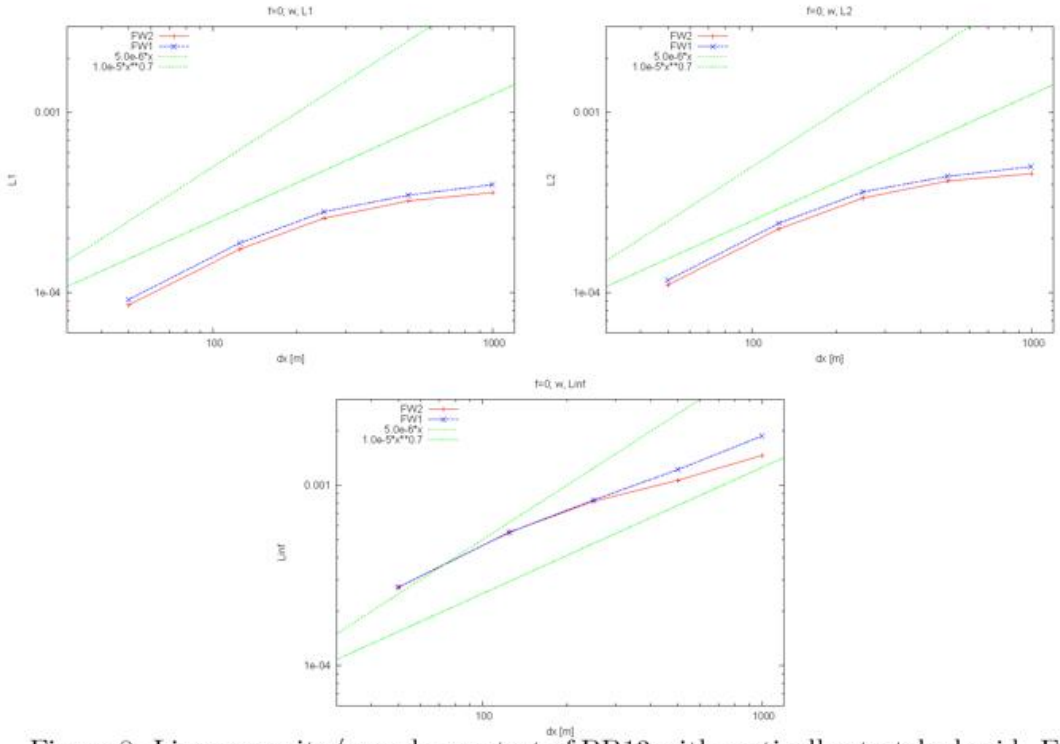

Figure 8: Linear gravity/sound wave test of BB13 with vertically stretched grid. Error norms of w for different resolutions.

9.3 3D linear flow over a hill

An analogous 3D test uses a single mountain with a rotational symmetric Gaussian shape

$$h(x) = h_{max} \cdot 2^{-\frac{x^2+y^2}{a^2}} \tag{167}$$

and a half width of $2a = 10000$ m. The hill is located exactly in the center of the simulation domain at the position $(100, 100)$ km.

Again the turbulence scheme and other parameterizations are switched off. The vertical stretching is done as in section 9.4. The inflow velocity is $u_0 = 20$ m/s, the atmospheric stratification $N = 0.01$ 1/s. The horizontal resolution is $\Delta x = \Delta y = 500$ m and a time step $\Delta t = 5$ s has been chosen.

Figure 10 shows horizontal cross sections of w after 24h simulation time. In this 3D test case the error norms of FW2 and FW1 (again against the analytic solution of ?) are almost the same, with an improvement of only about one percent for FW2.

9.4 2D flow over steep mountains

To inspect the ability to stably simulate flow over steep mountains, a single 2D mountain (i.e. a mountain ridge) with a Gaussian shape

$$h(x) = h_{max} \cdot 2^{-\left(\frac{x}{a}\right)^2} \tag{168}$$

and a half width of $2a = 6000$ m is used. A constant inflow velocity of $u_0 = 20$ m/s and a dry atmosphere with a stable stratification $N = 0.01$ 1/s are prescribed. In the following different values for the height h_{max} are tested.

500	FW2, 3D div.damp.	1.273	1.780	7.56

Table 2: 2D linear flow over flat mountains. Error measures for two different resolutions in a stretched grid.

The horizontal grid mesh size of the 2-dimensional simulations is $\Delta x = 1000$ m. Therefore a time step $\Delta t = 10$ s has been chosen. The vertical grid is stretched again by the quadratic stretching function (166). Here we choose $H_{top} = 25$ km, $ke = 65$, and $\beta = 0.95$, leading to $\Delta z_{bottom} = 24.9$ m and $\Delta z_{top} = 745$ m, which are quite realistic values for model applications. The simulations run with a turbulence scheme switched on, to prevent from unphysically strong wave breaking.

The simulation with FW1 remains stable until $h_{max} = 2100$ m, but becomes unstable for $h_{max} = 2200$ m. This latter mountain height corresponds to a maximum slope angle $\alpha \approx 27°$ and a maximum step size of the orography $\max_i |h_i - h_{i+1}| \approx 500$ m. The instability develops in the bottom grid boxes, where high vertical velocities occur (Fig. 11).

In contrast, the simulation with the new fast waves solver FW2 remains stable until $h_{max} = 3100$ m. This corresponds to a maximum slope angle $\alpha \approx 35°$ and a maximum step size of the orography $\max_i |h_i - h_{i+1}| \approx 710$ m (left panel in Fig. 12). The same height can be achieved both for the quasi-3D and for the full 3D-divergence damping.

Of course, one cannot expect a large increase in stability over steeper mountains, because the main time integration scheme is the same in the new and the old fast waves solver. In particular the treatment of the metric correction terms is nearly the same. But nevertheless, the better discretization of vertical operations seems to help a bit in stability.

The same simulation with Mahrer discretization (see section 4.2.2) allows even much higher mountains until $h_{max} = 4800$ m. This corresponds to a maximum slope angle $\alpha \approx 47°$ and

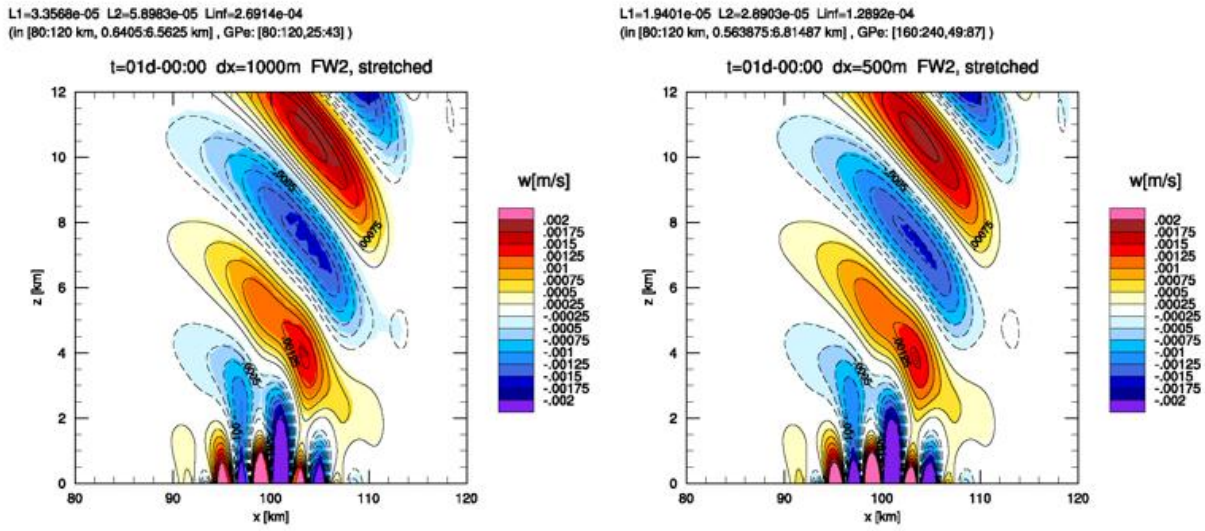

Figure 9: Linear flow over mountains (Schaer et al. 2002-setup) with vertical grid stretching by FW2. Vertical velocity w for $\Delta x = 1000$ m (left column) and $\Delta x = 500$ m (right column).

a maximum step size of the orography $\max_i |h_i - h_{i+1}| \approx 1100$ m (right panel in Fig. 12).

9.5 3D flow over steep mountains

To inspect stability over 3D steep mountains we use again a rotational symmetric Gaussian hill

$$h(x) = h_{max} \cdot 2^{-\frac{x^2+y^2}{a^2}} \tag{169}$$

with a half width of $2a = 6000$ m.

The horizontal resolution is $\Delta x = \Delta y = 1000$ m. Other model settings (vertical grid, time step, parameterizations, ...) are as in the section 9.4 before.

The simulation with FW1 is stable until a hill height of 1900 m (and becomes unstable for 2000 m). In contrast, the simulation with FW2 is stable until a hill height of 3000 m (and becomes unstable for 3100 m). Again much steeper slopes can be simulated with FW2 and the Mahrer discretization, here hill heights until 4600 m can be achieved (becomes unstable for 4700 m).

Compared to the values for the flow over 2D mountain ridges, all these maximum heights are a bit reduced for the 3D case. This indicates that more complex flows tend to reduce the maximum allowable slopes and orography steps.

9.6 Convective warm bubble test

The warm bubble test by ? is a standard test case to investigate the model behavior in strong convective situations.

An elliptic shaped 3D warm bubble with horizontal radius of $x_d = y_d = 10000$ m, a vertical radius of $z_d = 1400$ m and a maximum temperature increment of 2 K is set into a prescribed moist atmosphere (see figure 13). The atmosphere has a prescribed velocity profile with no velocity at the bottom and an increasing velocity with height until $u_{max} = 30$ m/s (this value is used here).

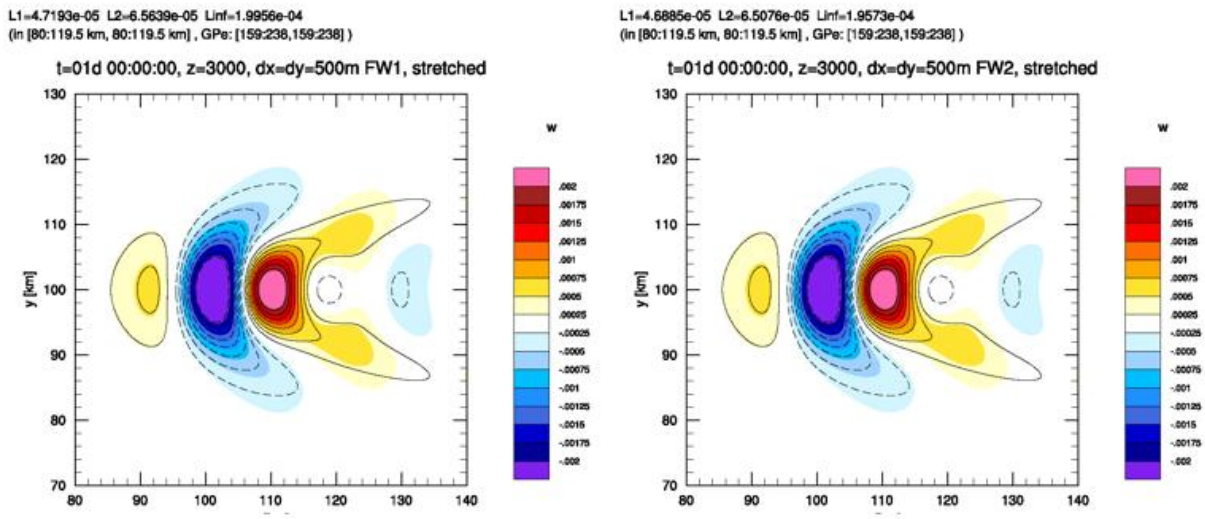

Figure 10: Vertical velocity w for linear Flow over a 3D Gaussian shaped mountain with height 1 m. Vertical velocity w simulated with the old (left) and new (right) fast waves solver (FW2) after 24 h. Cross section in $z = 3000$ m. Shaded: COSMO simulation, black lines: analytic solution

The COSMO setup has been chosen as close as possible to WK82; exceptions are a higher horizontal resolution of $\Delta x = \Delta y = 1000$ m, a time step of $\Delta t = 10$ sec., and the use of the 6-class graupel microphysics scheme (i.e. the prognostic variables q_v, q_c, q_i, q_r, q_s, q_g are used). The vertical grid points are prescribed again by (166) with $ke = 65$, $H_{top} = 22$ km, and $\beta = 0.95$. Figure 14 shows the specific mass concentrations after 30 min. and 1 h simulation time for three different model setups. The runs with FW1 generates higher maximum values of graupel and rain compared to the runs with FW2, whereas FW2 produces higher maxima of cloud ice and snow.

Figure 15 shows the time development of the maximum vertical velocity. The first cumulonimbus cloud with maximum updrafts develops after about 30 min. This structure then dissipates and generates new clouds later on. Generally these values are in a realistic range, nevertheless they are a bit higher than those of ?. But one should notice, that their simulations have been done with $\Delta x = \Delta y = 2000$ m, probably leading to more diffusion compared to the higher resolution used here. FW2 produces slightly higher values of $w_{max}(t)$ than FW1, in particular for later times.

The simulations with FW2 have been performed with 2 setups: one with the standard quasi-3D divergence damping (i.e. $\alpha^v_{div} = 0$) and one with the full 3D divergence damping (i.e. $\alpha^v_{div} = \alpha^h_{div}$). The differences between these two versions are quite small. Therefore the slightly unphysical modification of the dispersion relation for gravity waves by the quasi-3D divergence damping mentioned in ? seems to be not too strong in this case.

An interesting aspect in connection with divergence damping is the treatment of the first small time step. For the quasi-3D version it is absolutely necessary for real case simulations to perform *no* divergence damping in the first step; otherwise instabilities occur. These are obviously induced by complex terrain, because they haven't been neither seen in the stability analysis without orography (?) nor do they occur in idealized tests with simple orographies. In contrast to this, simulations with the full 3D divergence are independent from the treatment of the first small time step: they run stable, both if it is applied in the first step or not. [5]. In this respect, the full 3D divergence damping is also more satisfying

[5]To force the application of divergence damping also in the first small time step, one has to set the *internal*

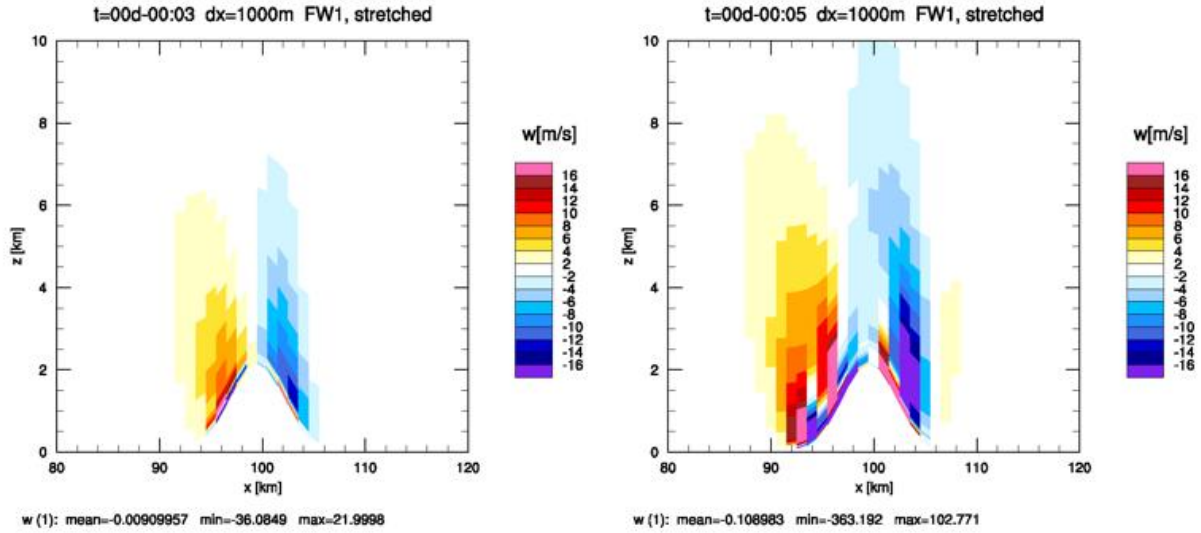

Figure 11: Flow over a 2D Gaussian shaped mountain with height 2200m. Vertical velocity w simulated with FW1 after 3 and 5 minutes. The run crashed only a few time steps later.

from a theoretical viewpoint than the quasi 3D version (the better dispersion properties of the full 3D version have been mentioned already in the introduction 2).

10 Real cases

The predominant feature of the new fast waves solver is its higher stability property. This has been demonstrated in the idealized tests in sections 9.4 and 9.5. There have been numerous examples of real case simulations which have been stabilized by using FW2. To list some of them:

The operational deterministic COSMO-DE and several COSMO-DE-EPS ensemble runs at '28.06.2011, 6 UTC' crashed by a shear instability after about 16 hours simulation time. Although this should be cured by a Smagorinsky diffusion, the runs with the new FW2 remained stable.

Another problem occurs, if the velocity fields near the ground become too noisy. This happened for the operational COSMO-DE run at '12.07.2011, 6 UTC', where q_r 'exploded' in the Alps. This could be cured by the more stable version of the tracer advection scheme, namely with the Strang-splitting variant of the Bott advection scheme. Otherwise, without this measure, the runs with the new FW2 remained stable, too.

Other examples were several experimental COSMO-DE runs with 65 levels which crashed during the summer 2012 period. (e.g. the '15.07.2011, 12 UTC' run crashed after only 215 time steps (i.e. after about 1.5 h)) FW2 experiments didn't show any crash during July and August 2012.

O. Fuhrer reported an operational COSMO-2 '16.06.2011, 0 UTC' run model crash after 1190 time steps (6.6 h). A. Seifert reported a model crash of an experimental COSMO-1 (resolution 0.01° (about 1.1km), 1700 * 1700 grid points) at the '24.08.2011 after only 10 time steps. Again these two runs have been stably simulated by FW2.

switch `l_no_div_damping_in_1st_step=.FALSE.` in module `fast_waves_sc`.
Attention: the runs with the 3D divergence damping *and* `l_no_div_damping_in_1st_step=.TRUE.` do *not work* in COSMO 4.27 due to a bug in the code. This will probably be fixed in version 4.28.

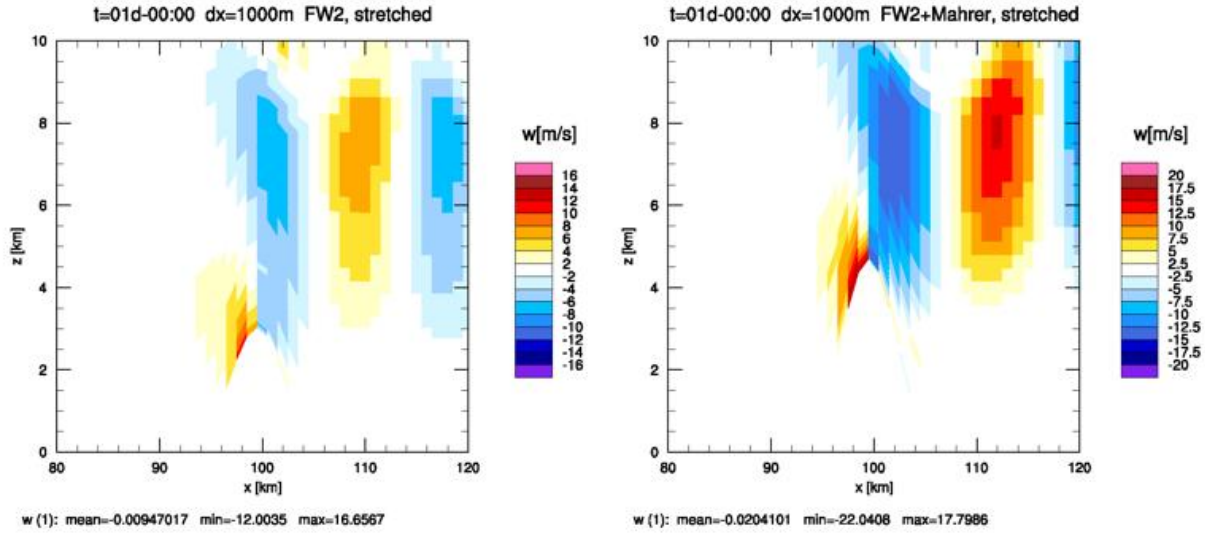

Figure 12: Flow over a 2D Gaussian shaped mountain. Vertical velocity w simulated with the new fast waves solver (FW2) after 24 h. Left: with conventional pressure discretization and a mountain height $h_{max} = 3100$ m. Right: with Mahrer (1984)-discretization and $h_{max} = 4800$ m.

Though a slightly higher accuracy of FW2 compared to FW1 has been shown in the idealized tests, the verification results for several periods at DWD didn't show larger deviations between these two versions. In particular during the winter period 2012/2013 there occured slight improvements in the pressure bias but a slight negative behavior in the cloud coverage. Nevertheless, the higher stability of the new fast waves solver led to the decision to introduce it both in COSMO-DE (2.8 km) and COSMO-EU (7 km) at 16 January 2013 after a 5 month testing period at DWD.

One should notice, that for a proper interpolation form driving initial and boundary data, the interpolation program INT2LM (since version 1.20) must use the same reference state as COSMO for the *half levels*, too. Therefore, the namelist switch `lanalyt_calc_T0p0` must be set to `.TRUE.` if `itype_fast_waves=2` is used (to be precise: this is only necessary, if the older reference atmosphere `irefatm=1` is used). The same holds for possible postprocessing programs, e.g. the `lmstat` feedback file generator.

11 Conclusions

The development of a new fast waves solver for the COSMO model has been described in this report. This new development is available since COSMO version 4.24 and should be used together with the interpolation program INT2LM since version 1.20. The slightly better accuracy properties and in particular the better stability properties in steeper terrain has been demonstrated. In the end, the new fast waves solver was introduced operationally at DWD for both model setups 2.8 km COSMO-DE (deterministic and ensemble mode) and 7 km COSMO-EU at 16 January 2013.

On the NEC SX9 (DWD) the new fast waves solver needs about 30 percent more computation time compared to the old one. This results in an increase of runtime of about 6 percent for the whole COSMO model. A certain increase in runtime is understandable due to the larger number of computations and storage loads by the additional vertical weightings. These values are also quite dependent from the computer architecture. On some Intel based computers

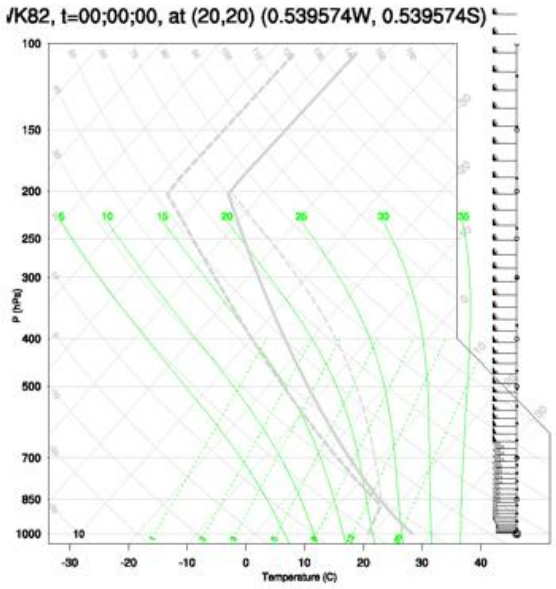

Figure 13: skew T - log p -digram for the environment atmosphere of the Weisman, Klemp (1982) test case.

these run times can be even higher, but a report from our Russian colleagues (running COSMO on an SGI ALTIX, built on Intel(R) Xeon(R) X5560 processors) indicates, that the runtime can even be much smaller with the new FW solver.

Of course, there is still enough work to be done. For example, until now it is not possible to use the exact boundary condition for Z and hence for the divergence, which is a bit unsatisfying. Though the Mahrer discretization (section 4.2.2) has been proven as advantageous in idealized steep mountain tests and as stable in many real case simulations, a detailed verification and assessment is still needed, possibly together with an improvement of the lower boundary treatment. Finally, the isotropic 3D divergence damping offers theoretical advantages and runs stable in several real test cases. Consequently, it should be further investigated. The full 3D divergence damping results in an about 10 percent longer runtime for the fast waves solver, resulting in an about 2 percent longer runtime for the whole COSMO model. Therefore, the question remains, if these additional computational costs justify its usage in operational applications.

The new solver was developed for the Runge-Kutta time integration scheme, which is now used by every NWP center of the COSMO consortium and by the most (if not all) climate runs of the climate CLM community. But in principle, there is no reason, why the new solver shouldn't be used for the 'old' leapfrog time integration scheme, too (a certain harmonization of other discretizations used in the leapfrog scheme and the vertical weightings introduced here is probably needed, before). Hence, there is a certain hope to replace the other fast waves solvers in future by this new development and therefore to reduce complexity and maintenance efforts in the COSMO code.

12 Acknowledgments

The author is grateful to Günther Zängl (Deutscher Wetterdienst), who initiated this project and helped a lot with many discussions about the topic. Many thanks also to Andreas Will

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1. Introduction

Numerical weather prediction (NWP) models as well as other simulation models of atmospheric flow often apply numerical or computational smoothing in order to control small scale noise at or near the two grid interval ($2\Delta x$) wavelength. As these scales cannot be resolved adequately by the discretized dynamics, they have to be damped since otherwise large errors in the numerical solution can arise.

Numerical noise of such type is continuously generated by numerical dispersion, especially within the Leapfrog time integration using centred difference operators for advection as, e.g., in the current operational version of the Lokal-Modell (LM). Also, weak nonlinear numerical instabilities resulting from aliasing can contribute to the generation of small-scale noise, and physical processes, which in general act discontinuous at single grid points, will always introduce noise at the $2\Delta x$-scale. The formation of non-resolvable small-scale structures will also arise from topographical forcing and from surface inhomogeneities.

High-order scale-selective spatial filters can be applied to remove small-scale noise from the numerical solution (Shapiro, 1975, and Raymond, 1988). But most NWP models use computationally more efficient high-order numerical diffusion schemes to provide a scale selective control of small-scale noise. These schemes, however, have unwanted side effects. First, they are in general not monotonic and thus can introduce negative values on fields that are positive definite as, e.g., the cloud water content or the specific humidity. Second, they introduce noise by themselves on the resolvable scales via the so-called Gibbs phenomenon.

Another problem of using high-order numerical diffusion schemes in NWP models arises from the fact that smoothing is usually applied as a horizontal diffusion, that is along terrain-following model layers and not explicitly in the vertical direction. A full 3-D formulation would have to take into account a large number of metric terms from the terrain-following coordinate transformation and thus is too expensive for an operational application. In case of high-resolution modelling with steep slopes of the model layers, however, a 2-D numerical diffusion along model layers will imply a large but unwanted vertical mixing (e.g. between mountain tops and narrow valleys), especially in an atmosphere with strong stratification of the thermodynamic variables. To tackle this problem, a simple orographic flux-limiter is proposed which reduces numerical diffusion with increasing steepness of the topography.

The formulation of a monotonic scheme for horizontal numerical diffusion in the LM is based on the work of Xue (2000), who proposed two types of schemes: one based on Zalesak-type flux-correction (Zalesak, 1979) using the combination of high- and low-order schemes, and the other based on a simple flux-limiter which ensures that the diffusive fluxes are downgradient. The latter formulation, however, was found to be not strictly monotonic when applied to real cases. Thus, a third scheme is formulated which is based on direct multi-dimensional flux-limiting.

Section 2 summarizes the basic features of high-order numerical diffusion, followed by a description of three monotonic schemes in Section 3. The application of these schemes to simple 1-D and 2-D square wave tests is described in Section 4. In Section 5, an additional flux-limiter related to the slope of the model layers is introduced. The application of the new scheme to simulation of real cases with the LM is discussed in Section 6, and results from parallel test suites at MeteoSwiss and at DWD are described in Section 7. Finally, an outline of the technical implementation is given in Section 8.

2. High-Order Numerical Smoothing

Computational diffusion is mostly realized by introducing an additional operator to the right hand side of the prognostic equations:

$$\frac{\partial \psi}{\partial t} = S(\psi) + (-1)^{m/2+1} \alpha_m \nabla^m \psi \,, \tag{1}$$

where ψ is one of the prognostic variables and S represents all physical and dynamical source terms for ψ. The last term in Eq.(1) is the added linear diffusion term where m ($m = 2, 4, 6, \cdots$) denotes the (even) order of computational diffusion and α_m is the corresponding diffusion coefficient of order m.

The higher the order of the diffusion operator, the more scale selectively wavelength components are damped. Figure 1 shows the amplification factor (here: damping factor) for a one dimensional version of Eq.(1) using a forward in time and centred in space finite difference scheme for integration, plotted against the normalized wavelength $k\Delta x$ where k is the wavenumber and Δx is the grid spacing. For each of the second, fourth and sixth order schemes the corresponding diffusion coefficient α_m is chosen so that the shortest waves representable on a discrete grid ($2\Delta x$, i.e. $k\Delta x = \pi$) are damped completely within one integration time step.

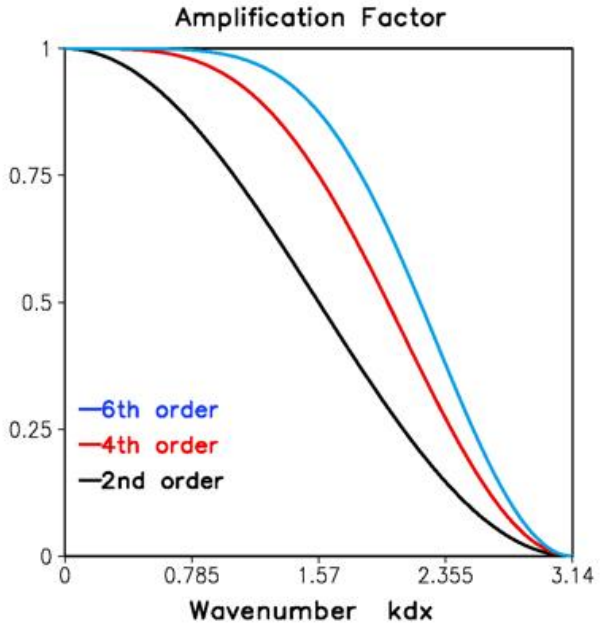

Figure 1: Amplification factor plotted against the normalized wavenumber

As can be seen from Fig. 1, all schemes damp not only the two grid interval wavelength, but also longer wave components in a wave spectrum. For example, the amplitude of a $4\Delta x$

wave is reduced by a factor of 0.5 in the second order scheme, and longer waves are also damped significantly. The fourth and sixth order scheme have much less damping for these longer waves, which contain physical meaningful information in a simulation and should not be affected by a numerical filter. Clearly, higher order schemes provide a more scale selective damping.

Many models use the 4th order linear computational diffusion scheme because of its relative computational efficiency compared to the 6th order scheme and of its superior damping properties compared to the second order scheme. Schemes of higher than 2nd order, however, have unwanted side effects. The 2nd order scheme has a Laplacian form and thus is always monotonic: by transferring higher values of the field into regions with smaller values no new minima or maxima can be created. This is not the case for the 4th, 6th and even higher order schemes, where spatial oscillations are introduced (Gibbs phenomenon), as can be seen in Fig. 2.

Figure 2 shows the one dimensional numerical solution of Eq.(1) (with $S = 0$) for 2nd, 4th and 6th order diffusion applied to an initial rectangular structure. The second order scheme (left) is strongly diffusive even for the large scale structure. At the end of the integration ($t = 100$) the amplitude of the entire square wave is significantly reduced. The 4th (middle) and 6th order (right) schemes retain the initial structure much better, and at the lateral edges, where short wavelengths components dominate, the sharp gradients are maintained in the solution (somewhat better by using the 6th order scheme).

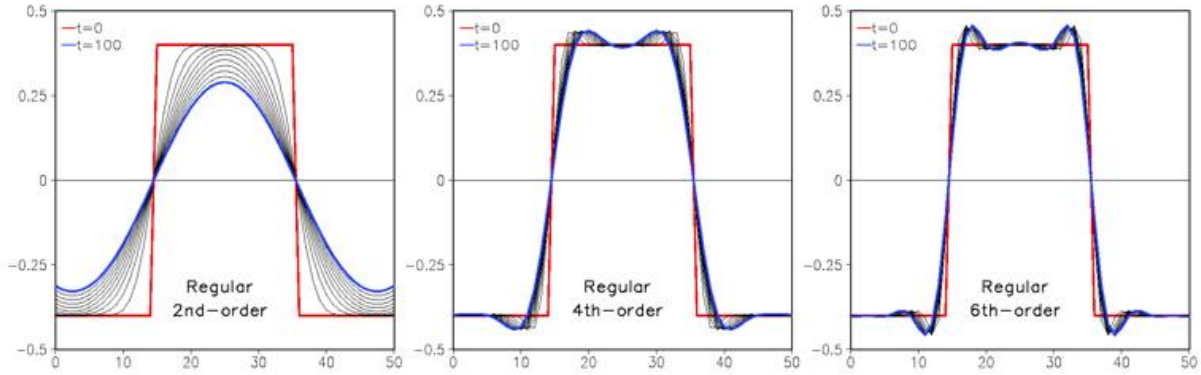

Figure 2: 1-D numerical solution of Eq.(1) for an initial square wave (red, $t = 0$) in case of 2nd (left), 4th (middle) and 6th order (right) linear diffusion. The domain has 51 grid points with a grid spacing of 1/50 m and the time step is 1 sec. The diffusion coefficients are chosen such that there is full damping of a $2\Delta x$ wave within one time step, i.e. $\alpha_m = (\Delta x/2)^m/\Delta t$. The solutions are plotted at 10 timestep intervals (thin lines).

However, over- and undershoots are generated by the numerical solution. The amplitude of these unphysical, both positive and negative spatial oscillations is increased by increasing the order of the diffusion operator. That is, going to higher than 4th order diffusion will not cure this side effect. Obviously, the $2\Delta x$ waves are removed from the solution, but at the cost of *introducing new noise on the resolvable scales.* In the context of a full simulation model these oscillations will interact nonlinearly with the physics as well as with the dynamics (as they are on the resolvable scales) and thus can result in unforeseeable effects. Moreover, negative oscillations are unacceptable for positive definite fields such as cloud water content or specific humidity.

3. Monotonic Diffusion Operators

This section describes three types of monotonic diffusion schemes. The first one is based on a Zalesak-type flux correction, similar to that used in many advection schemes. The second scheme is based on a simple flux limiter proposed by M. Xue (2000). And the third scheme uses a multidimensional flux limiter, where the formulation of the limiter factor closely follows the approach of Smolarkiewicz (1989).

The basic pre-requisite to apply these schemes is to rewrite the diffusion operator in Eq.(1) in a flux form. Omitting the source term S, the diffusive tendency then reads

$$\frac{\partial \psi}{\partial t} = (-1)^{m/2+1} \alpha_m \nabla^m \psi = -\nabla \cdot \mathbf{F}\,, \tag{2}$$

where $\mathbf{F}$ denotes the diffusive flux being defined by

$$\mathbf{F} \equiv (-1)^{m/2} \alpha_m \nabla (\nabla^{m-2} \psi)\,. \tag{3}$$

(a) Zalesak-type Flux Correction

Using the notations from Eqs.(2) and (3), the numerical scheme to integrate the 1-D version of the diffusion equation (the extension to more than one dimension is readily adopted) for a forward in time and centred in space scheme reads

$$\psi_i^{n+1} \;=\; \psi_i^n - (A_{i+1/2}^n - A_{i-1/2}^n), \tag{4}$$

where n denotes the time level, i is the gridpoint index and

$$A_{i+1/2}^n \equiv F_{i+1/2}^n \Delta t / \Delta x \tag{5}$$

denotes the normalized diffusive flux. Following the flux correction idea of Zalesak (1979), that was applied to the advection equation, Xue proposed a flux corrected scheme based on the combination of a low-order and a high-order diffusion scheme. Let A^L be the low-order diffusive flux, which is chosen to be of second order and thus will guarantee monotonicity, and A^H be a higher order diffusive flux, e.g. 4th or 6th order. Denoting the difference between the high-order diffusive flux A^H and the 2nd order one by

$$A^{HL} \;=\; A^H - A^L\,, \tag{6}$$

the Zalesak-type time integration scheme (4) can be written as

$$\begin{aligned} \psi_i^* &= \psi_i^n - (A_{i+1/2}^L - A_{i-1/2}^L)\,, \\ \psi_i^{n+1} &= \psi_i^* - (C_{i+1/2} A_{i+1/2}^{HL} - C_{i-1/2} A_{i-1/2}^{HL})\,. \end{aligned} \tag{7}$$

The factor C is called the flux correction coefficient or flux limiter, where $0 \leq C \leq 1$. When $C = 0$, the integration scheme (7) reduces to the 2nd order scheme, and when $C = 1$ it becomes purely high order. The idea is to use the high order scheme to the maximum extend possible, i.e. to reduce the fluxes by a factor C (to be determined for each grid interval interface) only when the monotonicity constraint is not met. As has been pointed out by Xue, the diffusion coefficients α_m of the low- and high-order schemes in the two step scheme (7) have to be chosen to be consistent with each other. To do so, it is required that two grid interval waves are damped by the same amount per time step. This means that different diffusion coefficients have to be used in the high-order flux A_H and in the low-order flux A_L. Longer waves, however, will be damped by a different amount.

Since the diffusion process should not generate new minima or maxima by stepping from the current time level n to the future time level $n+1$, the monotonicity constraint is chosen to be

$$\psi_i^{min} \leq \psi_i^{n+1} \leq \psi_i^{max}, \tag{8}$$

where ψ_i^{min} and ψ_i^{max} are the minimum and the maximum of ψ at the gridpoint and the adjacent points at the current time level n:

$$\psi_i^{min} = \min\left(\psi_{i-1}^n, \psi_i^n, \psi_{i+1}^n\right), \quad \psi_i^{max} = \max\left(\psi_{i-1}^n, \psi_i^n, \psi_{i+1}^n\right). \tag{9}$$

Following Zalesak, a flux limiter satisfying condition (8) can be defined as

$$C_{i+1/2} = \begin{cases} \min\left(1, R_{i+1}^+, R_i^-\right) & \text{if} \quad A_{i+1/2}^{HL} \geq 0\,, \\ \min\left(1, R_i^+, R_{i+1}^-\right) & \text{if} \quad A_{i+1/2}^{HL} < 0\,, \end{cases} \tag{10}$$

where

$$\begin{aligned} R_i^+ &= (\psi_i^{max} - \psi_i^*)/(A_i^{in} + \epsilon)\,, \\ R_i^- &= (\psi_i^{min} - \psi_i^*)/(A_i^{out} + \epsilon)\,. \end{aligned} \tag{11}$$

Here, ϵ is a small positive number to avoid division by zero. A_i^{in} and A_i^{out} are, respectively, the sum of all incoming and outgoing corrective fluxes A^{HL} of a grid box.

(b) The Xue Flux-Limiter

The monotonic scheme described above guarantees monotonicity, the computational costs, however, appear to be quite high. Xue pointed out that diffusive fluxes in high order schemes are not necessarily downgradient (as they are in the monotonic second order scheme) because they are no longer related to the local gradient of the diffused variable ψ. Upgradient fluxes can result in unphysical solutions and explain the over- and undershoots when applying high order schemes.

As a simple way to prevent upgradient fluxes to occur, Xue proposed to set the diffusive fluxes to zero whenever they have the same sign as the gradient of ψ. In the time integration scheme (4), the normalized fluxes A are thus replaced by

$$\tilde{A}_{i+1/2} = -A_{i+1/2} \min[0, \mathrm{sign}(A_{i+1/2}\delta_x\psi)]\,, \tag{12}$$

where the sign-function returns the sign of the argument. The application of this simple flux limiter in higher order diffusion schemes seems to prevent over- and undershoots in simple test cases. Obviously, the Xue-limiter (12) is far more efficient than the Zalesak-type flux corrected scheme since the extra computational costs are very small.

However, it cannot be shown analytically that the limiter will ensure strict monotonicity of the solution. Tests of the simple flux limiter (12) for the 4th order diffusion of real field distributions of cloud water and specific humidity have shown that over- and undershoots may still be present (see Section 4).

(c) Multidimensional Flux-Limiter

The multidimensional flux limiting scheme follows closely the ideas of the Zalesak-type flux correction scheme described above, but uses a direct limiter instead of the correction method based on antidiffusive fluxes. In this way, the two-step time integration scheme (7) as well as the problem of using consistent diffusion coefficients for low- and high-order fluxes is avoided. The construction of the limiter follows the approach of Smolarkiewicz (1989).

The numerical scheme for integrating the 2-D version of the diffusion equation using a forward in time and centred in space scheme reads

$$\psi_{i,j}^{n+1} = \psi_{i,j}^{n} - (A_{i+1/2,j}^{n} - A_{i-1/2,j}^{n} + A_{i,j+1/2}^{n} - A_{i,j-1/2}^{n}), \tag{13}$$

where n denotes the time level, (i,j) are the gridpoint indices with i counting in x-direction and j in y-direction, and

$$A_{\cdot,\cdot}^{n} \equiv F_{\cdot,\cdot}^{n} \Delta t / \Delta x \tag{14}$$

are the normalized $(m-1)$-th order diffusive fluxes at cell interfaces calculated from Eq. (3). The numerical scheme (14) can be rewritten as

$$\psi_{i,j}^{n+1} = \psi_{i,j}^{n} + A_{i,j}^{in} - A_{i,j}^{out}, \tag{15}$$

with $A_{i,j}^{in}$ denoting the sum of all fluxes into a grid cell and $A_{i,j}^{out}$ denoting the sum of all fluxes going out of a grid cell. Both the sum of the incoming and outgoing fluxes, $A_{i,j}^{in}$ and $A_{i,j}^{out}$, respectively, are defined to be positive. Using the notation

$$A_{\cdot,\cdot}^{+} = \max\left(A_{\cdot,\cdot}^{n}, 0\right), \quad A_{\cdot,\cdot}^{-} = \min\left(A_{\cdot,\cdot}^{n}, 0\right) \tag{16}$$

to indicate positive and negative fluxes at the cell interfaces, the sum of the incoming and outgoing fluxes is given by

$$\begin{aligned} A_{i,j}^{in} &= -A_{i+1/2,j}^{-} + A_{i-1/2,j}^{+} - A_{i,j+1/2}^{-} + A_{i,j-1/2}^{+}, \\ A_{i,j}^{out} &= +A_{i+1/2,j}^{+} - A_{i-1/2,j}^{-} + A_{i,j+1/2}^{+} - A_{i,j-1/2}^{-}. \end{aligned}$$

The difference $A_{i,j}^{in} - A_{i,j}^{out}$ is equivalent to the discretized total flux divergence. Since a monotonic numerical scheme shall not produce new minima or maxima within a time step, the monotonicity constraint is

$$\psi_{i,j}^{min} \leq \psi_{i,j}^{n+1} \leq \psi_{i,j}^{max}, \tag{17}$$

where $\psi_{i,j}^{min}$ is the minimum and $\psi_{i,j}^{max}$ is the maximum of the field variable ψ at the point (i,j) and the adjacent grid points at time level n:

$$\begin{aligned} \psi_{i,j}^{min} &= \min\left(\psi_{i,j}^{n}, \psi_{i+1,j}^{n}, \psi_{i-1,j}^{n}, \psi_{i,j+1}^{n}, \psi_{i,j-1}^{n}\right), \\ \psi_{i,j}^{max} &= \max\left(\psi_{i,j}^{n}, \psi_{i+1,j}^{n}, \psi_{i-1,j}^{n}, \psi_{i,j+1}^{n}, \psi_{i,j-1}^{n}\right). \end{aligned}$$

Using the monotonicity constraint (17) in the numerical scheme (15) yields

$$\psi_{i,j}^{min} \leq \psi_{i,j}^{n} + A_{i,j}^{in} - A_{i,j}^{out} \leq \psi_{i,j}^{max}. \tag{18}$$

Thus, the following conditions on the sum of the incoming and outgoing fluxes are sufficient to ensure monotonicity:

$$\begin{aligned} A_{i,j}^{in} &\leq \psi_{i,j}^{max} - \psi_{i,j}^{n}, \\ A_{i,j}^{out} &\leq \psi_{i,j}^{n} - \psi_{i,j}^{min}. \end{aligned}$$

With these conditions, the sum of all incoming fluxes cannot add more mass within one time step than that required to reach the maximum value $\psi_{i,j}^{max}$ and the sum of all outgoing fluxes cannot remove more mass than that to fall to the minimum value $\psi_{i,j}^{min}$. These conditions can be rewritten in the form of flux limiter ratios

$$\begin{aligned} \beta_{i,j}^{in} &= \frac{\psi_{i,j}^{max} - \psi_{i,j}^{n}}{A_{i,j}^{in} + \epsilon} \\ \beta_{i,j}^{out} &= \frac{\psi_{i,j}^{n} - \psi_{i,j}^{min}}{A_{i,j}^{out} + \epsilon}, \end{aligned} \tag{19}$$

where ϵ is a small number to avoid division by zero in the computer program. Whenever $\beta^{in}_{i,j} \geq 1$, the total incoming flux does not need to be modified. But if $\beta^{in}_{i,j} < 1$ the incoming fluxes are overestimated and the flux limiter has to be applied. Similar, if $\beta^{out}_{i,j} \geq 1$, the total outgoing fluxes will ensure monotonicity, but if $\beta^{out}_{i,j} < 1$, the outgoing fluxes are overestimated and have to be limited.

Since the total incoming and outgoing fluxes are additively composed of the fluxes at the cell interfaces, the limiter (19) is applied for each of these fluxes. And as the limiter for the incoming fluxes has been constructed independently of the limiter for the outgoing fluxes and because the outgoing flux at a cell interface is equivalent to the incoming flux at the adjacent cell, it is sufficient to simply take the minimum of both limiters. The application of the limiters (19) to the fluxes at the cell interfaces in the i- and j-direction can be written in a compact manner:

$$\begin{aligned} \tilde{A}^n_{i+1/2,j} &= \min\left(1, \beta^{out}_{i,j}, \beta^{in}_{i+1,j}\right) A^+_{i+1/2,j} + \min\left(1, \beta^{out}_{i+1,j}, \beta^{in}_{i,j}\right) A^-_{i+1/2,j}\,, \\ \tilde{A}^n_{i,j+1/2} &= \min\left(1, \beta^{out}_{i,j}, \beta^{in}_{i,j+1}\right) A^+_{i,j+1/2} + \min\left(1, \beta^{out}_{i,j+1}, \beta^{in}_{i,j}\right) A^-_{i,j+1/2}\,. \end{aligned} \tag{20}$$

For example, if the flux $A_{i+1/2,j}$ at the cell interface separating cell (i,j) and $(i+1,j)$ is positive, i.e. is an outgoing flux from cell (i,j) and thus an incoming flux for cell $(i+1,j)$, it will be limited with the minimum of the limiter $\beta^{out}_{i,j}$ of cell (i,j) and the limiter $\beta^{in}_{i+1,j}$ from cell $(i+1,j)$. By replacing the normalized fluxed A in the time integration scheme (13) with the limited normalized fluxes $\tilde{A}$ from Eq. (20), a monotonic diffusion scheme is finally obtained.

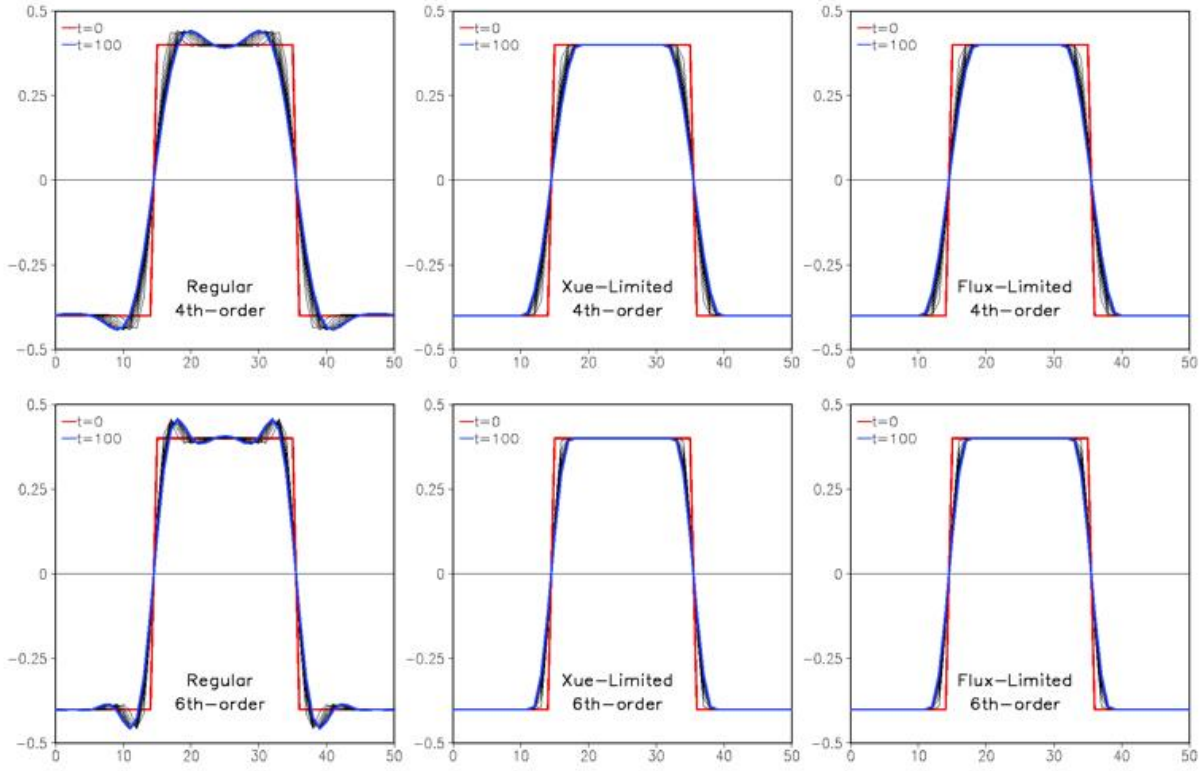

Figure 3: As in Fig. 2, but for 4th (upper panel) and 6th order (lower panel) linear diffusion. Left: Regular diffusion. Middle: Xue-limited diffusion. Right: Flux-limited diffusion.

4. Results from Simple Tests Cases

The solutions of the one-dimensional square waves test using 4th and 6th order regular diffusion as well as the monotonic scheme based on the Xue flux-limiter (12) and the scheme (20) based on direct flux limiting are shown in Figure 3.

Obviously, the unwanted numerical effects associated with the Gibbs phenomena are no longer present when using the simple Xue-limiter or the full flux limiter, but the smoothing characteristic is maintained in both schemes. The solution obtained with the Zalesak-type flux correction method (not shown) are very similar.

The extension of the monotonic schemes described in Section 3 to more than one dimension is straightforward. Fig. 4 shows the field distribution at initial time and the numerical solution obtained with 2nd-order diffusion after 100 time steps for the 2-D square wave test, where initially a block of 20 by 20 gridlines with a field value of 0.4 is placed in a background field having a value of -0.4. All parameters are the same as in the 1-D test, except that the diffusion coefficient for maximal damping has been adopted for the twodimensional case. Similar to the 1-D case, the initial distribution is significantly smoothed even at the larger scales. The peak value of 0.4 is reduced to 0.28 and the initial rectangular structure is no longer visible.

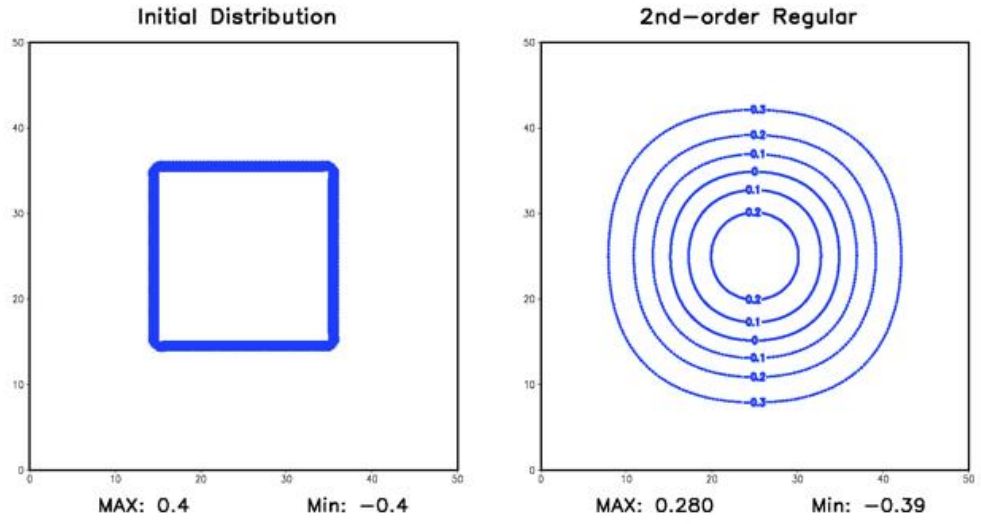

Figure 4: Contour maps of a field for the 2D square wave test. Left: Initial field distribution, where a block with field values with 0.4 is placed in a background field having the value of -0.4. Right: Solution of the 2nd-order regular diffusion after 100 time steps. The contour interval is 0.1

The results of the 4th-order regular linear diffusion and of the three alternative monotonic 4th-order schemes from Section 3 are shown in Fig. 5. When compared to the 2nd-order scheme, much sharper gradients at the lateral sides are retained by using the regular 4th-order diffusion scheme. Also, the large scale features of the initial field distribution are still visible. However, the 4th-order scheme suffers significantly from the Gibbs phenomenon, with severe overshoots of the order of 10% and undershoots of the order of 5% of the initial amplitude.

This effect is completely avoided by applying the Zalesak flux-correction scheme, the Xue-limiter or the multidimensional flux limiter. In all three schemes no over- or undershooting exists and the maxima and minima values of the field are exactly 0.4 and -0.4, respectively. Also, a slightly better gradient is maintained by the monotonic schemes compared to the solution from the regular 4th-order scheme and the rectangular shape of the contour lines

is retained somewhat better. The noisy appearance of the 0.4 and -0.4 contour line in the solution by the Zalesak scheme is due to roundoff errors which, however, have no detrimental impact.

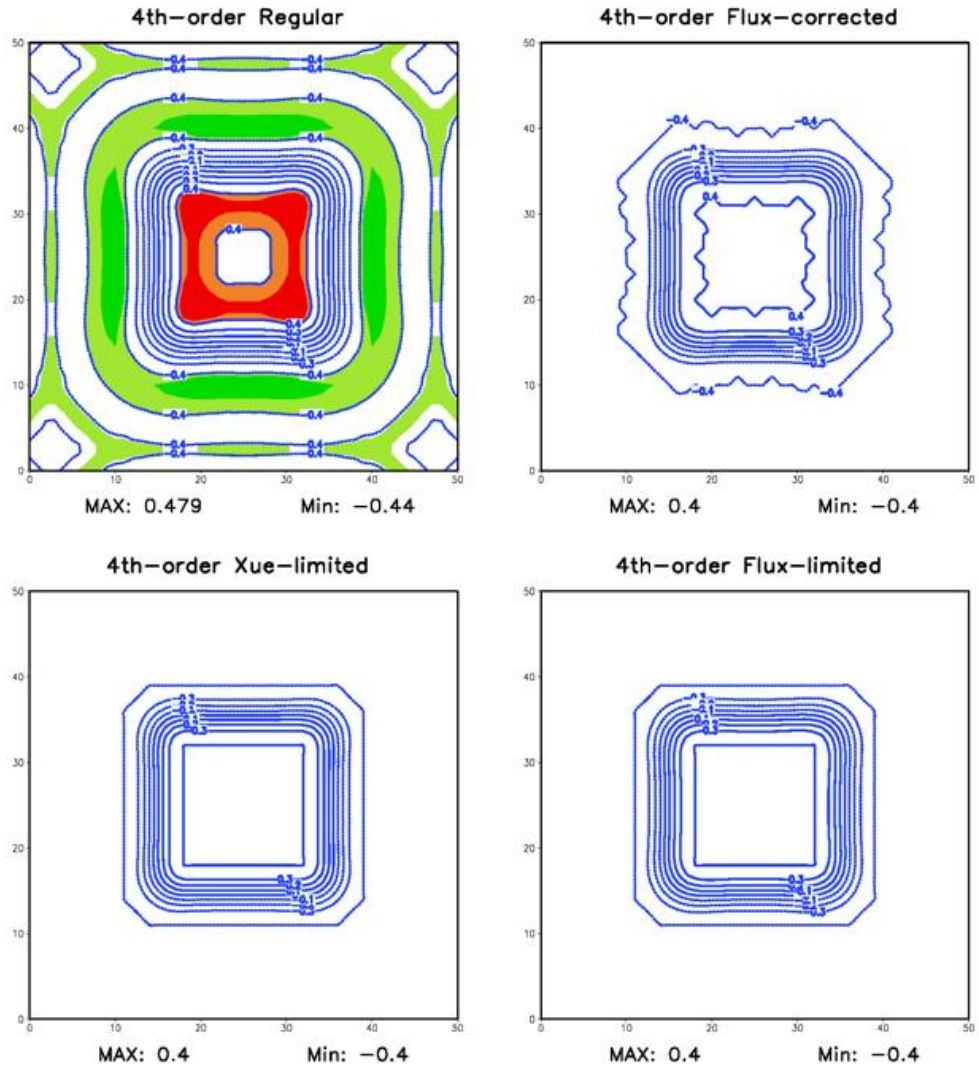

Figure 5: 2-D numerical solution of Eq.(1) for the square wave test after 100 time steps. Top left: 4th-order regular diffusion. Top right: 4th-order flux corrected. Bottom left: 4th-order Xue-limiter. Bottom right: 4th-order flux limited. Red shading indicates regions of overshoots, green shading regions of undershoots. The contour interval is 0.1.

All three schemes with monotonic limiters give very similar numerical solutions, but the simple Xue-limiter is the most efficient one as the additional computational costs are very small. Compared to the regular 4th-order diffusion, the computation time ratio of the Zalesak flux-correction scheme is 3.6, of the multidimensional flux-limiting scheme is 3.1, but is only 1.9 for the simple Xue-limiter (on an SGI Octane workstation).

Thus, from a practical point of view, the Xue-limiter seems to be the most efficient scheme to ensure monotonicity of high-order numerical diffusion. When applied to the cloud water field (a field with values varying within a few orders of magnitude) in simulations of real cases with the LM, however, this limiter was found to be not strictly monotonic. At a large number of gridpoints with a positive definite field distribution at the beginning of a time step, negative field values are observed after subjecting to 4th order diffusion with the Xue-limiter. To demonstrate this, a few gridpoint values (normalized by a factor) of a real

case simulation are chosen as initial condition for a 1-D numerical solution of the diffusion equation over 10 timesteps. In the beginning, a high value of water content is prescribed, with two much smaller side-maxima to the left and right, but separated by a zero value (see Fig.6). Structures like this are not too frequent but not unusual in simulations of real cases.

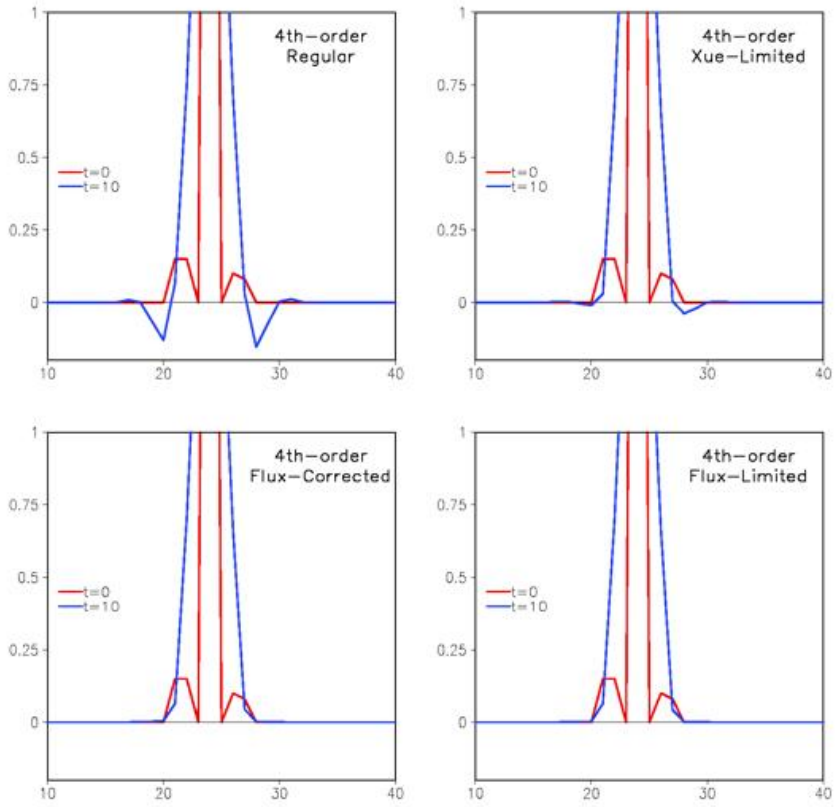

Figure 6: As in Fig. 2, but for a non-regular initial distribution (t=0, red) after 10 time steps (t=10, blue) for 4th-order diffusion. Top left: Regular. Top right: Xue-limiter. Bottom left: Flux-correction. Bottom right: Flux-limiting. The peak value of the initial distribution is 6.0.

The results of applying 4th-order numerical diffusion to this initial distribution using the regular scheme, the Xue-limiter, the Zalesak-limiter and the flux-limiter are shown in Fig. (6). Quite large undershoots with negative cloud water contents are generated by the regular scheme. This characteristic effect is drastically reduced by using the Xue-limiter, but is not cured completely: small negative values are still present in the solution. Both the flux-corrected and the flux-limited schemes guarantee a smooth and strictly monotonic solution.

Thus, the simple Xue flux-limiter seems not to be suited for application to the specific humidity and the specific water variables in a numerical prediction model, since spurious negative values of these variables may still be generated. For such fields, the schemes based on flux-correction or on flux-limiting should be used, where the multidimensional flux limiter is a little bit in favor because of its slightly better computational efficiency and a simpler formulation. For fields being not positive definite, as e.g. the velocity components, the Xue limiter is a viable and efficient alternative.

5. An Orographic Flux Limiter

Most mesoscale NWP models use a terrain-following sigma-type vertical coordinate and numerical smoothing is realized as horizontal diffusion, i.e. along quasi-horizontal surfaces of constant vertical coordinate. Over complex terrain, this may lead to systematic numerical biases which are induced by horizontal diffusion, as an unwanted vertical mixing in physical space will be implied. Clearly, the impact of this type of numerical error will increase with increasing steepness of the topography and is thus more noticeable in models with very high resolution.

For instance, if horizontal diffusion is applied directly to temperature in the prognostic equation for temperature, the smoothing will tend to cool the valleys and to heat the mountain tops in any stratification where the temperature decreases with height. Similarly, in an atmosphere with decreasing specific humidity with height, horizontal diffusion will dry the valley and moisten the mountains, which can have an unwanted positive feedback to precipitation formation over mountain tops.

Various modifications have been proposed to reduce the spurious biases resulting from quasi-horizontal mixing. Most models use a so-called slope correction for horizontal smoothing in the temperature equation, where instead of the actual temperature the difference of temperature and a reference profile is diffused. In LM, we use the model base state for this purpose. Errors from unwanted vertical mixing are then zero when the actual vertical temperature gradient is identical to the gradient of the base-state profile. However, when the profiles deviate from each other, large error may still be introduced (e.g. in very stable or unstable stratification). Slope corrections for other variables are normally not used.

Another popular method is the use of "true" horizontal diffusion, i.e. along surfaces of constant height or constant pressure (e.g. Zängl, 2000). Here, the values of the diffused variables at the adjacent gridpoints are interpolated to the height or pressure level of each gridpoint before diffusion is applied. Since the gridpoints usually have different heights, however, the diffusive fluxes at the cell interfaces will differ for neighboring gridpoints. Thus, mass conservation cannot be guaranteed with such a scheme. One could also try to locally reduce the value of the diffusion coefficient depending on the steepness of the orography (a commonly used measure is the Laplacian of topographical height). But here again the diffusive fluxes at the cell interface between two neighboring gridpoints will be different and mass can be artificially generated or lost.

Numerical smoothing schemes which introduce uncontrollable sources or sinks in momentum, heat or water mass are problematic, especially in an operational NWP model. With the flux-limited scheme discussed in the preceding Section, we have the opportunity to reduce the topography-induced biases without violating mass conservation: One can simply reduce the diffusive fluxes at the cell interfaces, depending on the steepness of the model surfaces. As the scheme is in flux-form, mass will be conserved automatically. And if the fluxes are artificially reduced before the monotonic flux limiters are applied, the monotonicity of the diffused field will also be guaranteed.

Two variants of this methods have been tested. The first is a non-continuous formulation, where the diffusive fluxes are simply set to zero whenever the height difference between two neighboring grid points exceeds a threshold value. Defining this height differences at cell interfaces and denoting them by

$$\Delta h_{i+1/2,j} = |h_{i+1,j} - h_{i,j}|\,, \quad \Delta h_{i,j+1/2} = |h_{i,j+1} - h_{i,j}|\,, \tag{21}$$

where $h_{i,j}$ is the geometrical height of a grid point at a surface of constant vertical coordinate,

the limiter function for the diffusive fluxes A in Eq. (13) can be written as

$$A_{i+1/2,j} = \begin{cases} F_{i+1/2,j}\frac{\Delta t}{\Delta x}, & \text{if} \quad \Delta h_{i+1/2,j} \leq H_{max}\,, \\ 0\,, & \text{if} \quad \Delta h_{i+1/2,j} > H_{max}\,, \end{cases}$$
$$A_{i,j+1/2} = \begin{cases} F_{i,j+1/2}\frac{\Delta t}{\Delta x}, & \text{if} \quad \Delta h_{i,j+1/2} \leq H_{max}\,, \\ 0\,, & \text{if} \quad \Delta h_{i,j+1/2} > H_{max}\,. \end{cases} \tag{22}$$

Here, H_{max} is a threshold value for the maximal height difference. Another approach is to gradually reduce the fluxes with increasing steepness. One can try various functional dependences, but to keep things simple we apply a simple quadratic form, where the fluxes become zero when the threshold value for the height difference is exceeded:

$$A_{i+1/2,j} = \max\{\,0\,, 1 - (\Delta h_{i+1/2,j}/H_{max})^2\} \cdot F_{i+1/2,j}\frac{\Delta t}{\Delta x}\,.$$
$$A_{i,j+1/2} = \max\{\,0\,, 1 - (\Delta h_{i,j+1/2}/H_{max})^2\} \cdot F_{i,j+1/2}\frac{\Delta t}{\Delta x}\,. \tag{23}$$

Tests of the application of the orographic flux limiters (22) and (23) are discussed in Section 6.2.

6. Results from Test Simulations with the LM

This Section describes some results from single test simulations of real cases using the current operational version of LM (lm_f90, V 2.6). The basic model setup is identical to the operational configuration (7km grid spacing, 40 sec timestep, full physics). First, the impact of monotonicity is discussed in Section 6.1. Second, the application of the orographic flux-limiters is described in Section 6.2.

6.1 The Impact of Monotonic Flux-Limiting

As a first test, the Xue limiter was applied to all prognostic variables for a randomly chosen real case from 18 September 2000. Figure 7 shows the vertically integrated cloud water content of a 12h-forecast starting at 00 UTC. Concerning the structure of the two cloud bands over Denmark and over the Northern Sea, no apparent differences between the reference run using regular 4th order diffusion and the model version with monotonic diffusion can be noticed. However, the area mean value of the integrated cloud water content is slightly reduced from 41 to 38 gm^{-2}.

This can also be noticed from the scatter diagram (Figure 7, right), where the gridpoint values of the integrated cloud water content of the reference run (y-axis) are plotted against those from the experiment (x-axis). Obviously, the values obtained from the reference are on average somewhat larger than those resulting from the run with monotonic diffusion. The same type of impact can also be noticed in the precipitation amount, which is slightly smaller in the experiment (not shown). One could attribute this to the removal of overshoots from the solution for the cloud water field. In a complex nonlinear model, however, such a clear assignment of cause and effect is not possible. Due to the noticeable effect on the cloud water content, a more thorough evaluation is necessary to assess the impact of the monotonic diffusion scheme on the cloud-radiation interactions.

6.2 The Impact of Orographic Flux-Limiting

First test integrations using the monotonic flux limiter (20) in connection with the orographic limiter (23) have been performed for a number of cases from the period October-November 2000. During this time, a synoptic-scale weather situation with southerly flow over the Alps

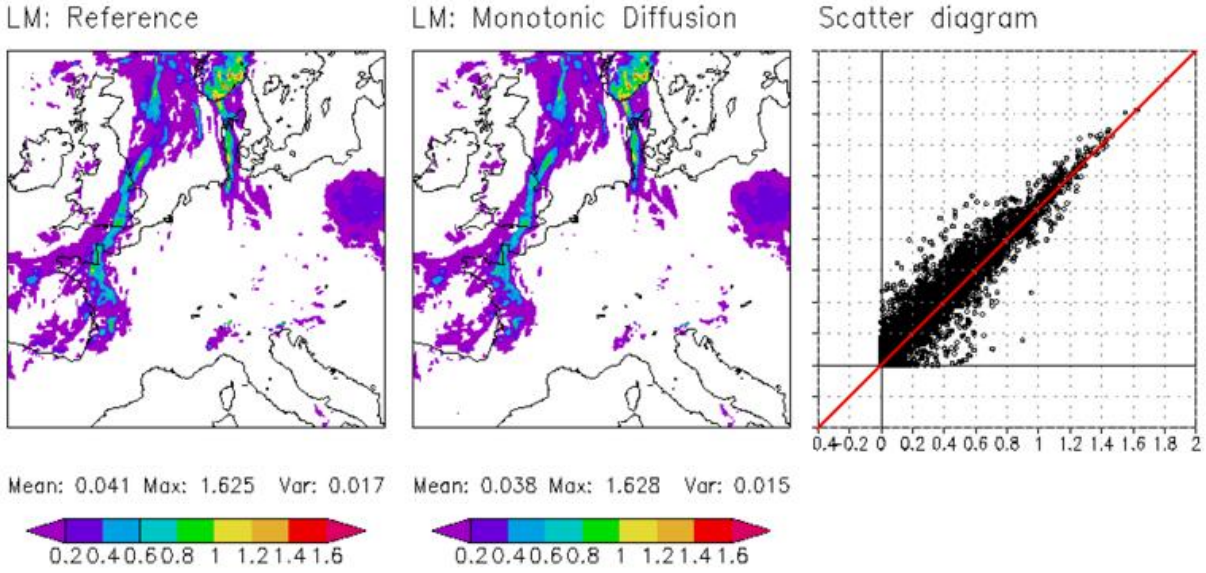

Figure 7: Vertically integrated cloud water (kg/m^2) content of a 12-h LM forecast starting at 18 September 2000 00 UTC. Left: reference solution with 4th oder regular diffusion; middle solution from a run with monotonic Xue limited diffusion; right: Scatter diagram of values from the reference (y-axis) viz. experiment (x-axis) runs.

prevailed, causing often a Föhn-effect in regions to the north of the Alps with blocking or weakening of cold fronts from the west. In the operational forecasts with the LM at DWD, however, the Föhn-effect was overestimated in most cases. This can be noticed when comparing the monthly mean precipitation from the forecasts and from a high resolution observation network for October 2000 in Fig. 8: The precipitation amount for southwestern Germany and for Bavaria is severely underpredicted due to a too frequent blocking or too strong weakening of fronts. A similar underprediction is noticed for the northern and western parts of Switzerland.

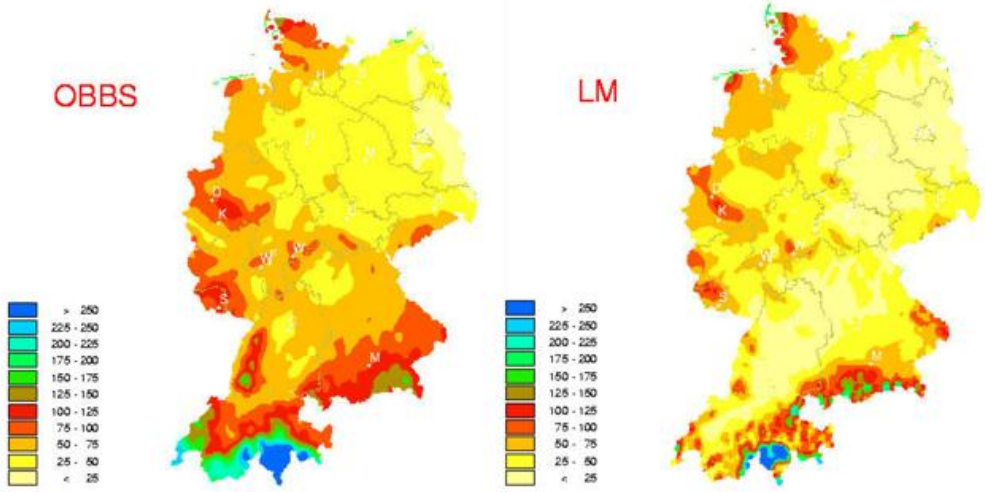

Figure 8: Monthly precipitation amount (mm) for October 2000 as observed (OBBS) by climate networks (max: 525 mm, mean: 63mm) and derived from 00 UTC LM forecasts (+30h - 06h) at DWD (max: 999 mm, mean: 69mm).

During a number of experimental studies related to the failure of the model forecasts for these Föhn situations, it was found that horizontal diffusion has an unexpected large dynamical

impact on the onset and strength of the Föhn flow. As an example, we choose here the forecast starting from 00 UTC at 11 October 2000. For experimentation, a somewhat smaller model domain (241x241 gridpoints) than the operational one (325x325 gridpoints) has been used. The initial and boundary conditions come from interpolated GME data.

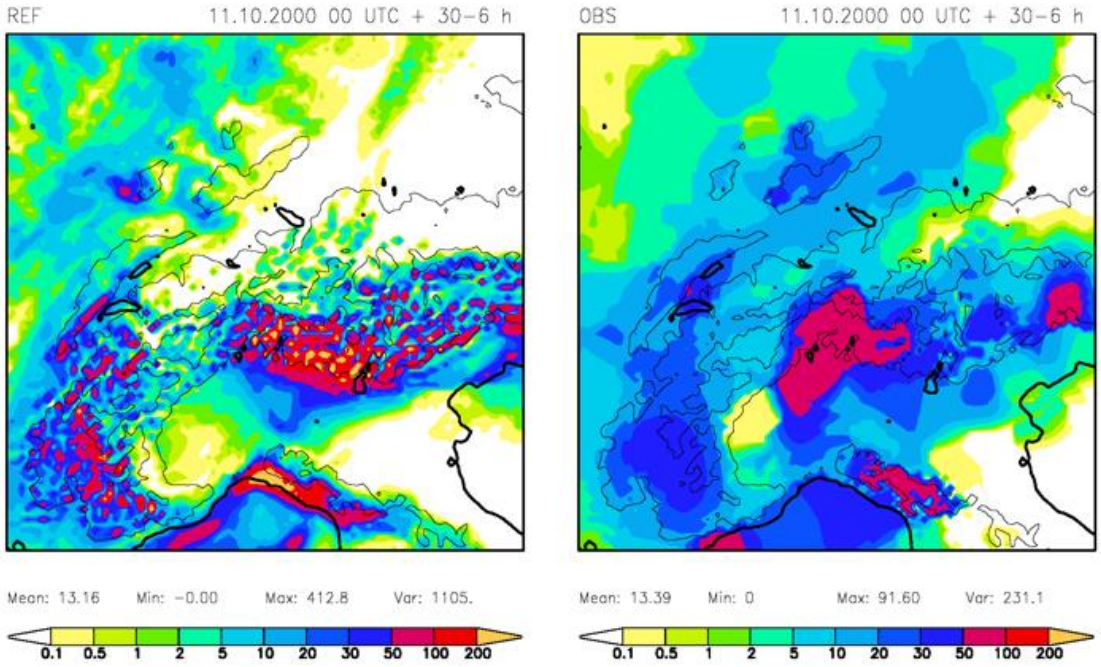

Figure 9: 24h accumulated precipitation (mm) for 11 October 2000 00 UTC +06h ...+30h. Left: Reference run. Right: Analysis based on Synop observation. The thick contour lines show the land-sea mask, the thin lines are the 700m and 2100m contour lines of orography

Fig. 9 compares the 24 h accumulated precipitation amount from the reference run (left) and from the Synop observations (right) on a model subdomain of about 700x700 km covering the Alpine region. As the observation come from the rather coarse SYNOP network, the structure of the precipitation field is only a first guess and many details may be lost. Nevertheless, the observation indicate a large region along the southern ridge of the Alps with precipitation amounts in the range 50 - 100 mm (which resulted in a severe flooding event in the Turin region). This is well captured by the model forecast, the centre is shifted somewhat to the east. The peak precipitation, however, is certainly overestimated by the model. Another region with high precipitation amounts is along the western ridge of the alps, but also here the peak values seem to be too high. In general, the forecasted precipitation field looks very noisy, with $2\Delta x$ structures located in regions of steep topography. This is not believed to be realistic.

The effect of a too strong blocking by southerly Föhn flow is obvious in the northern part of the Alps: whereas the observations indicate precipitation amounts in the range of 5 - 20 mm in a region extending from the Lake of Geneva over the Lake of Constance into the southwestern parts of Bavaria, the forecast gives almost no indication of precipitation at all, except for a spotty structure over northern Switzerland. Another typical feature of many LM precipitation forecasts can also be noticed: The valley of Valais, a steep valley extending southeast of the Lake of Geneva, remains almost dry, whereas a large amount of rain and snow falls over the mountain tops at the valley sides. The observations, however, indicate significant precipitation at the valley ground.

The impact of monotonic and orographic flux limiting for horizontal diffusion to the precipitation forecast is quite large. The left picture in Fig. 10 displays the result obtained with the quadratic form (23) of the orographic limiter with H_{max} set to 250 m. This limiter is only applied for temperature perturbation, specific humidity and cloud water content, whereas pressure perturbation and the wind components are treated with the computationally more efficient Xue limiter. Experiments have shown that the application of the flux-limiter scheme to the latter variables has not a significant impact to the forecasts. They are thus treated with the computationally more efficient Xue-scheme.

When compared to the reference run, the precipitation pattern looks less noisy than in the reference run and a part of the $2\Delta x$ structures are gone or their amplitude appears to be smaller: the field variance is reduced from 1105 mm down to 890 mm and the field maximum from 413 mm to 355 mm. Also, the southwest-northeast orientation of the small-scale precipitation bands over the western parts of the Alps has changed to a more northwest-southeast orientation. As a distinct feature of the new scheme, the "dry valley effect" seems to be cured: with flux-limited horizontal diffusion a significant precipitation amount is now predicted for the valley of Valais. Most interestingly, a coherent rainband extending from northern Switzerland to western Bavaria is now formed, with an eastern boundary close to the observed one. Clearly, a large part of precipitation is still missing to the west of this band, but this experiment indicates that a too strong horizontal diffusion over steep terrain can have significant effects to the fields far away.

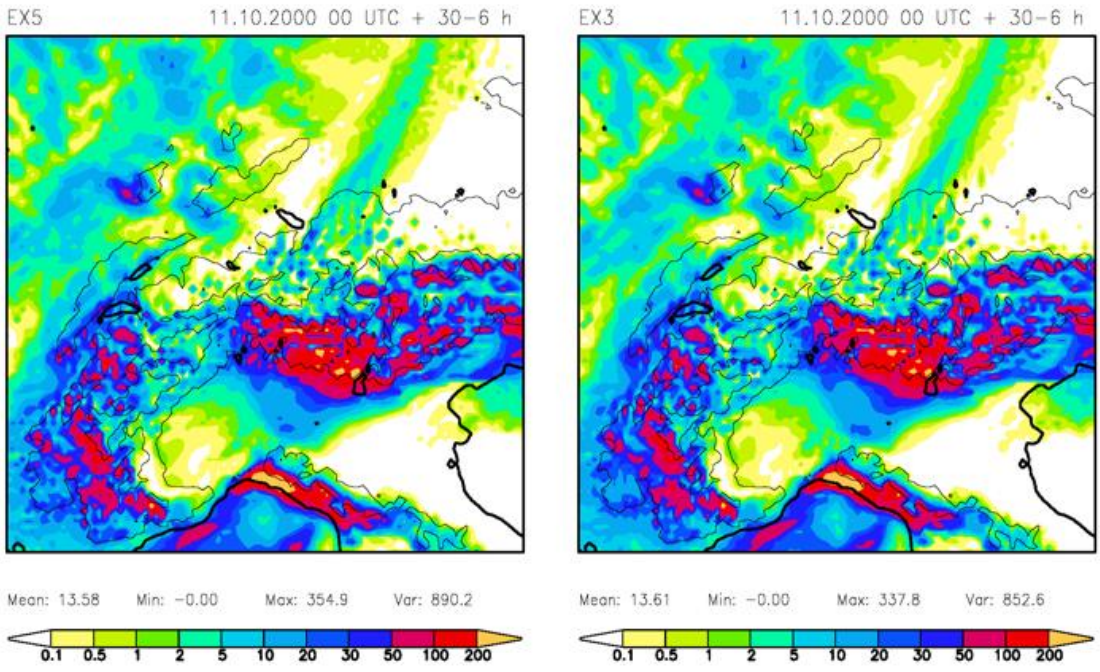

Figure 10: As in Fig. 9 but for the flux-limited diffusion scheme using the quadratic form (23) of the orographic flux limiter (left). Right: The same scheme, but with generally reduced diffusion coefficients for temperature and pressure perturbation (by a factor of 0.6) and for water vapour and cloud water (by a factor of 0.3).

Also, a number of test runs using generally reduced diffusion coefficients have been performed since overdamping over complex terrain was found to be crucial for the failure of the precipitation forecasts. The right picture in Fig. 10 shows the result from a run using a reduction factor of 0.6 and of 0.3 for the default diffusion coefficient for temperature and pressure perturbation and for water vapour and cloud water, respectively. There is not too much difference between the results, the run with reduced coefficients is slightly more smooth

and has a lower field maximum. This beneficial impact of smaller diffusion coefficients is lost with a further reduction, since a certain amount of damping is necessary to control small-scale noise. As a default for the reduction factors for the diffusion coefficients for heat and moistures, the values 0.75 and 0.5 have been implemented.

The stepwise form (22) of the orographic limiter behaves in general very similar to the continuous quadratic form (23). The latter version, however, gives a slightly more smooth solution and the extra computational costs are negligible. Thus, the limiter (23) was implemented. Additional sensitivity tests concerning the threshold value H_{max} for the maximum height difference between neighboring gridpoints in the limiter function (23) have been performed. For a very high value of H_{max} the results tend to become similar to the monotonic scheme using no orographic limiter, and for a very low value the scheme tends to produce an underdamped, i.e. very noisy solution. For values between 200 m and 300 m, the results are quite similar and thus $H_{max} = 250$ m has been implemented as a default. Clearly, this applies only for the current 7 km grid spacing, and a resonable value has to be set for other horizontal resolutions.

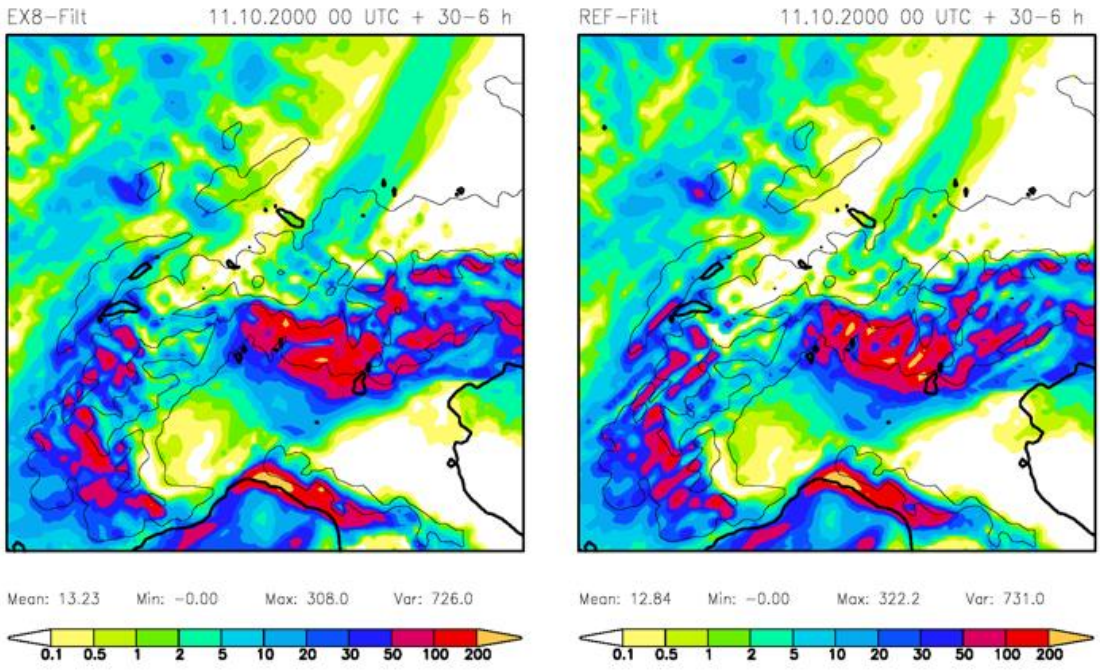

Figure 11: As in Fig. 9 but for the filtered topography. Left: Quadratic form (23) of the orographic flux limiter and with reduced diffusion coefficients for heat (factor 0.75) and moisture (factor 0.50) (left). Right: reference run.

All test runs described above have been done with the original mean topography at the grid scale. Using a mean topography, however, constantly forces the generation of $2\Delta x$-waves, which are represented hopelessly inaccurate in numerical models. Thus, a filtering of topography has been introduced in the operational applications of the LM in order to get a more correct interaction of dynamics with the surface. For this purpose, the Raymond (1988) filter is applied which removes $2\Delta x$ and $3\Delta x$ wave components from the mean orography (Gassmann, 2001).

Since the filtered orography is smoother and less steep, the errors from horizontal diffusion are expected to become smaller. And indeed, reruns of cases from the Föhn period during October-November 2000 showed a beneficial impact of topographical filtering to precipitation and 2m-temperature forecasts. The right hand picture in Fig. 11 displays the 24-h

precipitation amount for the 11 October case using the filtered topography and standard horizontal diffusion. When compared to the reference run using the mean topography (Fig. 9, left), the precipitation field has become much less noisy. Also, the blocking effect north of the Alps is reduced and a rainband in southern Germany appears. However, there is still a noticeable impact of using monotonic horizontal diffusion with the orographic limiter (Fig. 11, left): The rainband appears to be slightly broader and more intense, and the unrealistic southeast-northwest orientation of precipitation bands over the western part of the Alps is removed.

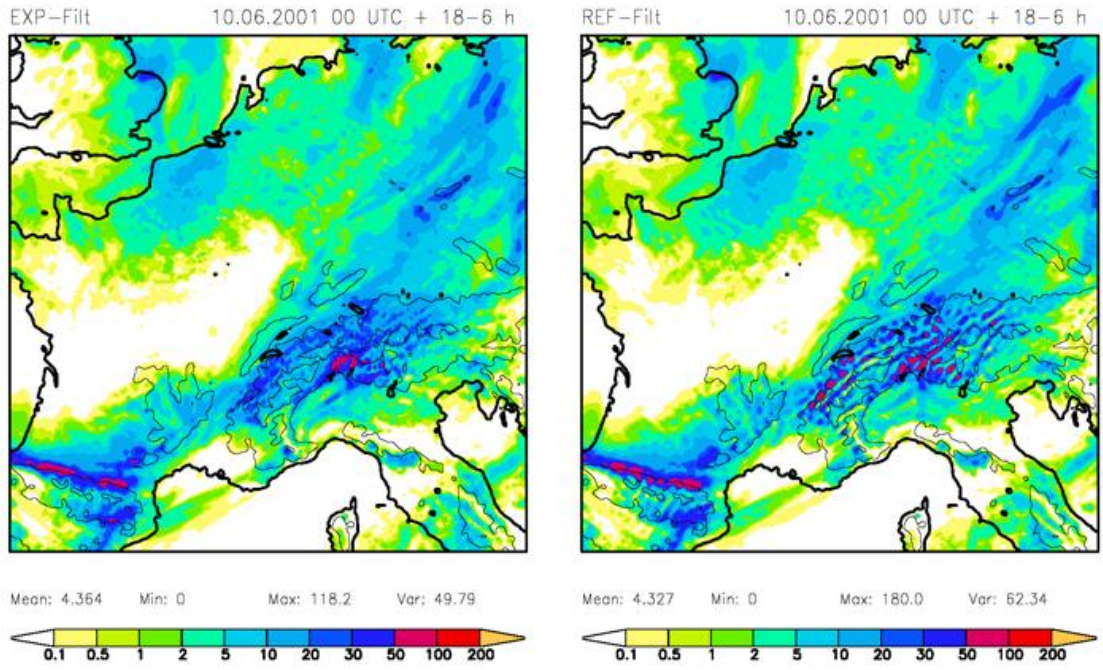

Figure 12: 24h accumulated precipitation (mm) for 10 June 2001 00 UTC +06h ...+18h. Left: Default version of the flux-limited scheme for horizontal diffusion. Right: Reference run. The thick contour lines show the land-sea mask, the thin lines are the 700m and 2100m contour lines of orography

The beneficial impact of the new diffusion scheme is noticeable also in cases other than Föhn flow. For instance, Fig. 12 compares the 12-h precipitation amount for 10 June 2001 as predicted with the standard scheme for horizontal diffusion (right) and with the default version of the flux-limited scheme (left), where in both runs the filtered topography is used. On this day, a frontal system moved slowly eastwards with only weak winds over the Alpine region. Most of the precipitation is stratiform since a stable thermodynamic stratification prevailed. In the reference run, the predicted precipitation is rather noisy with high peak values over the Alps and the Pyrenees. Also, there is an organization of the maxima along a southeast-northwest line in these areas, which is related to bands of positive and negative vertical velocity being formed perpendicular to the flow direction. These structures are not believed to be realistic but the mechanisms for their formation are not yet clear. In the run with the new diffusion scheme, the amplitude of these vertical velocity bands is strongly reduced, resulting in a much smoother precipitation field over the mountainous regions.

7. Results from Parallel Experiments

Tests experiments with the modified horizontal diffusion scheme have been conducted at MeteoSwiss and at DWD over longer time periods. At MeteoSwiss, the LM was rerun for November 2000 and compared with the operational implementation and with model versions

using topographical filtering. The stepwise form (22) of the orographic limiter was used. At DWD, the period from 31 July 2001 to 24 August 2001 was rerun using the continuous form (23) of the topographical limiter function. In this experiment, the full data assimilation cycle including the soil moisture analysis has been involved. Also, a weak filtering of topography is used as in the operational model version. For the impact of the filtering of LM-topography, see Gassmann (2001).

7.1 Parallel Runs at MeteoSwiss

The test experiment for November 2000 was evaluated using the standard Swiss verification package (F. Schubiger, pers. comm.) for surface parameters. The verification is against measurements taken by synoptical and automatic stations in Switzerland (the ANETZ).

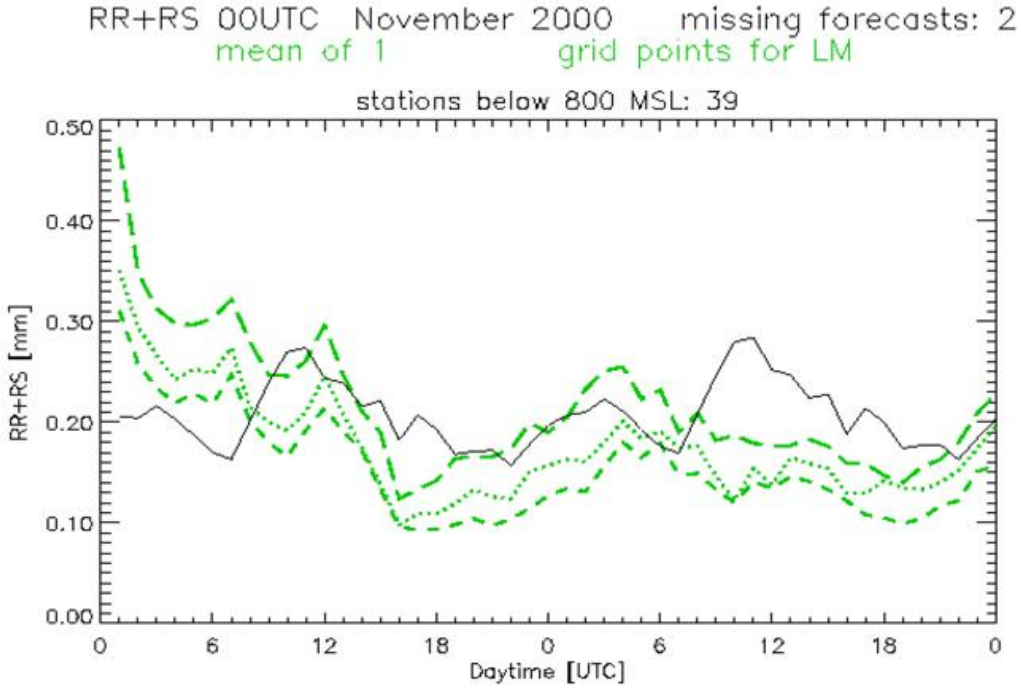

Figure 13: Monthly mean diurnal cycle of predicted and observed precipitation for November 2000 at ANETZ-stations in Switzerland. Full line: observations. Short-dashed line: model version with weak filtering of topography. Dotted line: model version with strong filtering of topography. Long-dashed line: model version with weak filtering and modified horizontal diffusion.

Figure (13) shows the monthly mean diurnal cycle of total precipitation for the 48-h forecast period of all 00 UTC runs compared to the observations. All three model versions overestimate the precipitation amount during the first 6 hours of simulation time because of the spin-up phenomenon (no data assimilation has been used). Later on, the forecasts using a weak topographical smoothing with a filter-parameter $\epsilon = 0.1$ underestimate the observed amount of rain and snow significantly, but less than the former operational version without filtering (not shown). A much stronger smoothing of the topography by using $\epsilon = 10.0$ results in slightly larger precipitation amounts which, however, are still below the level indicated by the observed data. The combination of the weakly filtered topography with the new scheme for horizontal diffusion fits more closely to the observations during most of the simulation time.

The verification shown in Fig. (13) used the nearest-gridpoint method, i.e. only one LM-gridpoint was used for the comparison with the observation. It is interesting to note that

the results depend on the method used for verification: If a horizontal average of 5 or 13 gridpoints is used (upscaling), then the predicted precipitation amounts for the model versions using a filtered orography increase slightly to compare more favorably with the observations. However, when the modified diffusion scheme is applied, then the results depend much less on the verification method. This indicates a much smaller spatial variability than when using a filtered topography only.

Table 1: Frequency bias of 00 UTC LM precipitation forecasts during November 2000 at ANETZ-stations in Switzerland (all 6-h intervals of 48hr forecasts).

Station Selection	Model Version	Threshold (mm/6h) at				
		0.1	2.0	10.0	30.0	50.0
Stations < 800 m	LM filt+hdiff	108	93	89	170	-
	LM at Met.Sw.	87	57	61	105	-
	LM at DWD	74	48	48	35	-
All stations	LM filt+hdiff	111	88	72	126	-
	LM at Met.Sw.	95	63	51	78	-
	LM at DWD	84	54	41	32	-

The frequency bias of the LM-forecasts for November 2000 at ANETZ-stations is shown in Table 1 for various threshold values, where all 6-h intervals of the 48-h forecasts have been considered. The upper part of the table gives the results for all stations with altitude below 800 m, i.e. mountain stations have been excluded. The operational LM-versions at MeteoSwiss and at DWD, which both were run without topographical filtering at that time, show a significant underestimation of precipitation, especially for precipitation amounts exceeding the 2mm/6h and 10mm/6h thresholds. This underestimation is more severe in the DWD model version (using a full data assimilation cycle). Note that the heavy precipitation class with a threshold of 30mm/6h is statistically not significant (only 0.3% of all cases) and thus is not considered here. By applying a weak topographical filtering and the new horizontal diffusion scheme (LM filt+hdiff), the higher precipitation amounts are much better represented in the model forecasts: there is still an underestimation, but it is much smaller than with the operational version. For smaller precipitation amounts with a threshold of 0.1 mm/6h, however, a slight overprediction can be noticed.

The impact of the new scheme for horizontal diffusion is much smaller for surface parameters other than precipitation. Figure (14) displays the mean diurnal cycle of 2m-temperature (top) and 2m-dewpoint depression (bottom) for November 2000 over Switzerland. The model version without filtering of topography underestimates the extrema of the 2m-temperature, but more severe the nighttime minimum, resulting in a too large amplitude of the 2m-temperature (5.7 K compared to the observed 3.6 K on day 2). The model version with filtered topography reduces this amplitude error by about 50 %, the amplitude is only 4.9 K in this case. An additional inclusion of the new horizontal diffusion scheme has only a slight impact with a further reduction of the amplitude to 4.7 K. The 2m-dewpoint depression appears to be too large in the standard model runs, i.e. the surface layer is too dry over the Alpine area. By using a filtered topography, this type of error is significantly reduced, especially during nighttime. At noon, the model is now simulating a slightly too moist surface layer. An additional moistening effect can be noticed from applying the new horizontal diffusion scheme.

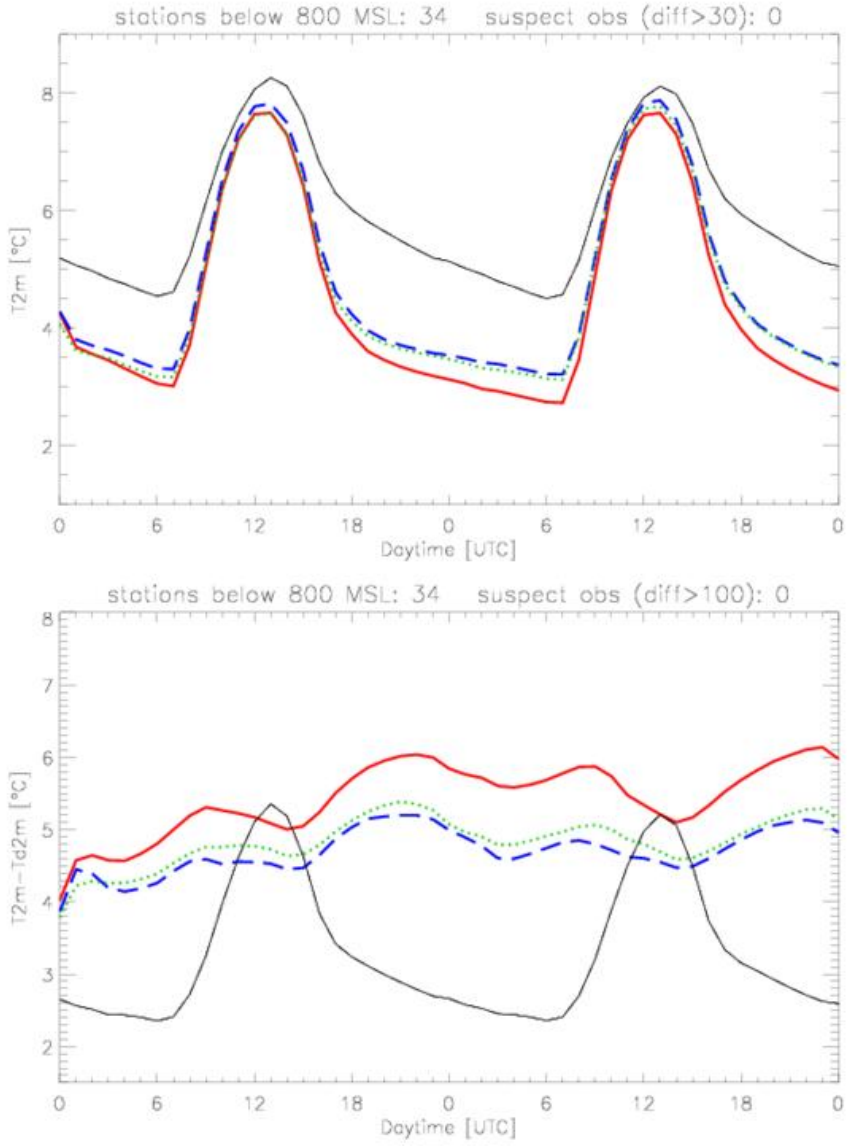

Figure 14: Monthly mean diurnal cycle of predicted and observed 2m-temperature (top) and 2m-dewpoint depression (bottom) for November 2000 at ANETZ-stations below 800m altitude in Switzerland. Full black line: observations. Full red line: former operational version without filtering of topography. Dotted green line: model version with weak filtering of topography. Dashed blue line: model version with weak filtering and modified horizontal diffusion.

7.2 Parallel Runs at DWD

The parallel test experiment at DWD for the August 2001 period was evaluated using the standard verification package for surface weather parameters (U. Damrath, pers. comm.). The verification is against observations from Synop Stations in the integration domain of LM at DWD, and the only difference between the operational and the experimental runs is the inclusion of the new horizontal diffusion scheme.

Fig. (15) shows mean verification scores of various surface parameters as a function of forecast time for all weather stations in the domain. The root mean square errors of 10m-wind, surface pressure, 2m-temperature and 2m-dewpoint depression, as well as the percent-correct score for cloud cover, are practically the same for the experimental and operational runs. A slight improvement with the new version of LM can be noticed for precipitation, especially for

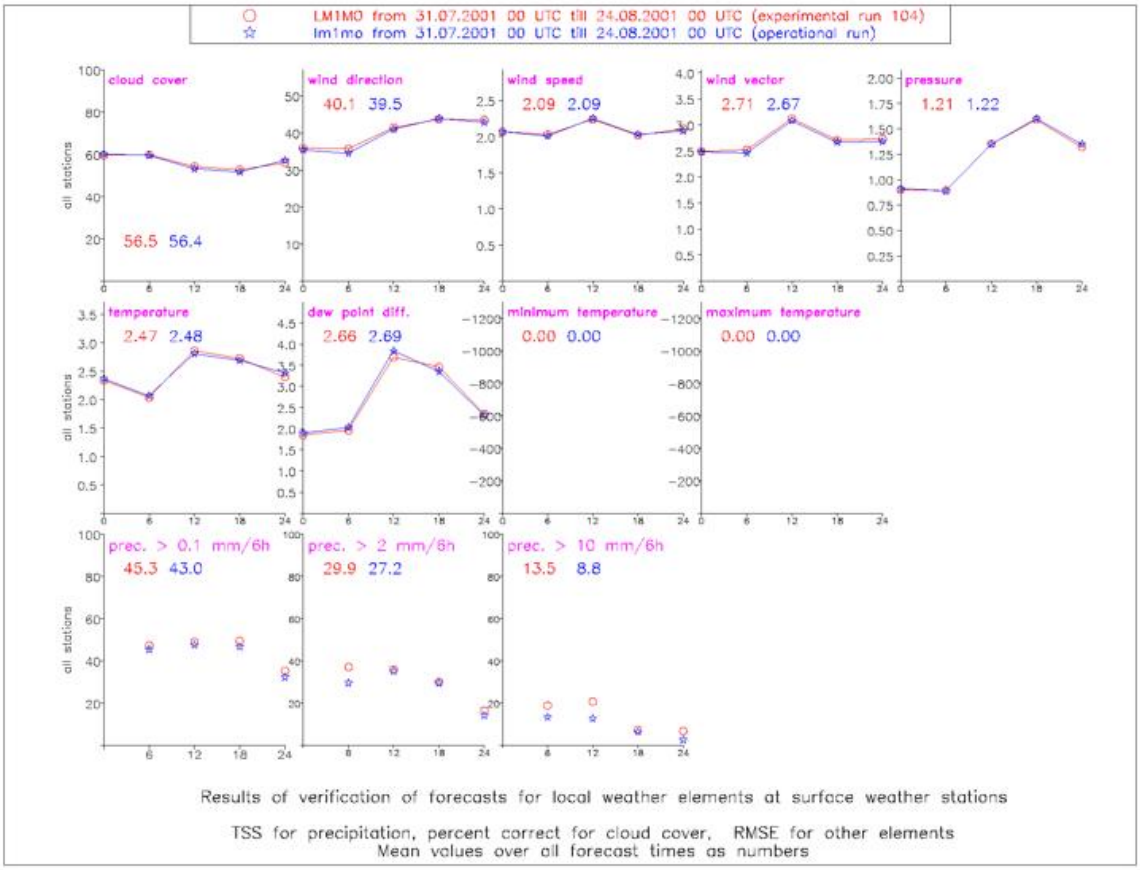

Figure 15: Mean verification scores at all Synop Stations in the LM integration domain for the period 31 July to 24 August 2001 as a function of forecast time (00, 06, 12, 18, 24 h). Verification time is 00 UTC. Red – experimental run exp_104, blue – operational run. Root-mean-square error for all elements except for cloud cover (percent correct) and precipitation (TSS); numbers are mean values over all forecast times. Top (from left to right): cloud cover, wind direction, wind speed, wind vector and surface pressure. Middle (from left to right): temperature, dew point difference, minimum and maximum temperature. Bottom: TSS of 6 h precipitation amounts (prec) for the three indicated threshold values.

higher precipitation amounts. For a threshold value of 10mm/6h the TSS score increases from 8.8 to 13.4, indicating a more reliable prediction of heavy precipitation events.

When considering mean verification scores of all stations in the domain, there will be a large contribution of stations in non-mountainous areas. Fig. (16) displays the mean verification scores for Synop Stations with an altitude between 300m and 800m above sea-level. These stations are representative for mountainous areas in the vicinity of steep terrain, where the impact of the orographical limiter in the diffusion scheme is expected to be more noticeable. As in case of all stations, the scores for the 10m-wind and surface pressure are indifferent to the change in the horizontal diffusion scheme. However, there is a marginal improvement of cloud cover, and the rmse-errors for the 2m-dewpoint depression are slightly smaller, whereas the rmse-errors of the 2m-temperature remain practically the same. This indicates – similar to the verification results in Fig. (14) for the diurnal cycle of 2m-temperature and dewpoint over Switzerland – that the near-surface moisture is affected by the orographically limited diffusion to a larger extend than temperature. The quality of the precipitation forecasts increases significantly for all threshold values, as seen in the lower panel of Fig. (16).

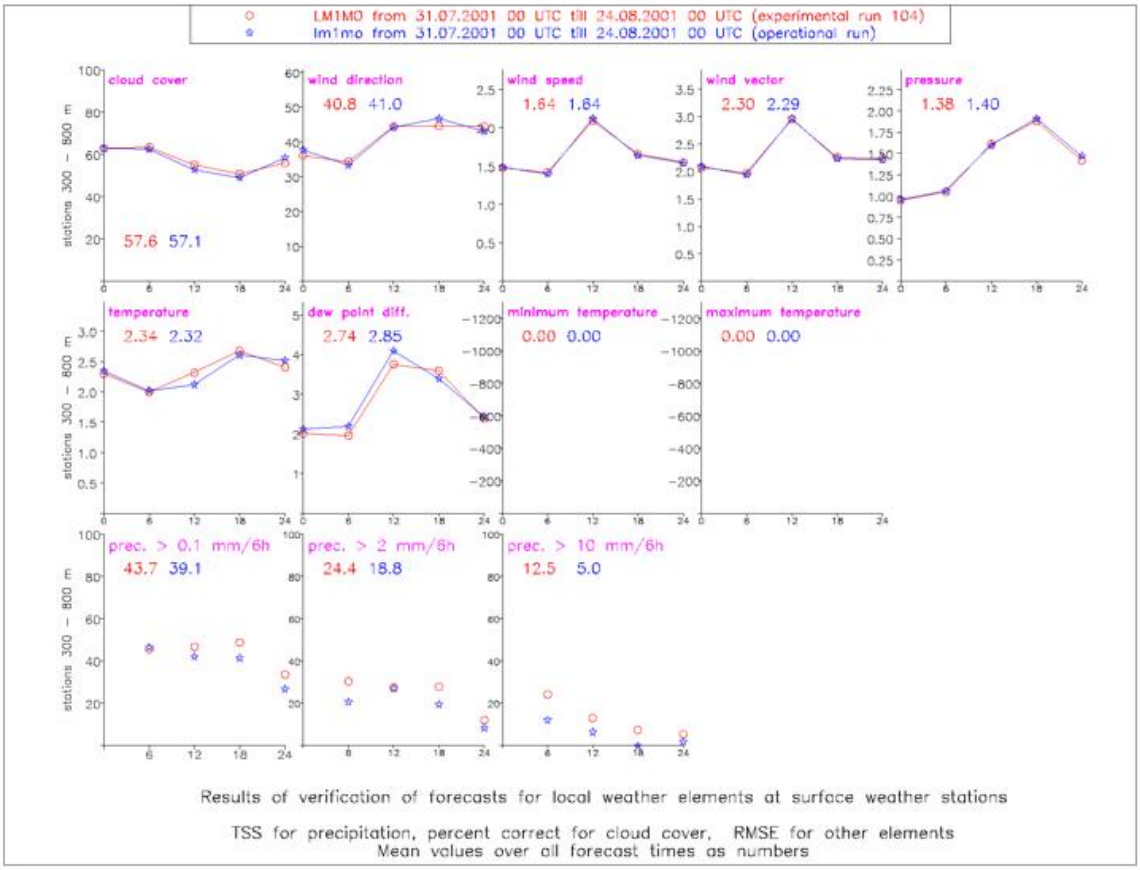

Figure 16: As in Figure 15 except for all Synop Stations with an altitude between 300m and 800m above sea-level.

8. Implementation of the Scheme

The new scheme for monotonic numerical diffusion including orographic flux limiting has been implemented as an option in model version `lm_f90 V 2.9`. It can be switched on by setting the parameter `itype_hdiff = 2` in the NAMELIST-Input list `INPUT_DYN`. Orographic limiting is done for temperature, specific humidity and specific cloud water content only. All other prognostic variables, i.e the three wind components and the perturbation pressure, are treated with the quasi-monotonic Xue limiter. Three additional control parameters have been introduced in this NAMELIST-Input group. Table 2 summarizes the new input parameters.

Table 2: New control parameters in the NAMELIST-Input group `INPUT_DYN`.

Parameter	Definition / Purpose	Default value
`itype_hdiff`	a switch to select a scheme for horizontal diffusion =1: regular 4th-order linear horizontal diffusion =2: new monotonic 4th-order scheme	`itype_hdiff = 2`
`hd_max:`	the threshold value H_{max} in the quadratic form (23) of the orographic flux limiter in m.	`hd_max = 250`
`hd_cor_t:`	a factor by which the standard coefficient for numerical diffusion is reduced in case of temperature and pressure smoothing.	`hd_cor_t = 0.75`
`hd_cor_q:`	a factor by which the standard coefficient for numerical diffusion is reduced in case of humidity and cloud water smoothing.	`hd_cor_q = 0.50`

9. Summary

Most NWP models require numerical smoothing to damp small-scale (2 grid interval) noise being related to stepwise or singular signals which are permanently generated in a nonlinear model. Regular high order linear diffusion, however, tends to introduce unphysical solutions and thus new noise on the resolvable scales. In order to achieve monotonic and mass-conserving numerical diffusion, a new scheme based on direct multi-dimensional flux-limiting has been constructed.

Tests with 1-D and 2-D idealized cases show the beneficial impact of the new scheme. All over- and undershoots are removed from the solution. In contrast to a simple version using the Xue-limiter, the scheme with a direct flux-limiter guarantees a strictly monotonic solution. In LM simulations of real cases considered so far, there is only a relatively small impact from using monotonic 4th order diffusion with a tendency for lower vertically integrated cloud water and smaller peak precipitation amounts.

Numerical smoothing is often realized as horizontal diffusion, i.e. along surfaces of constant vertical coordinate. As most NWP models use a terrain-following vertical coordinate, this will result in systematic numerical biases, as an unwanted vertical mixing in physical space is implied. This type of numerical error will increase with increasing steepness of the topography, and thus poses a severe problem in high-resolution regional models. Current remedies, such as doing diffusion on z- or p-surfaces or applying a local reduction of the diffusion coefficients, are not mass-conserving and will thus introduce other errors. With the new smoothing scheme, the topography-induced biases can be reduced without violating mass conservation while still maintaining monotonicity by simply applying an orographic limiter to the diffusive fluxes at cell interfaces.

LM test simulations with the orographical limiter in cases of southerly Föhn flow over the Alps showed a noticeable improvement of the predicted precipitation field. The spatial distribution of rain over mountainous areas appears to be much less noisy and the peak values over mountain tops are significantly reduced compared to the reference runs with standard 4th-order horizontal diffusion. Also, the dry valley effect is removed and the model's tendency for blocking frontal precipitation north of the Alps is weakened.

Parallel test experiments with the modified horizontal diffusion scheme have been conducted at MeteoSwiss and at DWD for longer time periods. The statistical evaluation against observed surface weather parameters revealed a neutral impact of the new smoothing scheme to most parameters, but a beneficial impact to the predicted precipitation, especially in mountainous areas.

Acknowledgements

Thanks to all colleagues who contributed to this work: J.-M Bettems implemented and supported the test suite at MetoSwiss, F. Schubiger did the statistical evaluation at MeteoSwiss, T. Hanisch supported the experimental test suite at DWD and U. Damrath did the statistical evaluation at DWD. Special thanks to A. Gassmann and D. Majewski for discussions and helpful suggestions.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *Consortium for Small-Scale Modelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (UGM, ARPA-SMR) and Switzerland (MeteoSwiss). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the Lokal-Modell (LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completition of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

Appendix F Stationary statistics of a time discrete higher-order OSDE 43

F.1 First-order numerical scheme 43

F.2 Third-order numerical scheme 43

1 Abstract

A generator of spatio-temporal pseudo-random Gaussian fields that satisfy the "proportionality of scales" property (Tsyroulnikov 2001) is presented. The generator is based on a third-order in time stochastic differential equation with a pseudo-differential spatial operator defined on a limited area 2D or 3D domain in the Cartesian coordinate system. The generated pseudo-random fields are homogeneous and isotropic in space-time. The correlation functions in any spatio-temporal direction belong to the Matérn class. The spatio-temporal correlations are non-separable. A spectral-space numerical solver is implemented and accelerated exploiting properties of real-world geophysical fields, in particular, smoothness of their spatial spectra. The generator is designed to simulate additive or multiplicative, or other spatio-temporal perturbations that represent uncertainties in numerical prediction models in geophysics. The generator is tested with the COSMO model as a source of additive spatio-temporal perturbations to the forecast model fields.

2 Introduction

2.1 Stochastic dynamic prediction

Since the works of [1] and [2], we know that accounting for the uncertainty in the initial forecast fields can improve weather (and other geophysical) predictions. Assigning a probability distribution for the truth at the start of the forecast (instead of using deterministic initial data) and attempting to advance this distribution in time according to the dynamic (forecast) model is called stochastic dynamic prediction.

The advantage of the stochastic dynamic prediction paradigm is twofold. First, the resulting forecast probability distribution provides a valuable measure of the *uncertainty* in the prediction, leading to probabilistic forecasting and flow-dependent background-error statistics in data assimilation. Second, for a nonlinear physical model, switching from the deterministic forecast to the mean of the forecast probability distribution improves the mean-square accuracy of the prediction, i.e. can improve the deterministic forecasting.

2.2 Model errors

Since [3], we realize that not only uncertainties in the initial data (analysis errors) matter, forecast model (including boundary conditions) imperfections also play an important role. Simulation of model errors is the subject of this study, so we define them now. Let the forecast model be of the form

$$\frac{\mathrm{d}\mathbf{x}}{\mathrm{d}t} = \mathbf{F}(\mathbf{x}), \tag{1}$$

where t is time, $\mathbf{x}$ is the vector that represents the (discretized) state of the system, and $\mathbf{F}$ is the model (forecast) operator. The imperfection of the model Eq.(1) means that the (appropriately discretized) truth does *not* exactly satisfy this equation. The discrepancy is called the model error [e.g. 4]:

$$\boldsymbol{\xi}^t = \mathbf{F}(\mathbf{x}^t) - \frac{\mathrm{d}\mathbf{x}^t}{\mathrm{d}t}. \tag{2}$$

The true model error $\boldsymbol{\xi}^t$ is normally unknown. In order to include model errors in the stochastic dynamic prediction paradigm, one *models* $\boldsymbol{\xi}^t(t)$ as a *random process*, $\boldsymbol{\xi}(t)$, or, in

other words, as a spatio-temporal random field $\xi(t, \mathbf{s})$ (where $\mathbf{s}$ is the spatial vector). The probability distribution of $\boldsymbol{\xi}(t)$ is assumed to be known.

Rearranging the terms in Eq.(2), and replacing the unknown $\boldsymbol{\xi}^t$ with its stochastic counterpart $\boldsymbol{\xi}$, we realize that the resulting model of truth is the stochastic dynamic equation

$$\frac{\mathrm{d}\mathbf{x}}{\mathrm{d}t} = \mathbf{F}(\mathbf{x}) - \boldsymbol{\xi}. \tag{3}$$

Thus, the extended stochastic dynamic prediction (or modeling) paradigm requires two input probability distributions (that of initial errors and that of model errors) and aims to transform them to the output (forecast) probability distribution.

2.3 Ensemble prediction

Stochastic dynamic modeling of complex geophysical systems is hampered by their high dimensionality and non-linearity. The output probability distribution appears to be in most cases analytically intractable. An affordable approximate solution is provided by the Monte-Carlo method called in geophysics *ensemble prediction*.

In ensemble prediction, the input uncertainties (i.e. initial and model errors) are represented by simulated *pseudo-random draws* from the respective probability distributions. A relatively small affordable number of these draws are fed to the forecast model giving rise to an *ensemble* of predictions (forecasts). Members of this ensemble (called ensemble forecasts) are solutions to Eq.(3) with $\boldsymbol{\xi}$ replaced with simulated pseudo-random draws from the model-error probability distribution. The ensemble forecasts start from the initial data perturbed according to the probability distribution of initial errors.

If initial and model errors are sampled from the correct respective distributions, then the forecast ensemble members are draws from the correct probability distribution of the truth given all available external data (initial and boundary conditions). This mathematically justifies the ensemble prediction principle. From the practical perspective, members of the forecast ensemble can be interpreted as "potential truths" consistent with all available information.

In what follows, we concentrate on the model error field $\xi(t, \mathbf{s})$. We briefly review existing models for $\xi(t, \mathbf{s})$ and then present our stochastic pattern generator, whose goal is to simulate pseudo-random draws of $\xi(t, \mathbf{s})$ from a meaningful and flexible distribution.

2.4 Practical model error modeling

In meteorology, our knowledge of the actual model error probability distribution is scarce. Justified stochastic model-error models are still to be devised and verified. In the authors' opinion, the best way to stochastically represent spatio-temporal forecast-model-error fields is to treat each error source separately, so that, say, each physical parametrization is accompanied with a spatio-temporal stochastic model of its uncertainty. Or, even better, to completely switch from deterministic physical parameterizations to stochastic ones. There is a growing number of such developments [see 5, for a review], but the problem is so complex that we cannot expect it to be solved in the near future. Its solution is further hampered by the fact that the existing meteorological observations are too scarce and too inaccurate for model errors to be objectively identified by comparison with measurement data with satisfactory accuracy [6].

As a result, in meteorology *ad-hoc* model-error models are in wide use. The existing approaches include generating pseudo-random additive or multiplicative perturbations of the right-hand sides of the model equations [e.g. 7, 8] in the course of forecast. These two model-error modeling techniques as well as Stochastic Kinetic Energy Backscatter schemes [9] require a pseudo-random spatio-temporal field as a stochastic input. Stochastic parameterization schemes can also demand such fields [see e.g. 10].

The simplest non-constant pseudo-random field is the white noise, i.e. the uncorrelated in space and time random field. The white noise is the default forcing in stochastic differential equations [e.g. 11, 12]. Its advantage is the complete absence of any spatio-temporal structure, it is a pristine source of stochasticity. But in model-error modeling, this lack of structure precludes its direct use as an additive or multiplicative perturbation field because model errors are related to the weather pattern and so should be correlated (dependent) both in space and time. Tsyrulnikov [13] showed in a simulation study that model errors can exhibit complicated spatio-temporal behavior.

A correlated pseudo-random spatio-temporal field can be easily computed by generating independent random numbers at points of a *coarse* spatio-temporal grid and then assigning each of them to all model grid points within the respective coarse-grid cell [8]. As a result, the model-grid field becomes correlated in space and time. The decorrelation space and time scales are, obviously, defined by the respective coarse-grid spacings. This determines the choice of the coarse grid, e.g. in [8] the spatial grid spacing was about 1000 km and the temporal one 6 hours). This technique is extremely simple but it suffers from two flaws.

First, the resulting model-grid field appears to be discontinuous and inhomogeneous. Second, the spatio-temporal structure of the field is not scale dependent, that is, the resulting temporal length scales do not depend on the respective spatial scales. In reality, longer spatial scales "live longer" than shorter spatial scales, which "die out" quicker. This 'proportionality of scales' is widespread in geophysical fields [see 14, and references therein] and other media, [e.g. 15, p.129], so we believe this property should be represented by model-error models. Note also that the "proportionality of scales" is a special case of the *non-separability* of spatio-temporal covariances. For a critique of simplistic separable space-time covariance models, see [16, 17, 18] and Appendix A in this report.

Another popular pseudo-random field generation technique in space and time employs a spectral transform in space and then imposes independent temporal auto-regressions for the coefficients of the spectral expansion [19, 9, 20, 21, 22]. This technique is more general and produces homogeneous fields, but the above implementations use *the same time scale* for all spatial wavenumbers so that there are still no space-time interactions in the generated spatio-temporal fields.

In this report, we propose and test a spatio-temporal Stochastic (pseudo-random) Pattern Generator (SPG) that accounts for the above "proportionality of scales" and imposes meaningful space-time interactions. The SPG operates on a limited-area domain. It is based on a (spectral-space) solution to a stochastic partial differential equation, more precisely, to a stochastic differential equation in time with a pseudo-differential spatial operator. In what follows, we present the technique, examine properties of the resulting spatio-temporal fields in 2D and 3D spatial domains, and describe the numerical scheme. We start with a first-order in time SPG model. Then we show that this model needs to be modified in order to meet all the criteria we impose. Eventually, we end up with a third-order in time model. The technique is implemented as a Fortran program freely available from https://github.com/gayfulin/SPG.

3 SPG: Requirements

The general requirements are:

- The SPG should produce stationary in time and homogeneous and isotropic in space Gaussian pseudo-random fields $\xi(t, \mathbf{s})$ in 3D and 2D spatial domains.
- The SPG should be fast enough so that it does not significantly slow down the forecast model computations.
- Variance as well as spatial and temporal length scales of $\xi(t, \mathbf{s})$ are to be tunable.

We also impose more specific requirements:

1. The random field $\xi(t, \mathbf{s})$ should have finite variance and continuous realizations (sample paths).
2. The spatio-temporal covariances should obey the "proportionality of scales" principle: larger (shorter) spatial scales should be associated with larger (shorter) temporal scales [14].
3. The SPG *ansatz* should be flexible enough to allow for practicable solutions in both physical space and spectral space.

4 The proposed solution

We select the general class of *linear evolutionary stochastic partial differential equations* (SPDE) as a starting point in the development of the SPG. This choice is motivated by the flexibility of this class of spatio-temporal models [e.g. 23]. In particular, for an SPDE, it is relatively easy to introduce inhomogeneity in space and time as well as local anisotropy—either by changing coefficients of the spatial operator or by changing local properties of the driving noise. One can also produce non-Gaussian fields by making the random forcing non-Gaussian [e.g. 24, 25]. Physical-space discretizations of SPDEs lead to *sparse* matrices, which give rise to fast numerical algorithms. If an SPDE has constant coefficients, then it can be efficiently solved using spatial spectral-space expansions.

In this study, we develop the SPG that relies on a spatio-temporal stochastic model with *constant coefficients* so that both physical-space and spectral-space solvers can be employed. To facilitate the spectral-space solution, the general strategy is to define the SPG model on a standardized spatial domain. The operational pseudo-random fields are then produced by mapping the generated fields from the standardized domain to the forecast-model domain. In 3D, the standardized spatial domain is chosen to be triply periodic: the three-dimensional (3D) unit torus. In 2D, the standardized domain is the 2D unit torus. The 3D and 2D cases are distinguished by the dimensionality $d = 2$ or $d = 3$ in what follows. To simplify the presentation, the default dimensionality will be $d = 3$.

5 Tentative first-order SPG model

5.1 Physical-space model

The random field in question $\xi(t, \mathbf{s})$ is a function of the time coordinate t and the space vector $\mathbf{s} := (x, y, z)$, where (x, y, z) are the three spatial coordinates. Each of the spatial coordinates belongs to the the unit circle $\mathbb{S}^1$, so that $\mathbf{s}$ is on the unit torus $\mathbb{T}^3 \equiv \mathbb{S}^1 \times \mathbb{S}^1 \times \mathbb{S}^1$ ($\mathbb{T}^2$ in the 2D case).

We start with the simplest general form of a first-order Markov model:

$$\frac{\partial \xi(t, \mathbf{s})}{\partial t} + A\,\xi(t, \mathbf{s}) = \alpha(t, \mathbf{s}), \tag{4}$$

where A is the spatial linear operator to be specified and α is the driving noise postulated to be homogeneous in space and white in time.

The SPG is required to be fast, so we choose A to be a *differential* operator (because, as we noted, in this case a physical-space discretization of A gives rise to a very sparse matrix).

Further, since we wish $\xi(t, \mathbf{s})$ to be homogeneous and isotropic in space, we define A to be a polynomial of the negated spatial Laplacian:

$$A := P(-\Delta) := \sum_{j=0}^{q} c_j (-\Delta)^j, \tag{5}$$

where $P(x)$ is the polynomial and q its degree (a positive integer). We will refer to q as the spatial order of the SPG model. Note that the negation of the Laplacian is convenient because $(-\Delta)$ is a non-negative definite operator.

The coefficients c_j are selected to ensure that the spatial operator $\sum c_j(-\Delta)^j$ has only positive eigen-values not close enough to 0, which can be achieved if all $c_j \geq 0$ and $c_0 > 0$; this guarantees *stability* of the SPG.

The model Eq.(5) appears to be too rich for the purposes of the SPG at the moment, so in what follows we employ an even more reduced (but still quite flexible) form

$$A = P(-\Delta) := \mu(1 - \lambda^2 \Delta)^q, \tag{6}$$

where μ and λ are positive real parameters.

So, we start with the following SPG equation:

$$\frac{\partial \xi(t, \mathbf{s})}{\partial t} + \mu(1 - \lambda^2 \Delta)^q\, \xi(t, \mathbf{s}) = \alpha(t, \mathbf{s}). \tag{7}$$

5.2 Spectral-space model

On the torus $\mathbb{T}^d$, a Fourier series is an expansion in the basis functions $\mathrm{e}^{\mathrm{i}(\mathbf{k},\mathbf{s})} \equiv \mathrm{e}^{\mathrm{i}(\mathrm{mx}+\mathrm{ny}+\mathrm{lz})}$, where the wavevector $\mathbf{k}$ is the triple of integer wavenumbers, $\mathbf{k} := (m, n, l)$. We perform the Fourier decomposition for both $\alpha(t, \mathbf{s})$ and $\xi(t, \mathbf{s})$,

$$\alpha(t, \mathbf{s}) = \sum_{\mathbf{k} \in \mathbb{Z}^d} \tilde{\alpha}_{\mathbf{k}}(t) \mathrm{e}^{\mathrm{i}(\mathbf{k},\mathbf{s})} \tag{8}$$

and

$$\xi(t,\mathbf{s}) = \sum_{\mathbf{k}\in\mathbb{Z}^d} \tilde{\xi}_{\mathbf{k}}(t)\mathrm{e}^{\mathrm{i}(\mathbf{k},\mathbf{s})} \tag{9}$$

(where $\mathbb{Z}$ denotes the set of integer numbers) and substitute these expansions into Eq.(7). Noting that the application of $P(-\Delta)$ to $\mathrm{e}^{\mathrm{i}(\mathbf{k},\mathbf{s})}$ returns $P(\mathbf{k}^2)\,\mathrm{e}^{\mathrm{i}(\mathbf{k},\mathbf{s})}$, recalling that $P(-\Delta)$ is defined by Eq.(6), and using orthogonality of the basis functions, we obtain that Eq.(7) decouples into the set of ordinary stochastic differential equations [OSDE, e.g. 11, 12] in time:

$$\frac{\mathrm{d}\tilde{\xi}_{\mathbf{k}}}{\mathrm{d}t} + a_{\mathbf{k}}\,\tilde{\xi}_{\mathbf{k}}(t) = \tilde{\alpha}_{\mathbf{k}}(t), \tag{10}$$

where

$$a_{\mathbf{k}} := \mu(1+\lambda^2\mathbf{k}^2)^q. \tag{11}$$

From the postulated homogeneity of α in space, its spectral-space coefficients $\tilde{\alpha}_{\mathbf{k}}(t)$ are mutually independent. This is well known for random fields on $\mathbb{R}^d$ (where spectra are continuous), see e.g. Chapter 2 in [26] or section 8 in [27], and can be directly verified in our case of the fields on the torus (where spectra are discrete). Therefore, for different wavevectors $\mathbf{k}$, the resulting spectral-space equations, Eqs.(10)–(11), are probabilistically completely *independent* from each other. This greatly simplifies the solution of the SPG equations because instead of handling the complicated SPDE Eq.(7) we have to solve a number of independent simple OSDEs Eq.(10).

Further, from the postulated whiteness of α in time, all $\tilde{\alpha}_{\mathbf{k}}(t)$ are white in time random processes (see Appendix B.4). So, we may write

$$\tilde{\alpha}_{\mathbf{k}}(t) = \sigma_{\mathbf{k}}\,\Omega_{\mathbf{k}}(t), \tag{12}$$

where $\Omega_{\mathbf{k}}(t)$ are independent *standard* white noises, i.e. derivatives of independent standard Wiener processes $W_{\mathbf{k}}(t)$ such that

$$\Omega_{\mathbf{k}}(t)\mathrm{d}t = \mathrm{d}W_{\mathbf{k}}(t) \tag{13}$$

and $\sigma_{\mathbf{k}}$ are *intensities* of the white-noise processes. In space, $\sigma_{\mathbf{k}}^2$ is proportional to the spatial spectrum of the driving noise $\alpha(t,\mathbf{s})$, see Eq.(8), Eq.(12), and Appendix B. If $\sigma_{\mathbf{k}} = \mathsf{const}$, then $\alpha(t,\mathbf{s})$ is white both in space and time, otherwise $\alpha(t,\mathbf{s})$ is a colored in space and white in time noise.

Thus, the first-order SPG model reduces to a series of OSDEs

$$\mathrm{d}\tilde{\xi}_{\mathbf{k}} + \mu(1+\lambda^2\mathbf{k}^2)^q\,\tilde{\xi}_{\mathbf{k}}\,\mathrm{d}t = \sigma_{\mathbf{k}}\,\mathrm{d}W_{\mathbf{k}}. \tag{14}$$

For practical purposes the series is truncated, so that $\mathbf{k} \equiv (m,n,l)$ is limited: $|m| < m_{max}$, $|n| < n_{max}$, and $|l| < l_{max}$, where m_{max}, n_{max}, and l_{max} are the truncation limits. If not otherwise stated, all the truncation limits are the same and denoted by n_{max}.

5.3 Stationary spectral-space statistics

Equation (14) is a first-order OSDE with constant coefficients sometimes called the Langevin equation, see e.g. [12] or Example 4.12 in [11]. Its generic form is

$$\mathrm{d}\eta + a\eta\,\mathrm{d}t = \sigma\mathrm{d}W, \tag{15}$$

where $\eta(t)$ is the random process in question, a and σ are constants, and $W(t)$ is the standard Wiener process. The solution to Eq.(15) is known as the Ornstein-Uhlenbeck random process, whose stationary (steady-state) temporal covariance function is

$$B_\eta(t) = \frac{\sigma^2}{2a}\,\mathrm{e}^{-\mathrm{a}|\mathrm{t}|} \tag{16}$$

[e.g. 11, Example 4.12]. From Eq.(16), it is clear that a has the meaning of the inverse temporal length scale $\tau := 1/a$.

Now, consider the stationary covariance function of the elementary random process $\tilde{\xi}_{\mathbf{k}}(t)$,

$$\mathsf{E}\,\tilde{\xi}_{\mathbf{k}}(t_0) \cdot \overline{\tilde{\xi}_{\mathbf{k}}(t_0 + t)} = b_{\mathbf{k}} \cdot C_{\mathbf{k}}(t), \tag{17}$$

where $b_{\mathbf{k}}$ is the variance and $C_{\mathbf{k}}(t)$ the correlation function. According to Eq.(9), $\tilde{\xi}_{\mathbf{k}}$ is the spatial spectral component of the random field in question $\xi(t, \mathbf{s})$. Therefore $b_{\mathbf{k}} = \mathsf{Var}\,\tilde{\xi}_{\mathbf{k}}$ is called the *spatial spectrum* of $\xi(t, \mathbf{s})$. From Eqs.(14) and (16), we have

$$b_{\mathbf{k}} = \frac{\sigma_{\mathbf{k}}^2}{2\mu(1 + \lambda^2\mathbf{k}^2)^q} \tag{18}$$

and

$$C_{\mathbf{k}}(t) = \mathrm{e}^{-\frac{|\mathrm{t}|}{\tau_{\mathbf{k}}}}, \tag{19}$$

where

$$\tau_{\mathbf{k}} := \frac{1}{a_{\mathbf{k}}} = \frac{1}{\mu(1 + \lambda^2\mathbf{k}^2)^q} \tag{20}$$

is the temporal length scale associated with the spatial wavevector $\mathbf{k}$.

Note that by the spectrum (e.g. $b_{\mathbf{k}}$), we always mean the *modal* spectrum, i.e. the variance associated with a single basis function (a single wavevector $\mathbf{k}$); the modal spectrum is not to be confused with the variance (or energy) spectrum.

5.4 Physical-space statistics

In the stationary regime (i.e. after an initial transient period has passed), the above independence of the spectral random processes $\tilde{\xi}_{\mathbf{k}}(t)$ (see section 5.2) implies that the random field $\xi(t, \mathbf{s})$ is spatio-temporally *homogeneous*, i.e. invariant under shifts in space and time:

$$\mathsf{E}\,\xi(t, \mathbf{s}) \cdot \overline{\xi(t + \Delta t, \mathbf{s} + \Delta\mathbf{s})} = B(\Delta t, \Delta\mathbf{s}), \tag{21}$$

where

$$B(t, \mathbf{s}) = \sum_{\mathbf{k}} b_{\mathbf{k}}\, C_{\mathbf{k}}(t)\, \mathrm{e}^{\mathrm{i}(\mathbf{k},\mathbf{s})}. \tag{22}$$

In particular, the spatial covariance function is

$$B(\mathbf{s}) = B(t = 0, \mathbf{s}) = \sum_{\mathbf{k}} b_{\mathbf{k}}\, \mathrm{e}^{\mathrm{i}(\mathbf{k},\mathbf{s})}, \tag{23}$$

where it is seen that the spatial spectrum $b_{\mathbf{k}}$ is the Fourier transform of the spatial covariance function $B(\mathbf{s})$. Finally, the variance is

$$\mathsf{Var}\,\xi = B(t = 0, \mathbf{s} = \mathbf{0}) = \sum_{\mathbf{k}} b_{\mathbf{k}}. \tag{24}$$

5.5 Imposing the SPG requirements

In section 3, we have formulated requirements 1–3 the SPG model should satisfy. In more specific terms, they imply the following three conditions.

Requirement 1 states, in particular, that

$$\mathsf{Var}\,\xi < \infty. \tag{25}$$

Next, the more precise formulation of requirement 2 states that that for large k, the temporal length scale $\tau_{\mathbf{k}}$ should be inversely proportional to k:

$$\tau_{\mathbf{k}} \sim \frac{1}{k} \quad \text{as} \quad k \to \infty. \tag{26}$$

Finally, requirement 3 entails that the driving noise $\alpha(t, \mathbf{s})$ should be white not only in time but also in space:

$$\sigma_{\mathbf{k}} = \sigma = \mathsf{const}. \tag{27}$$

This is because the physical-space simulation of the discretized white noise is cheap (since its grid-point values are just independent zero-mean Gaussian pseudo-random variables), whereas to simulate a non-white noise requires building a model for the noise and solving its equations, which is normally expensive (and complicates the design of the SPG).

In the rest of this section we show that these three conditions cannot be simultaneously satisfied for the first-order SPG model Eq.(7).

5.5.1 "Proportionality of scales" implies that $q = \frac{1}{2}$

We start with condition Eq.(26). Substituting Eq.(20) into Eq.(26) yields

$$(1 + \lambda^2 k^2)^q \sim k \quad \text{as k} \to \infty \quad \Leftrightarrow \quad \boxed{q = \frac{1}{2}}. \tag{28}$$

Note that here and elsewhere, boxed equations are the ones that present the key aspects of our final SPG model.

With $q = \frac{1}{2}$, the model's spatial operator A becomes (see Eq.(6))

$$\boxed{A = \mu(1 - \lambda^2 \Delta)^{\frac{1}{2}} \equiv \mu\sqrt{1 - \lambda^2 \Delta}}. \tag{29}$$

This is a pseudo-differential operator [e.g. 28] with the *symbol*

$$\boxed{a(k) := \mu\sqrt{1 + \lambda^2 k^2}}, \tag{30}$$

so that the action of A on the test function $\varphi(\mathbf{s})$ is defined as follows. First, we Fourier transform $\varphi(\mathbf{s})$ getting $\{\tilde{\varphi}_{\mathbf{k}}\}$. Then, $\forall \mathbf{k} \in \mathbb{Z}^d$, we multiply $\tilde{\varphi}_{\mathbf{k}}$ by the symbol $a(k)$. Finally, we perform the backward Fourier transform of $\{a(k)\tilde{\varphi}_k\}$ retrieving the result, the function $(A\varphi)(\mathbf{s})$.

Obviously, there is no problem with the above fractional negated and shifted Laplacian in spectral space (as its action on test functions is well defined, see the previous paragraph). Importantly, the pseudo-differential operator A appears to have nice properties in physical space, too. Specifically, A can be approximated by a discrete-in-space operator which is

a *very sparse matrix*, see Appendix C. So, in both spectral space and physical space, the resulting operator A with the fractional degree $q = \frac{1}{2}$ is numerically tractable.

The spectral-space SPG model Eq.(14) becomes

$$\mathrm{d}\tilde{\xi}_{\mathbf{k}} + \mu\sqrt{1+\lambda^2\mathbf{k}^2}\,\tilde{\xi}_{\mathbf{k}}\,\mathrm{d}t = \sigma_{\mathbf{k}}\,\mathrm{d}W_{\mathbf{k}}. \tag{31}$$

The resulting spatial spectrum is

$$b_k = \frac{\sigma_{\mathbf{k}}^2}{2\mu\sqrt{1+\lambda^2 k^2}}. \tag{32}$$

The SPG model becomes

$$\frac{\partial\xi(t,\mathbf{s})}{\partial t} + \mu\sqrt{1-\lambda^2\Delta}\cdot\xi(t,\mathbf{s}) = \alpha(t,\mathbf{s}). \tag{33}$$

Below, we will see that the choice $q = \frac{1}{2}$ implies that besides the "proportionality of scales", the generated spatio-temporal field has other nice properties.

5.5.2 For $\mathsf{Var}\,\xi(t,\mathbf{s})$ to be finite, $\alpha(t,\mathbf{s})$ needs to be a red noise in space

Next, we turn to condition Eq.(25) in section 5.5. Substituting Eq.(32) into Eq.(24) yields

$$\mathsf{Var}\,\xi = \frac{1}{2\mu}\sum\frac{\sigma_k^2}{\sqrt{1+\lambda^2k^2}}. \tag{34}$$

Assuming that σ_k is smoothly varying, we may approximate the sum in this equation with the integral (where $\sigma(k) = \sigma(\mathbf{k})$ for integer wavenumbers), getting

$$\mathsf{Var}\,\xi \approx \int_{\mathbb{R}^d}\frac{\sigma_k^2}{\sqrt{1+\lambda^2k^2}}\,\mathrm{d}\mathbf{k} \propto \int_{\mathbb{R}}\frac{\sigma_k^2}{\sqrt{1+\lambda^2k^2}}\,k^{d-1}\,\mathrm{d}k. \tag{35}$$

To check the convergence of the integral in Eq.(35), we examine the $k\to\infty$ limit (where $\sqrt{1+\lambda^2k^2}\sim k$). As we know, the integral of this kind converges if the integrand decays faster than $\frac{1}{k^{1+\epsilon}}$ with some $\epsilon > 0$. This is the case whenever

$$\sigma_k^2 \sim \frac{1}{k^{d-1+\epsilon}} \quad \text{as} \quad k\to\infty. \tag{36}$$

So, to satisfy the requirement $\mathsf{Var}\,\xi < \infty$, the spectrum σ_k^2 needs to be a *decaying* function of its argument k. This clearly contradicts to white-in-space-driving-noise condition Eq.(27).

5.5.3 Implications for the SPG design

As we have just seen, the conditions Eqs.(25)–(27) cannot be met by the first-order SPG model. So, the model Eq.(7) is to be somehow changed. The solution is to increase the temporal order of the stochastic model.

6 Higher-order in time model

6.1 Motivation and formulation

Equation (36) shows that with the first order SPG model, we could met both the the finite-variance condition Eq.(25) and the proportionality-of-scales condition Eq.(26) if we specified

a *red* in space (i.e. with the decaying spectrum) driving noise α. The red noise can be obtained by the application of a linear integral operator *with the decaying symbol* to the white noise. The problem here is that with the quite rapidly decaying red-noise spectrum Eq.(36), the support of the physical-space integral operator will be rather large, resulting in a computationally expensive numerical scheme.

The idea is, instead of introducing of an expensive *integral* operator with a decaying symbol to the *right-hand side* of the model, Eqs.(4) or (7) or (33), to introduce a *differential* operator (with a growing symbol) to the *left-hand side* of the SPG equation. The simplest way of doing so is to raise the operator $\partial/\partial t + A$, which already acts in our model on ξ in the l.h.s. of Eq.(4), to a power. This implies that the *temporal order* of the SPG model increases:

$$\boxed{\left(\frac{\partial}{\partial t} + \mu\sqrt{1-\lambda^2\Delta}\right)^p \xi(t,\mathbf{s}) = \alpha(t,\mathbf{s})}, \tag{37}$$

where p is the temporal order of the modified SPG model (a positive integer) and α is white both in time and in space. In spectral space, the model Eq.(37) becomes, obviously,

$$\boxed{\left(\frac{\mathrm{d}}{\mathrm{d}t} + \mu\sqrt{1+\lambda^2 k^2}\right)^p \tilde{\xi}_{\mathbf{k}}(t) = \sigma\,\Omega_{\mathbf{k}}(t)}, \tag{38}$$

where, we recall, $\Omega_{\mathbf{k}}(t)$ are mutually independent standard white noises.

The resulting higher-order SPG model satisfies condition Eq.(27) by construction. Now, we show that the model Eq.(37) can be defined to satisfy the two remaining conditions, Eqs.(25)–(26).

6.2 Stationary spectral-space statistics

For each $\mathbf{k}$, Eq.(38) is a pth-order in time OSDE. In Appendix D, we examine properties the generic pth-order OSDE, specifically, the steady-state statistics of its solution. Using Table 2 in Appendix D, we can write down the stationary variance $b_{\mathbf{k}}$ and the temporal correlation function $C_{\mathbf{k}}(t)$ of the solution to Eq.(38), the process $\tilde{\xi}_{\mathbf{k}}(t)$:

$$b_{\mathbf{k}} \propto \frac{\sigma^2}{\mu^{2p-1}(1+\lambda^2 k^2)^{p-\frac{1}{2}}} \tag{39}$$

and

$$C_{\mathbf{k}}(t) = \left(1 + \frac{|t|}{\tau_{\mathbf{k}}} + r_2\frac{|t|^2}{\tau_{\mathbf{k}}^2} + \cdots + r_{p-1}\frac{|t|^{p-1}}{\tau_{\mathbf{k}}^{p-1}}\right)\mathrm{e}^{-\frac{|t|}{\tau_{\mathbf{k}}}}. \tag{40}$$

Here $r_2, \ldots, r_{p-1}$ are real numbers (given for $p = 1, 2, 3$ in Table 2) and $\tau_{\mathbf{k}}$ is the temporal length scale associated with the spatial wavevector $\mathbf{k}$:

$$\boxed{\tau_{\mathbf{k}} = \frac{1}{\mu\sqrt{1+\lambda^2 k^2}}}. \tag{41}$$

Specifically, for the temporal order $p = 2$, we have

$$b_{\mathbf{k}}|_{p=2} = \frac{\sigma^2}{4\mu^3(1+\lambda^2 k^2)^{\frac{3}{2}}} \tag{42}$$

and

$$C_{\mathbf{k}}(t)|_{p=2} = \left(1 + \frac{|t|}{\tau_{\mathbf{k}}}\right)\mathrm{e}^{-\frac{|t|}{\tau_{\mathbf{k}}}}. \tag{43}$$

For the temporal order $p = 3$, we have

$$\boxed{b_{\mathbf{k}}|_{p=3} = \frac{3\sigma^2}{16\mu^5(1+\lambda^2 k^2)^{\frac{5}{2}}}} \tag{44}$$

and

$$\boxed{C_{\mathbf{k}}(t)|_{p=3} = \left(1 + \frac{|t|}{\tau_{\mathbf{k}}} + \frac{1}{3}\frac{|t|^2}{\tau_{\mathbf{k}}^2}\right) \mathrm{e}^{-\frac{|t|}{\tau_{\mathbf{k}}}}.} \tag{45}$$

From Eq.(41), it is seen that the "proportionality of scales" condition Eq.(26) is indeed satisfied because $\tau_{\mathbf{k}}$ is indeed inversely proportional to k for large k. In order to achieve the desired dependency of $\tau_{\mathbf{k}}$ not only on k (which we already have from Eq.(41)), but also on λ (the greater is λ the greater should be $\tau_{\mathbf{k}}$), we parameterize μ as

$$\mu = \frac{U}{\lambda}, \tag{46}$$

where $U > 0$ is the velocity-dimensioned tuning parameter. With this parameterization, λ affects both the spatial length scale of ξ (due to Eq.(39)) and the temporal length scale (thanks to Eq.(41)). In contrast, U affects only the temporal length scale.

6.3 Finite-variance criterion

Substituting b_k from Eq.(39) into Eq.(24), approximating the sum over the wavevectors by the integral (as in Eq.(35)), and exploiting the isotropy of the integrand yields

$$\mathsf{Var}\,\xi \approx \mathsf{const} \cdot \int_0^\infty \frac{\sigma^2}{(1+\lambda^2 k^2)^{p-\frac{1}{2}}} k^{d-1}\,\mathrm{d}k, \tag{47}$$

so that $\mathsf{Var}\,\xi < \infty$, i.e. the finite-variance condition Eq.(25) is met, whenever

$$\boxed{p > \frac{d+1}{2}}. \tag{48}$$

Thus, in the higher-order-in-time model Eq.(37) we can rely on the white in space and time driving noise $\alpha(t, \mathbf{s})$ *provided that the temporal order is large enough*: in 2D, it is required that $p \geq 2$ whilst in 3D, we have to set up $p \geq 3$.

6.4 Isotropy in space-time

In this subsection, we show that, remarkably, $q = \frac{1}{2}$ is the unique spatial order for which the field $\xi(t, \mathbf{s})$ appears to be isotropic is space-time. In particular, the shape of the correlation function is the same in any spatial or temporal or any other direction in the spatio-temporal domain $\mathbb{T}^d \times \mathbb{R}$.

6.4.1 Spatial isotropy

First, we note that spatial isotropy of the random field ξ is invariance of its covariance function $B(\mathbf{s})$ under rotations. If we were in $\mathbb{R}^d$ rather than on $\mathbb{T}^d$, isotropy of $B(\mathbf{s}) = B(s)$, where $s := |\mathbf{s}|$, would be equivalent to isotropy of its Fourier transform (spectrum) $b(\mathbf{k})$, so that the latter would be dependent only on the modulus of the wavevector $\mathbf{k}$, i.e. the

total wavenumber $k := |\mathbf{k}| = \sqrt{m^2 + n^2 + l^2}$. On the torus, spectra are discrete, i.e. m, n, l take only *integer* values, so, strictly speaking, $b(\mathbf{k})$ cannot be isotropic there. To avoid this technical difficulty, we resort to the device used in sections 5.5.2 and 6.3, the approximation of a sum over the wavevectors by the integral.

Specifically, we assume that $b(\mathbf{k})$ is smooth enough (which is tantamount to the assumption that $B(\mathbf{s})$ decays on length scales much smaller than the domain's extents) for the validity of the approximation

$$B(\mathbf{s}) = \sum_{\mathbf{k}\in\mathbb{Z}^\mathrm{d}} b_\mathbf{k}\, \mathrm{e}^{\mathrm{i}(\mathbf{k},\mathbf{s})} \approx \int_{\mathbb{R}^\mathrm{d}} \mathrm{b}(\mathbf{k})\, \mathrm{e}^{\mathrm{i}(\mathbf{k},\mathbf{s})} \mathrm{d}\mathbf{k}, \tag{49}$$

where $b(\mathbf{k})$ is a smooth function of the real vector argument $\mathbf{k}$ such that $\forall \mathbf{k} \in \mathbb{Z}^\mathbf{d}, \mathbf{b}(\mathbf{k}) = \mathbf{b_k}$. From Eq.(49), it is obvious that $B(\mathbf{s})$ is indeed approximately invariant under rotations because so is $b(\mathbf{k})$, see Eq.(39).

In the theoretical analysis in this section, we will rely on the approximation Eq.(49) and thus assume that the "spectral grid" is dense enough for the spatial spectra to be treated as continuous ones.

6.4.2 Spatio-temporal spectra

Consider the OSDE Eq.(38) in the stationary regime. Following [27, section 8], the stationary random process can be spectrally represented as the stochastic integral

$$\tilde{\xi}_\mathbf{k}(t) = \int_{\mathbb{R}} \mathrm{e}^{\mathrm{i}\omega t}\, \mathrm{Z}_\mathbf{k}(\mathrm{d}\omega), \tag{50}$$

where ω is the angular frequency (temporal wavenumber) and Z is the orthogonal stochastic measure such that

$$\mathsf{E}\,|Z_\mathbf{k}(\mathrm{d}\omega)|^2 = b_\mathbf{k}(\omega)\,\mathrm{d}\omega, \tag{51}$$

where $b_\mathbf{k}(\omega)$ is the spectral density of the process $\tilde{\xi}_\mathbf{k}(t)$ and, at the same time, the spatio-temporal spectrum of the field ξ. In the spectral expansion of the driving white noise $\Omega_\mathbf{k}(t)$ (see Eq.(38)),

$$\Omega_\mathbf{k}(t) = \int_{\mathbb{R}} \mathrm{e}^{\mathrm{i}\omega t}\, \mathrm{Z}_{\Omega_\mathbf{k}}(\mathrm{d}\omega), \tag{52}$$

we have $\mathsf{E}\,|Z_{\Omega_\mathbf{k}}(\mathrm{d}\omega)|^2 = \mathsf{const}\cdot\mathrm{d}\omega$ because the white noise has constant spectral density. Next, we substitute Eqs.(50) and (52) into Eq.(38), getting

$$(\mathrm{i}\omega + \mu\sqrt{1+\lambda^2 k^2})^p Z_\mathbf{k}(\mathrm{d}\omega) = Z_{\Omega_\mathbf{k}}(\mathrm{d}\omega). \tag{53}$$

In this equation, taking expectation of the squared modulus of both sides yields

$$[(\omega^2 + \mu^2(1+\lambda^2 k^2)]^p\, b_\mathbf{k}(\omega) = \mathsf{const}, \tag{54}$$

whence, recalling that $\mu = U/\lambda$ and introducing the scaled angular frequency $\omega' := \omega/U$, we finally obtain

$$b_\mathbf{k}(\omega') \equiv b_\mathbf{K} \propto \frac{1}{(\lambda^{-2} + (\omega')^2 + k^2)^p} = \frac{1}{(\lambda^{-2} + \mathbf{K}^2)^p}, \tag{55}$$

where

$$\mathbf{K} = (\,\frac{\omega}{U}, \mathbf{k}) \equiv (\frac{\omega}{U}, m, n, l) \tag{56}$$

is the spatio-temporal wavevector.

From Eq.(55), one can see that with the scaled frequency (note that the change $\omega \to \omega/U$ corresponds to the change of the time coordinate $t \to t \cdot U$), the spatio-temporal spectrum $b_{\mathbf{k}}(\omega') = b_{\mathbf{K}}$ becomes *isotropic in space-time*. This implies that the correlation function of ξ in isotropic in space-time as well (with the scaled time coordinate). Note that this remarkable property can be achieved only with the spatial order $q = \frac{1}{2}$.

6.4.3 Continuity of realizations of ξ in space-time

The functional form of the spatio-temporal spectrum Eq.(55) together with the constraint Eq.(48) imply that the conditions of Theorem 3.4.3 in [26] are satisfied, so that spatio-temporal sample paths of the random field ξ are almost surely continuous, as we demanded in section 3, see requirement 1.

6.5 Spatio-temporal covariances: the Matérn class

The spatio-temporal field satisfying the p-th order SPG model Eq.(37) has the spatio-temporal correlation function belonging to the so-called *Matérn* class of covariance functions [e.g. 29, 30]. To see this, we denote

$$\nu := p - \frac{d+1}{2} > 0, \tag{57}$$

where positivity follows from Eq.(48). Then Eq.(55) rewrites as

$$b_{\mathbf{K}} \propto \frac{1}{(\lambda^{-2} + \mathbf{K}^2)^{\nu + \frac{d+1}{2}}}. \tag{58}$$

Note that here $d+1$ is the dimensionality of space-time. Equation (58) indeed presents the spectrum of the Matérn family of correlation functions, see e.g. Eq.(32) in [29]. The respective isotropic correlation function is given by the equation that precedes Eq.(32) in [29] or by Eq.(1) in [30]:

$$B(r) \propto (r/\lambda)^{\nu} K_{\nu}(r/\lambda), \tag{59}$$

where r is the distance (in our case, the spatio-temporal distance $r = \sqrt{(Ut)^2 + s^2}$, with s being the spatial distance) and K_{ν} is the MacDonald function (the modified Bessel function of the second kind).

The Matérn family is often recommended for use in spatial analysis due to its notable flexibility with only two free parameters: ν and λ, see e.g. [29] and [30]. Specifically, λ controls the length scale, whereas $\nu > 0$ determines the degree of smoothness (the higher ν the smoother sample paths of the random field, for illustration see Appendix E).

Table 1 lists the resulting spatial correlation functions for several combinations of d and p [see 30, for details].

With the fixed d, the larger p corresponds, according to Eq.(57), to the larger ν and so to the smoother in space and time field ξ. This allows us to change the degree of smoothness of the generated field by changing the temporal order of the SPG model.

From the constraint Eq.(48), the minimal temporal order p that can be used in both 2D and 3D is equal to 3. This value $\boxed{p = 3}$ will be used by default in what follows and in the current SPG computer program.

Table 1: **The spatial correlation functions $B(s)$ for some plausible combinations of the dimensionality d and the temporal order p**

d	p	$\nu = p - \frac{d+1}{2}$	$B(s)$
2	2	$\frac{1}{2}$	$\mathrm{e}^{-\frac{s}{\lambda}}$
2	3	$\frac{3}{2}$	$(1+\frac{s}{\lambda})\,\mathrm{e}^{-\frac{s}{\lambda}}$
2	4	$\frac{5}{2}$	$(1+\frac{s}{\lambda}+\frac{1}{3}\left(\frac{s}{\lambda}\right)^2)\,\mathrm{e}^{-\frac{s}{\lambda}}$
3	3	1	$\frac{s}{\lambda}K_1(\frac{s}{\lambda})$

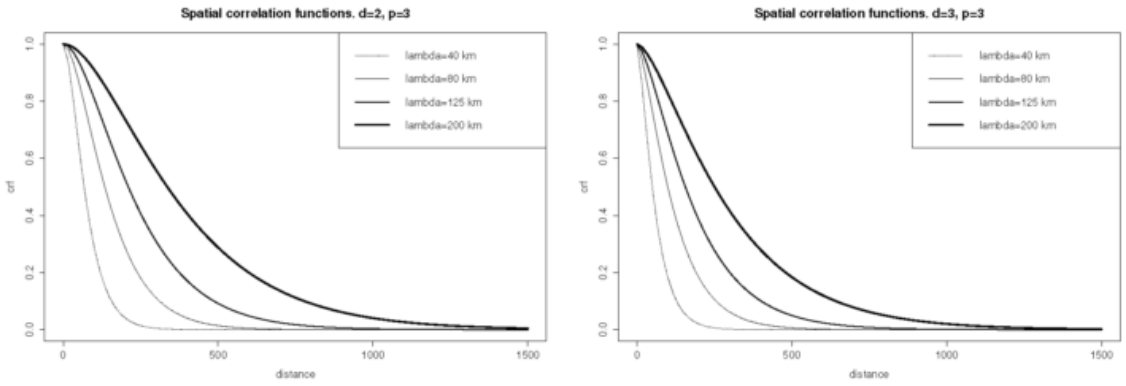

Figure 1: The spatial correlation functions for $p = 3$ in 2D (the left panel) and 3D (the right panel)—for four spatial length scales indicated in the legend.

6.5.1 Spatial correlation functions

The above spatio-temporal isotropy (see section 6.4.2 and Eq.(59)) means, in particular, that the spatial correlations are also isotropic. Figure 1 presents the *spatial* correlation functions calculated for different length scales in 2D and 3D following Eq.(59). To make the plots more accessible, it is arbitrarily assumed that the extent of the standardized spatial domain (the torus) in each dimension equals 3000 km, so that the distance is measured in kilometers. From Fig.1, one can notice, first, that the actual length scale is indeed well controlled by the parameter λ. Second, it is seen that in 2D (the left panel), where, according to Eq.(57), $\nu = \frac{3}{2}$, the correlation functions are somewhat *smoother* at the origin than in 3D (the right panel), where $\nu = 1$. This is consistent with the above statement that the greater ν the smoother the field. But in general, the 2D and 3D spatial correlation functions are quite similar.

6.5.2 Temporal correlation functions

Equation (59) shows that the spatial and temporal correlations have the same *shape*. The latter feature is very nice because atmospheric spectra are known to be similar in the spatial and in the temporal domain, e.g. the well-known "-5/3" spectral slope law is observed both in space and time, see e.g. [31, section 23]. So, our SPG does reproduce this observed in the nature similarity of spatial and temporal correlations.

Figure 2 shows the temporal correlation functions for the truncated (with $n_{max} = 90$) spatial spectral series Eq.(22). It is evident that the temporal length scale is well controlled by

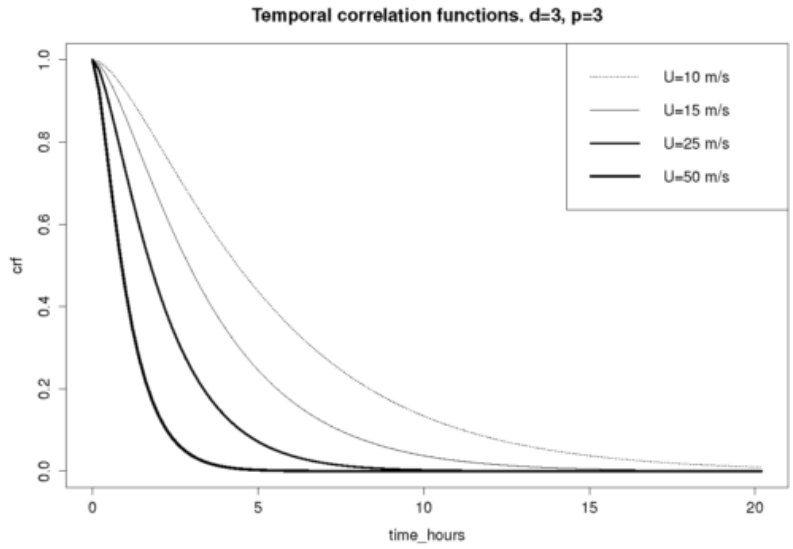

Figure 2: The temporal correlation functions in 3D for the four values of U indicated in the legend and $\lambda = 125$ km.

the parameter U. Comparing Fig.2 with Fig.1(right), one can observe that the spatial and temporal correlations indeed have the same shape; the effect of the spatial spectral truncation, which can cause a difference in the shapes, is barely visible.

6.5.3 Spatio-temporal correlations

Here, we explore the 3D spatio-temporal correlations calculated using Eq.(22) with the maximal wavenumbers in all three dimensions equal to $n_{max} = 90$, $\lambda = 125$ km, and $U = 20$ m/s. Figure 3 presents the spatial correlation functions for four time lags. Figure 4 displays the spatio-temporal correlation function.

From both Fig.3 and Fig.4, one can see the noticeable *non-separability* of the spatio-temporal covariances. The larger the time lag, the broader the spatial correlations. Note that this is consistent with the behavior of the spatio-temporal covariances found by [their Fig.8 16] in real-world wind speed data.

6.6 The final formulation of the SPG model

1. The temporal order of the SPG model is $\boxed{p = 3}$.
2. The driving noise $\alpha(t, \mathbf{s})$ is white both in time and space, so that the intensities of the spectral-space driving noises $\tilde{\alpha}_{\mathbf{k}}(t)$ are constant (and equal to σ). The intensity of the spatio-temporal white noise α is $(2\pi)^{d/2}\,\sigma$.

The resulting SPG model is

$$\boxed{\left(\frac{\partial}{\partial t} + \frac{U}{\lambda}\sqrt{1 - \lambda^2\Delta}\right)^3 \xi(t, \mathbf{s}) = \alpha(t, \mathbf{s})}. \tag{60}$$

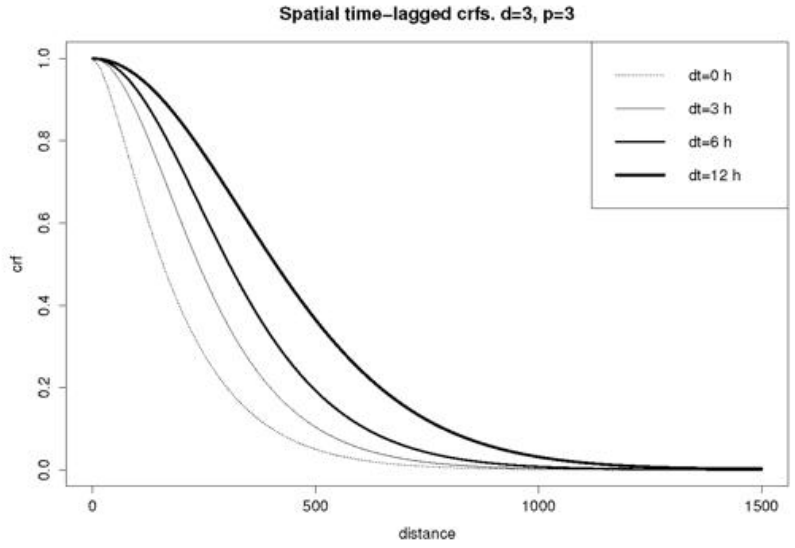

Figure 3: The spatial correlations in 3D for the four time lags indicated in the legend and $U = 20$ m/s.

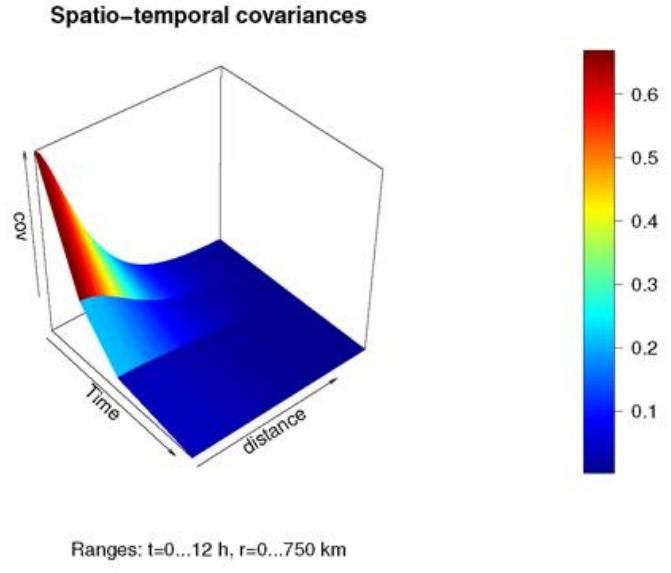

Figure 4: The spatio-temporal covariances.

In spectral space, each spectral coefficient $\tilde{\xi}_{\mathbf{k}}(t)$ satisfies the equation

$$\boxed{\left(\frac{\mathrm{d}}{\mathrm{d}t}+\frac{U}{\lambda}\sqrt{1+\lambda^2 k^2}\right)^3 \tilde{\xi}_{\mathbf{k}}(t)=\tilde{\alpha}_{\mathbf{k}}(t)=\sigma\,\Omega_{\mathbf{k}}(t)}, \tag{61}$$

where $\Omega_{\mathbf{k}}(t)$ are mutually independent complex standard white noise processes.

7 Time discrete solver for the third-order in time SPG model

In *physical space*, our final evolutionary model Eq.(60) can be discretized using the approximation of the operator $\sqrt{1-\lambda^2\Delta}$ proposed in Appendix C. The respective physical-space solver looks feasible but we do *not* examine it in this study. Below, we present our basic *spectral-space* technique. From this point on, we will consider only the *spectral* SPG.

7.1 The spectral solver

To numerically integrate the SPG model equations in spectral space, we discretize Eq.(61) using an implicit scheme. The model operator $(\frac{\mathrm{d}}{\mathrm{d}t}+a_{\mathbf{k}})^3$ (where, we recall, $a_{\mathbf{k}}:=\frac{U}{\lambda}\sqrt{1+\lambda^2k^2}$) is discretized by replacing the time derivative $\frac{\mathrm{d}}{\mathrm{d}t}$ with the backward finite difference $\frac{\mathcal{I}-\mathcal{B}}{\Delta t}$, where Δt is the time step, $\mathcal{I}$ is the identity operator, and $\mathcal{B}$ is the backshift operator. The r.h.s. of Eq.(61) (the white noise) is discretized following Appendix B, Eq.(89). As a result, we obtain the time discrete evolution equation

$$\hat{\xi}_{\mathbf{k}}(i)=\frac{1}{\varkappa^3}\left[3\varkappa^2\hat{\xi}_{\mathbf{k}}(i-1)-3\varkappa\hat{\xi}_{\mathbf{k}}(i-2)+\hat{\xi}_{\mathbf{k}}(i-3)+\sigma\Delta t^{\frac{5}{2}}\zeta_{\mathbf{k}t}\right], \tag{62}$$

where $i=0,1,2,\ldots$ denotes the discrete time instance, $\varkappa:=1+a_{\mathbf{k}}\Delta t$, and $\zeta_{\mathbf{k}t}\sim CN(0,1)$ are independent complex standard Gaussian pseudo-random variables (for their definition, see Appendix B.6). Note that the solution of the time-discrete Eq.(62) is denoted by the hat, $\hat{\xi}_{\mathbf{k}}(i)$, in order to distinguish it from the solution of the time-continuous Eq.(61), which is denoted by the tilde, $\tilde{\xi}_{\mathbf{k}}(t)$.

It can be shown that the numerical stability of the scheme Eq.(62) is guaranteed whenever $\varkappa>1$, which is always the case because $a_{\mathbf{k}}>0$, see Eq.(11).

Note that the derivation of the numerical scheme for a higher-order (i.e. with $p>3$) SPG model is straightforward: one should just raise the difference operator $\frac{\mathcal{I}-\mathcal{B}}{\Delta t}$ to a power higher than 3.

7.2 Correction of spectral variances

Because of discretization errors, the time discrete scheme Eq.(62) gives rise to the steady-state spectral variances $\hat{b}_{\mathbf{k}}:=\mathsf{Var}\,\hat{\xi}_{\mathbf{k}}(i)$, which are different from the "theoretical" ones, $b_{\mathbf{k}}$, given in Eq.(42) or Eq.(44). The idea is to correct $\hat{\xi}_{\mathbf{k}}(i)$ so that their steady-state variances coincide with $b_{\mathbf{k}}$. To this end, we derive $\hat{b}_{\mathbf{k}}$ from Eq.(62), see Eq.(104) in Appendix F, and then, knowing the "theoretical" $b_{\mathbf{k}}$, we introduce the correction coefficients, $\sqrt{b_{\mathbf{k}}/\hat{b}_{\mathbf{k}}}$, to be applied to $\hat{\xi}_{\mathbf{k}}(i)$. As a result of this correction, $\mathsf{Var}\,\hat{\xi}_{\mathbf{k}}(i)$ becomes, obviously, equal to the desired spectral variances $b_{\mathbf{k}}$. This simple device ensures that for any time step, the spatial spectrum and thus the *spatial* covariances are perfect. But the *temporal* correlations do depend on the time step, this aspect is discussed below in section 7.4.1.

7.3 "Warm start": ensuring stationarity from the beginning of time integration

To start the numerical integration of the third-order scheme Eq.(62) (for any wavevector $\mathbf{k}$), we obviously need three initial conditions. If the integration is the continuation of a previous run, then we just take values of $\hat{\xi}_{\mathbf{k}}(i)$ at the three last time instances i from that previous run; this ensures "continuity" of the resulting trajectory. If we start a new integration, we have to somehow generate values of $\hat{\xi}_{\mathbf{k}}(i)$ at $i = 1, 2, 3$, let us denote them here as the vector $\boldsymbol{\xi}^{ini} := (\hat{\xi}_{\mathbf{k}}(1), \hat{\xi}_{\mathbf{k}}(2), \hat{\xi}_{\mathbf{k}}(3))^{\top}$. Simplistic choices like specifying zero initial conditions give rise to a substantial initial transient period, which distorts the statistics of the generated field in the short time range.

In order to have the steady-state regime right from the beginning of the time integration and thus avoid the initial transient period altogether, we simulate $\boldsymbol{\xi}^{ini}$ as a pseudo-random draw from the multivariate Gaussian distribution with zero mean and the steady-state covariance matrix of $\hat{\xi}_{\mathbf{k}}(i)$. In Appendix F, we derive the components of this 3×3 matrix, namely, its diagonal elements (all equal to the steady-state variance), see Eq.(104), and the lag-1 and lag-2 covariances, see Eq.(105).

7.4 Computational efficiency

In this subsection, we describe two techniques that allow us to significantly decrease the computational cost of running the spectral SPG.

7.4.1 Making the time step Δt dependent on the spatial wavenumber k

For an ordinary differential equation, the accuracy of a finite-difference scheme depends on the time step. More precisely, it depends on the ratio of the time step Δt to the temporal length scale τ of the process in question. For high accuracy, $\Delta t \ll \tau$ is needed.

In our problem, $\tau_{\mathbf{k}}$ decays with the total wavenumber k, see Eq.(41). This implies that for higher k, smaller time steps are needed. To maintain the accuracy across the wavenumber spectrum, we choose the time step to be a portion of the time scale:

$$(\Delta t)_k := \gamma \tau_k. \tag{63}$$

The less γ, the more accurate and, at the same time, more time consuming the numerical integration scheme.

We note that in the atmospheric spectra, small scales have, normally, much less variance (energy) than large scales. But with the constant γ, the computational time would be, on the contrary, spent predominantly on high wavenumbers (because the latter require a smaller time step on the one hand and are much more abundant in 3D or 2D on the other hand). So, to save computer time whilst ensuring reasonable overall (i.e. for the whole range of wavenumbers) accuracy, we specify γ to be wavenumber dependent (growing with the wavenumber) in the following ad-hoc way:

$$\gamma_k := \gamma_{min} + (\gamma_{max} - \gamma_{min}) \left(\frac{k}{k_{max}} \right)^2, \tag{64}$$

where γ_{min} and γ_{max} are tunable parameters, $k = \sqrt{m^2 + n^2 + l^2}$, and $k_{max} := \max k$.

Note that the choice of γ depends on the shape of the temporal correlation function. For an OSDE of the type defined by Eq.(91) and τ defined to be equal to a^{-1}, the higher is the order p, the slower is the decay of the temporal correlation function for the same τ and thus the larger is to be γ.

The choice of the "optimal" γ_{min} and γ_{max} is discussed just below in section 7.4.2.

7.4.2 Introduction of a coarse grid in spectral space

Here we propose another technique to reduce the computational cost of the spectral solver. The technique exploits the *smoothness* of the SPG spectrum $b_{\mathbf{k}}$ Eq.(44). This smoothness allows us to introduce a *coarse grid in spectral space* and perform the integration of the time discrete spectral OSDEs Eq.(62) only for those wavevectors that belong to the coarse grid. The spectral coefficients $\hat{\xi}_{\mathbf{k}}(i)$ are then interpolated from the coarse grid to the dense (full) grid in spectral space.

The latter interpolation would introduce correlations between different spectral coefficients $\hat{\xi}_{\mathbf{k}}(i)$, which would destroy the spatial homogeneity. In order to avoid this, we employ a device used to generate so-called surrogate time series [32, section 2.4.1]. At each t, we multiply the interpolated $\hat{\xi}_{\mathbf{k}}(i)$ by $\mathrm{e}^{i\theta_{\mathbf{k}}}$, where $\theta_{\mathbf{k}}$ are independent *random phases*, i.e. independent for different $\mathbf{k}$ random variables uniformly distributed on the segment $[0, 2\pi]$. It can be easily seen that this multiplication removes any correlation between the spectral coefficients.

Note also that the random phase rotation does not destroy the Gaussianity because $\hat{\xi}_{\mathbf{k}}(i)$ are complex circularly-symmetric random variables with uniformly distributed and independent of $|\hat{\xi}_{\mathbf{k}}(i)|$ arguments (phases), see e.g. [33, section A.1.3].

To preserve the temporal correlations of the field $\xi(t, \mathbf{s})$, we keep the set of $\theta_{\mathbf{k}}$ constant during the SPG-model time integration.

The exact spectrum $b_{\mathbf{k}}$ after the trilinear (bilinear in 2D) interpolation of $\hat{\xi}_{\mathbf{k}}(i)$ from the coarse to the full spectral grid is imposed in a way similar to that described in section 7.2 as follows. At any time instance when we wish to compute the physical space field, for each $\mathbf{k}$ on the full spectral grid, the linearly interpolated value $\check{\xi}_{\mathbf{k}}$ is a linear combination of the closest coarse-grid points $\mathbf{k}_j$:

$$\check{\xi}_{\mathbf{k}} = \sum_{j=1}^{2^d} w_j \, \hat{\xi}_{\mathbf{k}_j} \tag{65}$$

where $\check{}$ denotes the interpolated value and w_j is the interpolation weight (note that the set of the closest coarse-grid points $\mathbf{k}_j$ depends, obviously, on $\mathbf{k}$). In Eq.(65), the coarse-grid variances $\mathsf{Var}\,\hat{\xi}_{\mathbf{k}_j} = b_{\mathbf{k}_j}$ are known for all $\mathbf{k}_j$ from the spectrum $\{b_{\mathbf{k}}\}$, see Eqs.(42) or (44). Therefore, we can find $\mathsf{Var}\,\check{\xi}_{\mathbf{k}} = \sum_j w_j^2 \, b_{\mathbf{k}_j}$. Besides, we know which variance $\check{\xi}_{\mathbf{k}}$ *should* have on the fine grid, namely $b_{\mathbf{k}}$. So, we normalize $\check{\xi}_{\mathbf{k}}$ by multiplying it by $\sqrt{b_{\mathbf{k}}/(\mathsf{Var}\,\check{\xi}_{\mathbf{k}})}$, thus imposing the exact spatial spectrum for all $\mathbf{k}$.

Technically, the 3D coarse spectral grid is the direct product of three 1D grids. Any of the (non-uniform) 1D coarse grids is specified as follows. The jth coarse grid point is located at the fine-grid wavenumber n_j, which equals j for $|j| \le n_0$ (where n_0 is an integer) and the closest integer to $n_0(1+\varepsilon)^{|n|-n_0}$ for $|j| > n_0$. Here, ε is a tunable small positive number. In the below numerical experiments, the coarse-grid parameters were $n_0 = 20$ and $\varepsilon = 0.2$, which resulted in the following positive 1D coarse-grid points: 1 2 3 ... 19 20 24 29 35 42 50 60 72 86 103 124 150 (if not otherwise stated, the 1D grid extent was 300 points and, correspondingly, the maximal wavenumber was 150).

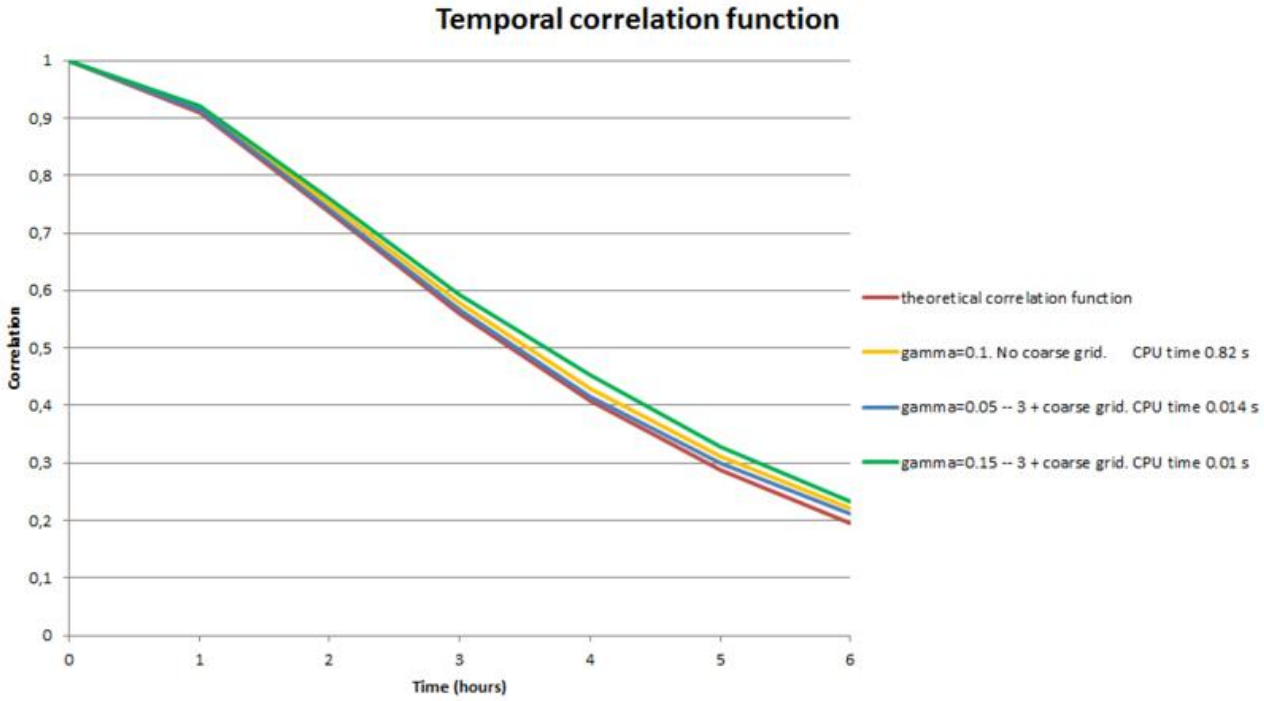

Figure 5: The theoretical and estimated temporal correlations and CPU times for the 2D SPG. The legend indicates the range γ_{min}–γ_{max} and whether the coarse grid was used. The respective spectral-space computation time (per one hour of time integration on one CPU) is also indicated in the legend. The SPG setup: $\lambda = 85$ km, $U = 12$ m/s.

7.4.3 Numerical acceleration: results

As the two above acceleration techniques guarantee that the *spatial* spectrum is always precise, we test how these techniques impact the *temporal* correlations (and what is the speedup).

In the numerical experiments, the introduction of the coarse spectral grid impacted the temporal correlations to a lesser extent than an increase in the time-step parameter γ. So, we examined the role of the two parameters γ_{min} and γ_{max} of the acceleration technique described in section 7.4.1, and the impact of the presence or absence of the coarse spectral grid introduced in section 7.4.2.

Figure 5 shows the temporal correlations functions for the different setups (indicated in the legend) of the 2D SPG. The respective CPU times for the spectral-space computations (on one CPU per one hour of model integration) are also shown in the legend. The discrete backward Fourier transforms were performed every hour of lead time.

From Fig.5, one can see that the combined effect of both numerical acceleration techniques (the green curve) was dramatic: the speedup was about 80 times as compared to the non-accelerated scheme (i.e. without the coarse grid and with constant $\gamma = 0.1$, the yellowish curve). The contributions of the two above numerical acceleration techniques to this speedup were comparable in magnitude (not shown). Most importantly, this big speedup was achieved at the very little cost: the temporal correlation length scale was distorted, as a result of approximations caused by the two acceleration techniques, by only some 5 percent w.r.t. the non-accelerated scheme and some 10 percent w.r.t. the theoretical model (the red curve).

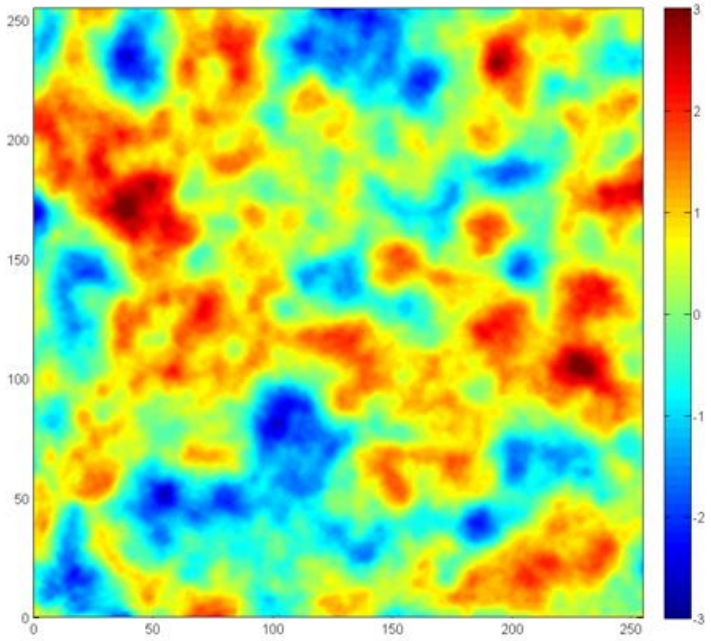

Figure 6: 2D (x-y) cross-section of a spatial SPG field.

Note that the speedup was for the spectral-space computations only, i.e. it did *not* include the cost of the discrete backward Fourier transform.

In summary, the 2D-in-space SPG took only 1 second on one CPU to perform the spectral-space model integration for as long as 100 hours of lead time. The respective cost of the backward Fourier transform performed every hour was about 4 seconds. The total cost was thus 5 seconds.

The same computations performed for the 3D-in-space grid with $300 \times 300 \times 64$ points took 60 seconds on one CPU for 100 hours of spectral-space model integration and 110 seconds for the hourly backward Fourier transform. The speedup of the spectral-space computations for the 3D scheme due to the two acceleration techniques was about 50 times.

7.5 Examples of the SPG fields

Figure 6 shows a "horizontal" x-y cross-section and Fig.7 a spatio-temporal x-t cross-section of a simulated pseudo-random field $\xi(t, x, y)$. Note that in each spatial direction, there were 300 grid points, whilst only 256 contiguous points are shown in the Figures. This is done in the SPG for practical purposes in order to avoid correlations between the opposite sides of the spatial domain, which would be spurious in real-world applications.

8 Application to the COSMO model

The SPG was embedded into the Fortran code of the limited-area meteorological non-hydrostatic model COSMO [34]. Within COSMO, the SPG code was parallelized using

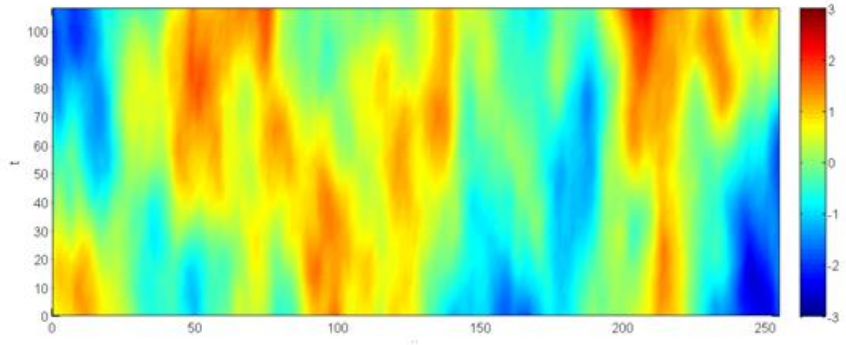

Figure 7: 2D (abscissa is x, ordinata is t) spatio-temporal cross-section of an SPG field.

MPI. The SPG was used to generate additive perturbations of the model's right-hand sides.

Figure 8 displays results of a numerical experiment, in which independent SPG perturbation fields for temperature and horizontal wind were simulated and added to the model fields every 15 minutes of lead time. The standard deviations of the SPG perturbations were specified as 0.005 K for temperature and 0.01 m/s for each of the two mutually orthogonal wind components. Besides, pressure perturbations were computed (and added to the model pressure 3D field) from the SPG temperature perturbation using the hydrostatic equation with the zero pressure perturbation at the model's top level.

The first generated by the SPG meridional wind perturbation field on the model level 25 (about 3 km above the ground) is displayed in Fig.8(top). The forecast (i.e. accumulated over time) meridional wind perturbation field after 3 hours of model integration is shown in Fig.8(bottom). Comparing the top and bottom panels of Fig.8 suggests that the perturbation field becomes more large-scale and, at the same time, less smooth over time. Specifically, the large-scale structure of the perturbation field becomes more large scale. This is to be expected because the time integration reduces (filters out) small-scale-in-time components of the spatio-temporal field and so, from the "proportionality of scales", filters out smaller scales also in space.

Besides, an opposite effect, namely appearance of a kind of fine structure can be seen in the forecast perturbation fields, see Fig.8(bottom). In particular, in the forecast perturbation field, there are many very localized features, which presumably develop due to a non-linear interaction with convection and effects related to steep orography. Finally, we note that in contrast to the "input" SPG model-error perturbation field, the "output" forecast perturbation field is clearly seen to be flow dependent (as desired in ensemble prediction and ensemble data assimilation schemes).

Figure 9 displays the growth of the meridional wind RMS forecast perturbation at the same model level 25 in response to the above SPG model-error perturbations. One can see that the magnitude of the forecast perturbation grows monotonically and "regularly" (as expected).

Finally, we note that at the time of writing, the numerical acceleration techniques described in section 7.4 were implemented only in the stand-alone version of the SPG. Without those accelerators, the cost of running the SPG within COSMO was about 0.8% of the total COSMO model wall-clock time per generated SPG field.

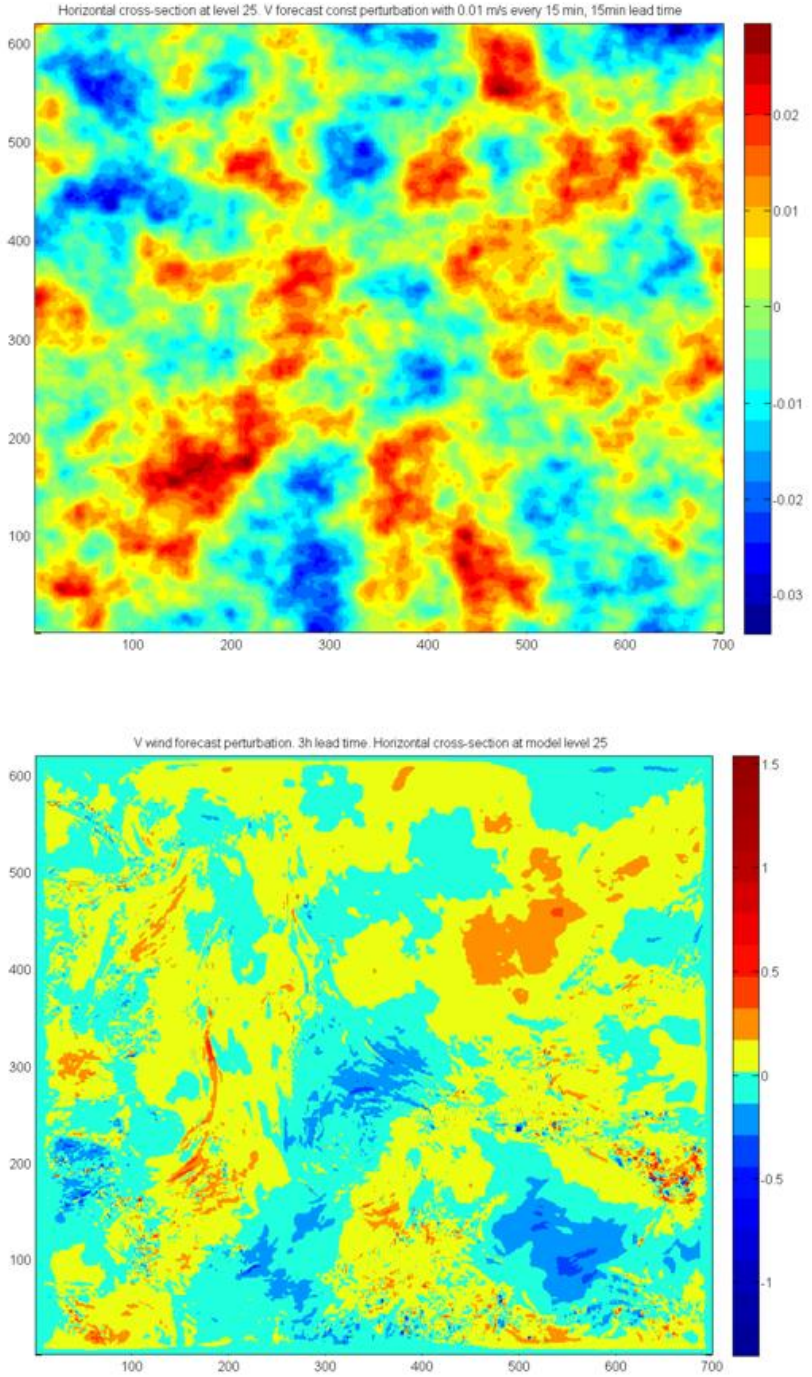

Figure 8: *The top panel*: The first SPG V-wind perturbation added to the COSMO field at the lead time 15 minutes. *The bottom panel*: the COSMO 3-h forecast V-wind perturbation field in response to the additive SPG perturbations of temperature, pressure, and both wind components added every 15 minutes of lead time.

9 Discussion

9.1 Physical-space or spectral-space SPG solver?

In this study, we have investigated both the spectral-space and the physical-space approximations of the SPG spatio-temporal model. We have found that both approaches can be used to build a practical SPG scheme. We have selected the spectral-space technique. Here, we briefly compare both approaches.

Advantages of the spectral-space technique are the following.

- Simplicity of realization. If the SPG model has constant coefficients, then the complicated SPG equation decouples into a series of simple OSDEs.
- Straightforward accommodation of non-local-in-physical-space spatial operators.

Advantages of the physical-space approach are:

- The relative ease of introduction of inhomogeneous and anisotropic capabilities to the SPG.
- The SPG solver can be implemented in domains with complex boundaries.
- Better suitability for an efficient implementation on massively parallel computers.

9.2 Extensions of the SPG

The proposed SPG technique can be extended in the future along the following lines.

- Development of a physical-space solver.

- Introduction of advection to the SPG model.
- Introduction of spatial inhomogeneity/anisotropy and non-stationarity.
- Introduction of non-Gaussianity. This can be done either by applying a nonlinear transform to the output SPG fields, or by introducing a non-Gaussian driving noise [as in 24, 25]. The former approach is simpler but the latter allows for much richer deviations from Gaussianity, including the multi-dimensional aspect.
- Going beyond additive and multiplicative perturbations for highly non-Gaussian variables like humidity and cloud fields.
- Simulation of several mutually correlated pseudo-random fields.
- Making the temporal order p a user defined variable. As noted above, the larger p the smoother the generated field.

10 Conclusions

10.1 Summary

- The proposed Stochastic Pattern Generator (SPG) produces pseudo-random spatio-temporal Gaussian fields on 2D and 3D spatial domains.
- The SPG model is defined on a standardized domain in space, specifically, on the unit 2D or 3D torus. Fields on a limited-area geophysical domain in question are obtained by mapping from the standardized domain.
- The SPG is based on a linear third-order in time stochastic model driven by the white in space and time Gaussian noise.
- The spatial operator of the stochastic model is built to ensure that solutions to the SPG model, i.e. the generated pseudo-random fields satisfy the "proportionality of scales" property: large-scale (small-scale) in space field components have large (small) temporal length scales.
- Besides the "proportionality of scales", the generated fields possess a number of other nice properties:
  - The spatio-temporal realizations are (almost surely) continuous.
  - With the appropriately scaled time coordinate, the spatio-temporal fields are isotropic in space-time.
  - The spatial and temporal correlation functions belong to the Matérn class.
  - The spatial and temporal correlations have the same shape.
- It is shown that the spatial operator of the SPG model can be effectively discretized both in physical space and spectral space.
- The basic SPG solver is spectral-space based.
- Two techniques to accelerate the spectral-space computations are proposed and implemented. The first technique selects the time step of the spectral-space numerical integration scheme to be dependent on the wavenumber, so that the discretization error is smaller for more energetic larger spatial scales and is allowed to be larger for

less energetic smaller scales. The second technique introduces a coarse grid in spectral space. The combined speedup for spectral-space computations from both techniques is as large as 50–80 times.

- The SPG is embedded in the COSMO model as a source of additive model-error perturbations. The numerical experiments show that the forecast perturbations in response to the SPG model-error perturbations behave as expected.
- For a peer reviewed publication on the SPG, see [35].

10.2 Applications

Potential applications of the SPG include ensemble prediction and ensemble data assimilation in meteorology, oceanography, hydrology, and other areas.

The SPG can be used to generate spatio-temporal perturbations of the model fields (in the additive or multiplicative or other mode), and of the boundary conditions.

Acknowledgements

The SPG has been developed as part of the Priority Project KENDA (Kilometer scale Ensemble Data Assimilation) of COSMO. We have used the discrete fast Fourier package `fft991` developed by C. Temperton at ECMWF in 1978. Christoph Schraff and Michael Baldauf kindly helped us to interpret the appearance of the small-scale noise in the COSMO forecast perturbation fields.

A Illustration of the "proportionality of scales" property

Figure 10 shows a realization of the spatio-temporal field with *non-separable* correlations that satisfy the "proportionality of scales" property (the top panel) and a realization of the field with *separable* spatio-temporal correlations (the bottom panel).

The non-separable spatio-temporal correlation function is defined as $B(x,t) = \exp(-r/L)$, where $r := \sqrt{x^2 + (Ut)^2}$, $U = 10$ m/s, $L = 200$ km, and the domain size in the x direction is 3000 km. The separable correlation function is $B(x,t) = \exp(-|x|/L) \cdot \exp(-|Ut|/L)$. So, both separable and non-separable fields have exactly the same spatial correlation functions and the same temporal correlation functions.

Note that both the separability and the exponential temporal correlation function is what the scale-independent first-order auto-regression used in [19, 9, 20, 21, 22] implies.

Comparing the two panels of Fig.10, one can see that the two fields are quite different. In the non-separable case, Fig.10(top), large spatial structures indeed tend to live longer than small structures, as it is expected from the "proportionality of scales" principle. In contrast, in the case with separable space-time correlations, Fig.10(bottom), the "longevity" of a spatial pattern is rather independent of its size (which is unphysical). Besides, in the non-separable case, a kind of spatio-temporal "organization" is evident, which is absent in the separable case. Finally, the field with non-separable correlations exhibits a sort of spatio-temporal isotropy, again, not visible in the separable case.

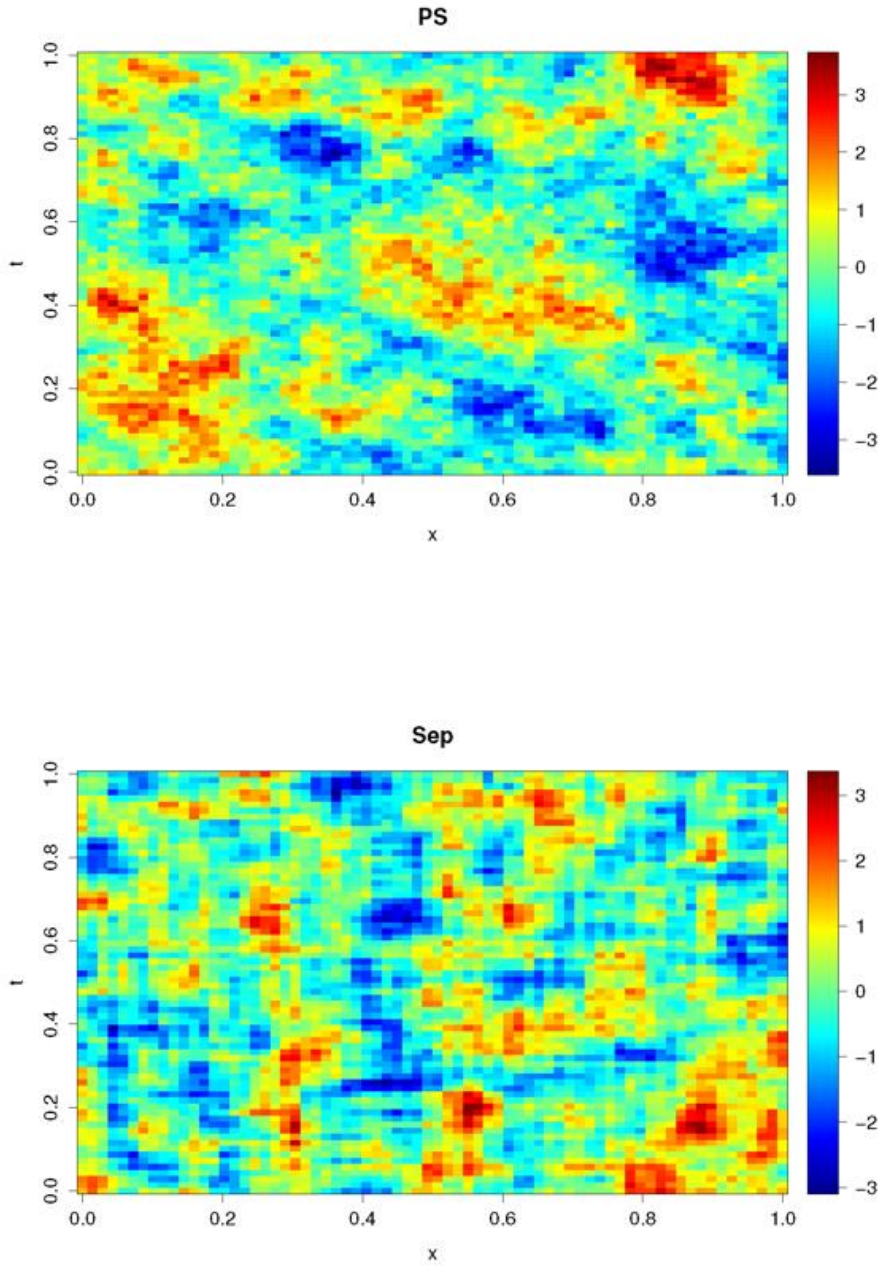

Figure 10: Simulated spatio-temporal fields. *Top*: With non-separable space-time correlations satisfying the "proportionality of scales" principle. *Bottom*: With separable space-time correlations.

B Spatio-temporal structure of the driving 4-D noise

Here, we recall the general definition of the white noise, define the spatial spectrum of the white noise on the d-dimensional unit torus, and find its spatial spectral decomposition in the spatio-temporal case. Then we introduce a colored in space and white in time noise, and find it spatial spectrum. Finally, we define the time discrete complex-valued white-noise process.

B.1 White noise

By definition, see e.g. [36, section 1.1.3] or [37, section 3.1.4], the *standard white noise* $\Omega(\mathbf{x})$ defined on a manifold $\mathbb{D}$ is a *generalized random field* that acts on a test function $\varphi(\mathbf{x})$ (where $x \in \mathbb{D}$) as follows:

$$(\Omega, \varphi) := \int \varphi(\mathbf{x})\, \Psi(\mathrm{d}\mathbf{x}), \tag{66}$$

where Ψ is the Gaussian orthogonal stochastic measure such that for any Borel set A, $\Psi(A)$ is a (complex, in general) Gaussian random variable with $\mathsf{E}\,\Psi(A) = 0$ and $\mathsf{E}\,|\Psi(A)|^2 = |A|$, where $|.|$ denotes the Lebesgue measure.

The equivalent definitions of the standard white noise are

$$\mathsf{E}\,|(\Omega, \varphi)|^2 := \int |\varphi(\mathbf{x})|^2\, \mathrm{d}\mathbf{x}, \tag{67}$$

and

$$\mathsf{E}\,(\Omega, \varphi) \cdot \overline{(\Omega, \psi)} := \int \varphi(\mathbf{x}) \overline{\psi(\mathbf{x})}\, \mathrm{d}\mathbf{x}, \tag{68}$$

where ψ is another test function. Thus, we have defined of the *standard* white noise. By the general Gaussian white noise, we mean a multiple of the *standard* white noise.

B.2 Spectrum of the white noise on $\mathbb{T}^d$

The formal Fourier transform of the spatial white noise $\Omega(\mathbf{s})$ (where $\mathbf{s} \in \mathbb{T}^3$),

$$\tilde{\Omega}_{\mathbf{k}} = \frac{1}{(2\pi)^d} \int_{\mathbb{T}^d} \Omega(\mathbf{s})\, \mathrm{e}^{-\mathrm{i}(\mathbf{k},\mathbf{s})}\, \mathrm{d}\mathbf{s}, \tag{69}$$

can be rigorously justified as the action of the white noise Ω on the test function

$$\chi(\mathbf{s}) := \frac{1}{(2\pi)^d}\, \mathrm{e}^{-\mathrm{i}(\mathbf{k},\mathbf{s})}. \tag{70}$$

Then, the spatial spectrum of $\Omega(\mathbf{s})$ is

$$b_{\mathbf{k}} := \mathsf{E}\,|\tilde{\Omega}_{\mathbf{k}}|^2 \equiv \mathsf{E}\,|(\Omega, \chi)|^2 = \int_{\mathbb{T}^d} |\chi(\mathbf{s})|^2\, \mathrm{d}\mathbf{s} = \frac{1}{(2\pi)^d}. \tag{71}$$

Here, the third equality is due to Eq.(67). We stress that it is the *modal* spectrum that is constant for the white noise (not the variance spectrum), see also remark at the end of section 5.3.

B.3 Space-integrated spatio-temporal white noise on $\mathbb{T}^d \times \mathbb{R}$

Let us consider the spatio-temporal white noise $\Omega = \Omega(t, \mathbf{s})$, where $t \in \mathbb{R}$ is time and $\mathbf{s} \in \mathbb{T}^d$ the spatial coordinate vector. Take a spatial test function $c(\mathbf{s})$ and define the temporal process $\Omega_1(t)$ formally as

$$\Omega_1(t) := \int_{\mathbb{T}^d} \Omega(t, \mathbf{s}) c(\mathbf{s}) \, \mathrm{d}\mathbf{s}, \tag{72}$$

so that it acts on a test function in the temporal domain, $\varphi(t)$, as

$$(\Omega_1, \varphi) := \int_{\mathbb{R}} \Omega_1(t) \varphi(t) \, \mathrm{d}t = \int_{\mathbb{R}} \int_{\mathbb{T}^d} \Omega(t, \mathbf{s}) c(\mathbf{s}) \varphi(t) \, \mathrm{d}\mathbf{s} \, \mathrm{d}t. \tag{73}$$

Here, we note that the latter double integral is nothing other than the result of action of the original white noise $\Omega(t, \mathbf{s})$ on the spatio-temporal test function $c(\mathbf{s}) \cdot \varphi(t)$. This enables us to mathematically rigorously *define* $\Omega_1(t)$ as the generalized random process that, with the fixed $c(\mathbf{s})$, acts on the test function $\varphi(t)$ as follows:

$$(\Omega_1(t), \varphi(t)) := (\Omega(t, \mathbf{s}),\, c(\mathbf{s})\varphi(t)). \tag{74}$$

Now, using the definition Eq.(67) of the white noise $\Omega(t, \mathbf{s})$, we have

$$\mathsf{E} \, |(\Omega(t, \mathbf{s}),\, c(\mathbf{s})\varphi(t))|^2 = \int_{\mathbb{T}^d} \int_{\mathbb{R}} |c(\mathbf{s})|^2 |\varphi(t)|^2 \, \mathrm{d}\mathbf{s} \, \mathrm{d}t = \int_{\mathbb{T}^d} |c(\mathbf{s})|^2 \, \mathrm{d}\mathbf{s} \int_{\mathbb{R}} |\varphi(t)|^2 \, \mathrm{d}t. \tag{75}$$

Since we have fixed $c(\mathbf{s})$, we observe that

$$\sigma^2 := \int |c(\mathbf{s})|^2 \, \mathrm{d}\mathbf{s} \tag{76}$$

is a constant such that

$$\mathsf{E} \, |(\Omega_1(t), \varphi(t))|^2 = \sigma^2 \int_{\mathbb{R}} |\varphi(t)|^2 \, \mathrm{d}t. \tag{77}$$

Comparing this equation with one of the definitions of the standard white noise, Eq.(67), we recognize $\Omega_1(t)$ as a general Gaussian white noise in time, i.e. the standard temporal white noise multiplied by σ. We call σ the *intensity* of the white noise.

B.4 Spatial spectrum of a spatio-temporal white noise

Now, we are in a position to derive the spatial spectrum of the standard spatio-temporal white noise $\Omega(t, \mathbf{s})$. In the formal Fourier decomposition

$$\Omega(t, \mathbf{s}) = \sum_{\mathbf{k}} \tilde{\Omega}_{\mathbf{k}}(t) \, \mathrm{e}^{\mathrm{i}(\mathbf{k}, \mathbf{s})}, \tag{78}$$

the elementary temporal processes $\tilde{\Omega}_{\mathbf{k}}(t)$ can be shown to be white noises in time. Indeed, again formally, we have

$$\tilde{\Omega}_{\mathbf{k}}(t) = \frac{1}{(2\pi)^d} \int_{\mathbb{T}^d} \Omega(t, \mathbf{s}) \, \mathrm{e}^{-\mathrm{i}(\mathbf{k}, \mathbf{s})} \, \mathrm{d}\mathbf{s}. \tag{79}$$

Here, we recognize an expression of the kind given by Eq.(72) with $c(\mathbf{s}) := \mathrm{e}^{-\mathrm{i}(\mathbf{k}, \mathbf{s})}/(2\pi)^{\mathrm{d}}$. Therefore, from Eq.(77), $\tilde{\Omega}_{\mathbf{k}}(t)$ is a temporal white noise with the intensity $\sigma^{\Omega}_{\mathbf{k}}$ squared equal to

$$(\sigma^{\Omega}_{\mathbf{k}})^2 = \int |c(\mathbf{s})|^2 \, \mathrm{d}\mathbf{s} = \frac{1}{(2\pi)^{2d}} \int_{\mathbb{T}^d} |\mathrm{e}^{-\mathrm{i}(\mathbf{k}, \mathbf{s})}|^2 \, \mathrm{d}\mathbf{s} = \frac{1}{(2\pi)^{\mathrm{d}}}. \tag{80}$$

In addition, using Eq.(68), it is easy to show that $\tilde{\Omega}_{\mathbf{k}}(t)$ and $\tilde{\Omega}_{\mathbf{k}'}(t)$ are mutually orthogonal for $\mathbf{k} \neq \mathbf{k}'$.

To summarize, $\tilde{\Omega}_{\mathbf{k}}(t)$ are mutually orthogonal white-in-time noises, all with equal intensities $\sigma_{\mathbf{k}}^{\Omega} = (2\pi)^{-d/2}$:

$$\tilde{\Omega}_{\mathbf{k}}(t) = \frac{1}{(2\pi)^{d/2}}\,\Omega_{\mathbf{k}}(t), \tag{81}$$

where $\Omega_{\mathbf{k}}(t)$ are the standard white noises.

B.5 Spectral decomposition of a white in time and colored in space noise

In order to introduce a white in time and colored in space noise, let us *convolve* the spatio-temporal white noise $\Omega(t, \mathbf{s})$ with a *smoothing kernel* in space $u(\mathbf{s})$, getting

$$\alpha(t, \mathbf{s}) := \int_{\mathbb{T}^d} u(\mathbf{s} - \mathbf{r})\,\Omega(t, \mathbf{r})\,\mathrm{d}\mathbf{r}. \tag{82}$$

In this equation, the stochastic integral is defined, for any t and $\mathbf{s}$, following Eq.(74) with $c(\mathbf{r}) := u(\mathbf{s} - \mathbf{r})$. Fourier transforming $u(\mathbf{s})$,

$$u(\mathbf{s}) = \sum_{\mathbf{k}} \tilde{u}_{\mathbf{k}}\,\mathrm{e}^{\mathrm{i}(\mathbf{k},\mathbf{s})}, \tag{83}$$

and, in space, $\alpha(t, \mathbf{s})$,

$$\alpha(t, \mathbf{s}) = \sum_{\mathbf{k}} \tilde{\alpha}_{\mathbf{k}}(t)\,\mathrm{e}^{\mathrm{i}(\mathbf{k},\mathbf{s})}, \tag{84}$$

we easily obtain that the elementary spectral processes $\tilde{\alpha}_{\mathbf{k}}(t)$ are independent white noises in time with the intensities squared

$$\sigma_{\mathbf{k}}^2 = (2\pi)^d |\tilde{u}_{\mathbf{k}}|^2, \tag{85}$$

so that the stochastic differential $\tilde{\alpha}_{\mathbf{k}}(t)\mathrm{d}t$ is

$$\tilde{\alpha}_{\mathbf{k}}(t)\,\mathrm{d}t = \sigma_{\mathbf{k}}\,\mathrm{d}W_{\mathbf{k}}(t). \tag{86}$$

Equivalently,

$$\tilde{\alpha}_{\mathbf{k}}(t) = \sigma_{\mathbf{k}}\,\Omega_{\mathbf{k}}(t). \tag{87}$$

B.6 Discretization of the spectral processes $\tilde{\alpha}_{\mathbf{k}}(t)$ in time

Being white noises, $\tilde{\alpha}_{\mathbf{k}}(t)$ have infinite variances. They become ordinary random processes if, e.g., we discretize them in time. With the time step Δt, we define the discretized process $\hat{\alpha}_{\mathbf{k}}(t_j)$ at the time instance t_j by replacing, in Eq.(86), $\mathrm{d}t$ with Δt and $\mathrm{d}W_{\mathbf{k}}$ with $\Delta W_{\mathbf{k}}$:

$$\hat{\alpha}_{\mathbf{k}}(t_j)\,\Delta t := \sigma_{\mathbf{k}}\,\Delta W_{\mathbf{k}}(t). \tag{88}$$

As $\mathsf{E}\,|\Delta W_{\mathbf{k}}(t)|^2 = \Delta t$, we obtain

$$\hat{\alpha}_{\mathbf{k}}(t_j) = \frac{\sigma_{\mathbf{k}}}{\sqrt{\Delta t}} \cdot \zeta_{\mathbf{k}j}, \tag{89}$$

where $\zeta_{\mathbf{k}j}$ are independent complex standard Gaussian random variables $CN(0, 1)$. The latter is defined as a complex random variable whose real and imaginary parts are mutually uncorrelated zero-mean random variables with variances equal to $1/2$. $CN(0, 1)$ is sometimes referred to as circularly symmetric complex Gaussian (normal) random variable [e.g. 33].

Equation (89) shows that the spatial spectrum of the time discrete driving noise is $\sigma_{\mathbf{k}}^2/\Delta t$.

C Physical-space approximation of the operator $\sqrt{1-\lambda^2\Delta}$

As we have discussed in section 5.5.1, the fractional power (square root) of the negated and shifted Laplacian operator, $\mathcal{L} := \sqrt{1-\lambda^2\Delta}$, is defined as the pseudo-differential operator with the symbol $\tilde{l}(\mathbf{k}) := \sqrt{1+\lambda^2\mathbf{k}^2}$. In the literature, one can find approaches to discretization of fractional powers of elliptic operators, e.g. finite elements were used in the spatial context in [38].

Here, we propose a simple technique to build a spatial discretization scheme that approximates the operator $\sqrt{1-\lambda^2\Delta}$ in the sense that the symbol of the approximating operator is close to $\sqrt{1+\lambda^2\mathbf{k}^2}$.

To this end, we do the following.

1. Perform the backward Fourier transform of the symbol $\tilde{l}(\mathbf{k})$, getting the function $l(\mathbf{s})$. As multiplication in Fourier space by $\tilde{l}(\mathbf{k})$ is equivalent to convolution in physical space with $l(\mathbf{s})$, we obtain that for any test function $\varphi(\mathbf{s})$,

$$(\mathcal{L}\varphi)(\mathbf{s}) = \int_{\mathbb{T}^3} l(\mathbf{s}-\mathbf{r})\,\varphi(\mathbf{r})\,\mathrm{d}\mathbf{r}. \tag{90}$$

   The crucial moment here is that the kernel function $l(\mathbf{s})$ appears to be oscillating while rapidly decreasing in modulus as $|\mathbf{s}|$ increases (see below). This enables its efficient approximation with a compact-support (truncated) function.

2. With the discretization on the grid with n points in each of the d dimensions on the torus $\mathbb{T}^d$, the kernel function $l(\mathbf{s})$ is represented by the set of its grid-point values $l(\mathbf{s_i})$, where $\mathbf{s} = (s_1, \ldots, s_d)$, $\mathbf{i} = (i_1, \ldots, i_d)$, and $\mathbf{s_i} = (s_1(i_1), \ldots, s_d(i_d))$. If $l(\mathbf{s})$ appears to be rapidly decreasing away from $\mathbf{s} = \mathbf{0}$, we truncate the $l(\mathbf{s_i})$ function by limiting its support near the origin, thus getting the function $l_{trunc}(\mathbf{s_i})$. E.g. in 3D, the support of $l_{trunc}(\mathbf{s_i})$ consists of the grid points $\mathbf{i} = (i_1, i_2, i_3)$ that simultaneously satisfy the following constraints: $|i_1| \le J$, $|i_2| \le J$, and $|i_3| \le J$, where J is the spatial order of the scheme. Below, we present results with $J = 1$ (3 grid points in the support of the truncated kernel function in each dimension) and $J = 3$ (7 grid points in the support in each dimension).

3. Fourier transform $l_{trunc}(\mathbf{s})$ back to the spectral space, getting the approximated symbol $\tilde{l}_{trunc}(\mathbf{k})$.

4. Compare $\tilde{l}(\mathbf{k})$ with $\tilde{l}_{trunc}(\mathbf{k})$ and conclude whether a parsimonious (that is, with a very small J) approximation is viable.

Now, we present the results. We found that for $d = 1$, $d = 2$, and $d = 3$, the goodness of fit was similar, so we examine the 3D case below.

We selected the grid of $n = 2 \cdot n_{max} = 256$ points in each of the three dimensions. We specified the spatial non-dimensional length scale λ to be much greater than the mesh size $h = 2\pi/n$ and much less than the domain's extents, 2π. Specifically, we chose $\lambda = 1/n_1$, where $n_1 := \sqrt{n_{max}}$. (The results were not much sensitive to changes in n_1 within the whole wavenumber range on the grid.)

Figure 11 displays the resulting kernel function $l(s)$ for positive s (note that $l(s)$ is an even function of the scalar distance s). One can see the remarkably fast decay of $|l(s)|$ with the growing s. Consequently, a stencil with just a few points in each dimension can be expected to work well.

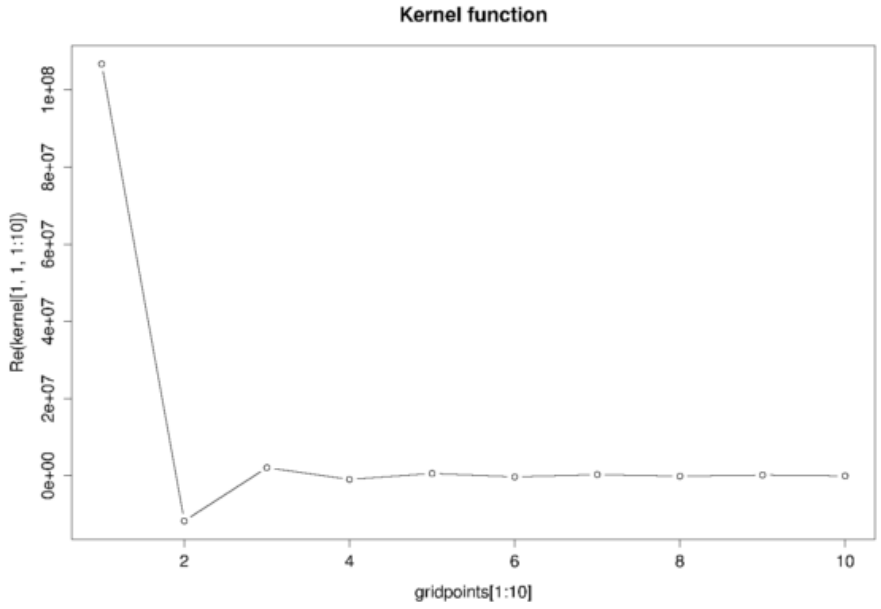

Figure 11: The kernel function

Figure 12 shows the exact and approximated symbols for the stencil that contains 3 grid points in each dimension (the left panel) and the stencil that contains 7 grid points in each dimension (the right panel). (The 5-point scheme worked not much better than the 3-point one and so its performance is not shown.)

From Fig.12, one can see that the 3-point scheme's performance is rather mediocre, whereas the 7-point scheme works very well (in terms of the reproduction of the operator's symbol).

Finally, we verified that the symbol $\tilde{l}_{trunc}(\mathbf{k})$ of the discrete operator for $J = 3, 5, 7$ was everywhere positive, which guarantees that the operator is positive definite and so the discretized SPG model should be stable.

To summarize, the operator $\sqrt{1-\lambda^2\Delta}$ can be approximated with parsimonious physical-space discretization schemes. For simulation of uncertainty in meteorology, where precise

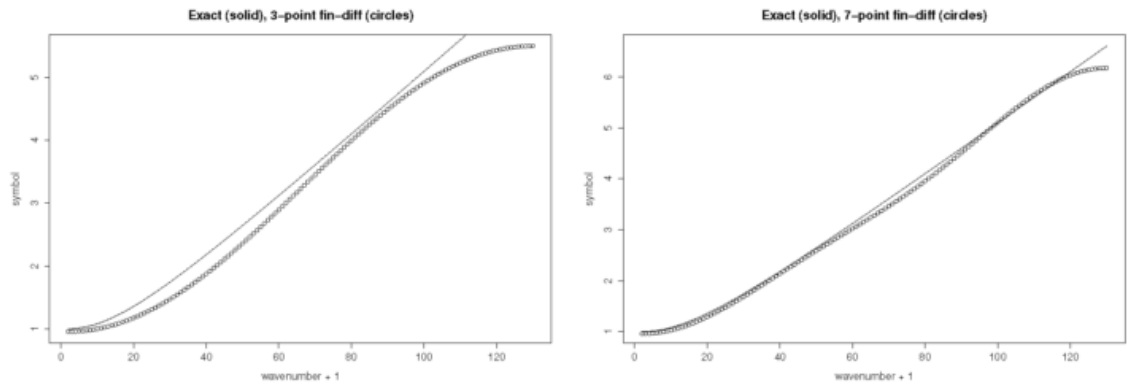

Figure 12: Goodness of fit of the symbol $\tilde{l}(\mathbf{k})$ (solid curve) by $\tilde{l}_{trunc}(\mathbf{k})$ (circles). Left: the 3-point stencil in each dimension. Right: the 7-point stencil

error statistics is not available, the simplest 3-point (in each direction) scheme seems most appropriate and computationally attractive. For more demanding applications, the 7-point scheme can be more appropriate.

D Stationary statistics of a higher-order OSDE

We examine the OSDE Eq.(38) in its generic form:

$$\boxed{\left(\frac{\mathrm{d}}{\mathrm{d}t}+a\right)^p \eta(t)=\sigma\Omega(t),} \tag{91}$$

where σ and a are the positive numbers, p is the positive integer, and $\Omega(t)$ is the standard white noise (see Appendix B).

The goal here is to find the variance and the correlation function of $\eta(t)$ in the stationary regime. The technique is to reduce the p-th order OSDE to a system of first-order OSDEs.

To simplify the exposition, we consider the third-order OSDE ($p=3$) and rewrite Eq.(91) as

$$\left(\frac{\mathrm{d}}{\mathrm{d}t}+a\right)\ \left\{\left(\frac{\mathrm{d}}{\mathrm{d}t}+a\right)\ \left[\left(\frac{\mathrm{d}}{\mathrm{d}t}+a\right)\eta(t)\right]\right\}=\sigma\Omega(t). \tag{92}$$

Here, by η_1 we denote the term in brackets,

$$\left(\frac{\mathrm{d}}{\mathrm{d}t}+a\right)\eta=:\eta_1 \tag{93}$$

and by η_2 the term in braces,

$$\left(\frac{\mathrm{d}}{\mathrm{d}t}+a\right)\eta_1=:\eta_2, \tag{94}$$

so that the original equation Eq.(91) can be rewritten as

$$\left(\frac{\mathrm{d}}{\mathrm{d}t}+a\right)\eta_2=\sigma\Omega. \tag{95}$$

In Eqs.(93)–(95), the last equation is the familiar first-order OSDE forced by the white noise, whereas the other equations are not forced by the white noise. Generalizing the above construction, Eqs.(92)–(95), to the arbitrary $p>0$, we form the following first-order vector-matrix OSDE (a system of first-order OSDEs):

$$\mathrm{d}\boldsymbol{\eta}+\mathbf{A}\boldsymbol{\eta}\mathrm{d}t=\boldsymbol{\Sigma}\boldsymbol{\Omega}\mathrm{d}t, \tag{96}$$

where $\boldsymbol{\eta}:=(\eta,\eta_1,\ldots,\eta_{p-2},\eta_{p-1})$, $\boldsymbol{\Omega}:=(0,0,\ldots,0,\Omega)$, and the design of the matrices $\mathbf{A}$ and $\boldsymbol{\Sigma}$ is obvious (not shown).

With Eq.(96) in hand, we derive a differential equation for the covariance matrix $\mathbf{P}:=\mathsf{E}\,\boldsymbol{\eta}\boldsymbol{\eta}^*$, where * denotes transpose complex conjugate [see e.g. 11, example 4.16]. First, we compute the increment of $\mathbf{P}$:

$$\Delta\mathbf{P}=\mathsf{E}\,(\boldsymbol{\eta}+\mathrm{d}\boldsymbol{\eta})(\boldsymbol{\eta}+\mathrm{d}\boldsymbol{\eta})^*-\mathsf{E}\,\boldsymbol{\eta}\boldsymbol{\eta}^*=\mathsf{E}\,\boldsymbol{\eta}\mathrm{d}\boldsymbol{\eta}^*+\mathsf{E}\,\mathrm{d}\boldsymbol{\eta}\boldsymbol{\eta}^*+\mathsf{E}\,\mathrm{d}\boldsymbol{\eta}\mathrm{d}\boldsymbol{\eta}^*. \tag{97}$$

Then, using Eq.(96) and the fact that $\mathsf{E}\,|\Omega\mathrm{d}t|^2=\mathsf{E}\,|\mathrm{d}W|^2=\mathrm{d}t$, we obtain the differential of $\mathbf{P}$ from Eq.(97):

$$\mathrm{d}\mathbf{P}=-\mathbf{A}\mathbf{P}\mathrm{d}t-\mathbf{P}\mathbf{A}^*\mathrm{d}t+\boldsymbol{\Sigma}\boldsymbol{\Sigma}^*\mathrm{d}t. \tag{98}$$

In the stationary regime $\mathrm{d}\mathbf{P}=0$, so the equation for the stationary covariance matrix is

$$\boxed{\mathbf{A}\mathbf{P}+\mathbf{P}\mathbf{A}^*=\boldsymbol{\Sigma}\boldsymbol{\Sigma}^*.} \tag{99}$$

Next, we look at the *first* diagonal entry of the resulting stationary covariance matrix $\mathbf{P}$, which represents the required $\mathsf{Var}\,\eta$ (because η is defined above to be the first entry of the

vector $\boldsymbol{\eta}$). Dropping tedious derivations, we present in Table 2 (second row) the formulas for the temporal orders $p = 1$, $p = 2$, $p = 3$, and for the general p.

Finally, we derive the temporal correlation function for the pth-order OSDE. To this end, we multiply Eq.(91) by $\eta(s)$ with $s < t$ and take expectation. Since a is non-stochastic, we may interchange the expectation and the differential operator $\left(\frac{\mathrm{d}}{\mathrm{d}t} + a\right)^p$, getting the pth-order ordinary differential equation for the temporal covariance function, whose solutions for different p are presented in row 3 of Table 2.

Table 2: **The variances $\mathsf{Var}\,\eta$ and correlation functions $C_\eta(t)$ of the stationary solution to Eq.(91) for different temporal orders p**

p	1	2	3	Arbitrary p
$\mathsf{Var}\,\eta$	$\frac{\sigma^2}{2a}$	$\frac{\sigma^2}{4a^3}$	$\frac{3\sigma^2}{16a^5}$	$\propto \frac{\sigma^2}{a^{2p-1}}$
$C_\eta(t)$	$\mathrm{e}^{-\mathrm{a\|t\|}}$	$(1 + a\|t\|)\,\mathrm{e}^{-\mathrm{a\|t\|}}$	$(1 + a\|t\| + \frac{a^2t^2}{3})\,\mathrm{e}^{-\mathrm{a\|t\|}}$	$\propto R_{p-1}(a\|t\|) \cdot \mathrm{e}^{-\mathrm{a\|t\|}}$

Here $R_{p-1}(x)$ is a polynomial of order $p - 1$.

E Smoothness of sample paths of the spatial Matérn random field for different ν

Here, we show how sample paths (realizations) of the Matérn random field with the smoothness parameter ν look. Specifically, in Fig.13, we present three plots with 1D cross-sections of randomly chosen realizations of the Matérn random field for the following three values of ν: 1/2, 3/2, and 5/2. The spatial length scale parameter λ is selected in each of the three cases in such a way that the spatial correlation function intersects the 0.7 level at approximately the same distance (we denote this distance by $L_{0.7}$): $L_{0.7} = 500$ km. Again, as in section 6.5 and Appendix A, we assume, for convenience, that the extent of the spatial domain in each coordinate direction is 3000 km (rather than 2π). For comparison, we also display a realization with $L_{0.7} = 1500$ km for $\nu = 1/2$ (the bottom panel of Fig.13).

One can see that, indeed, the larger ν, the smoother the realizations—in the sense that they have less small-scale "noise". By contrast, increasing the length scale λ (compare the top and bottom panels of Fig.13) makes the *large-scale* pattern smoother but does *not* remove the smallest scales. So, the *large-scale* behavior is determined by the length scale λ, whereas the degree of *small-scale* smoothness/roughness depends predominantly on the smoothness parameter ν.

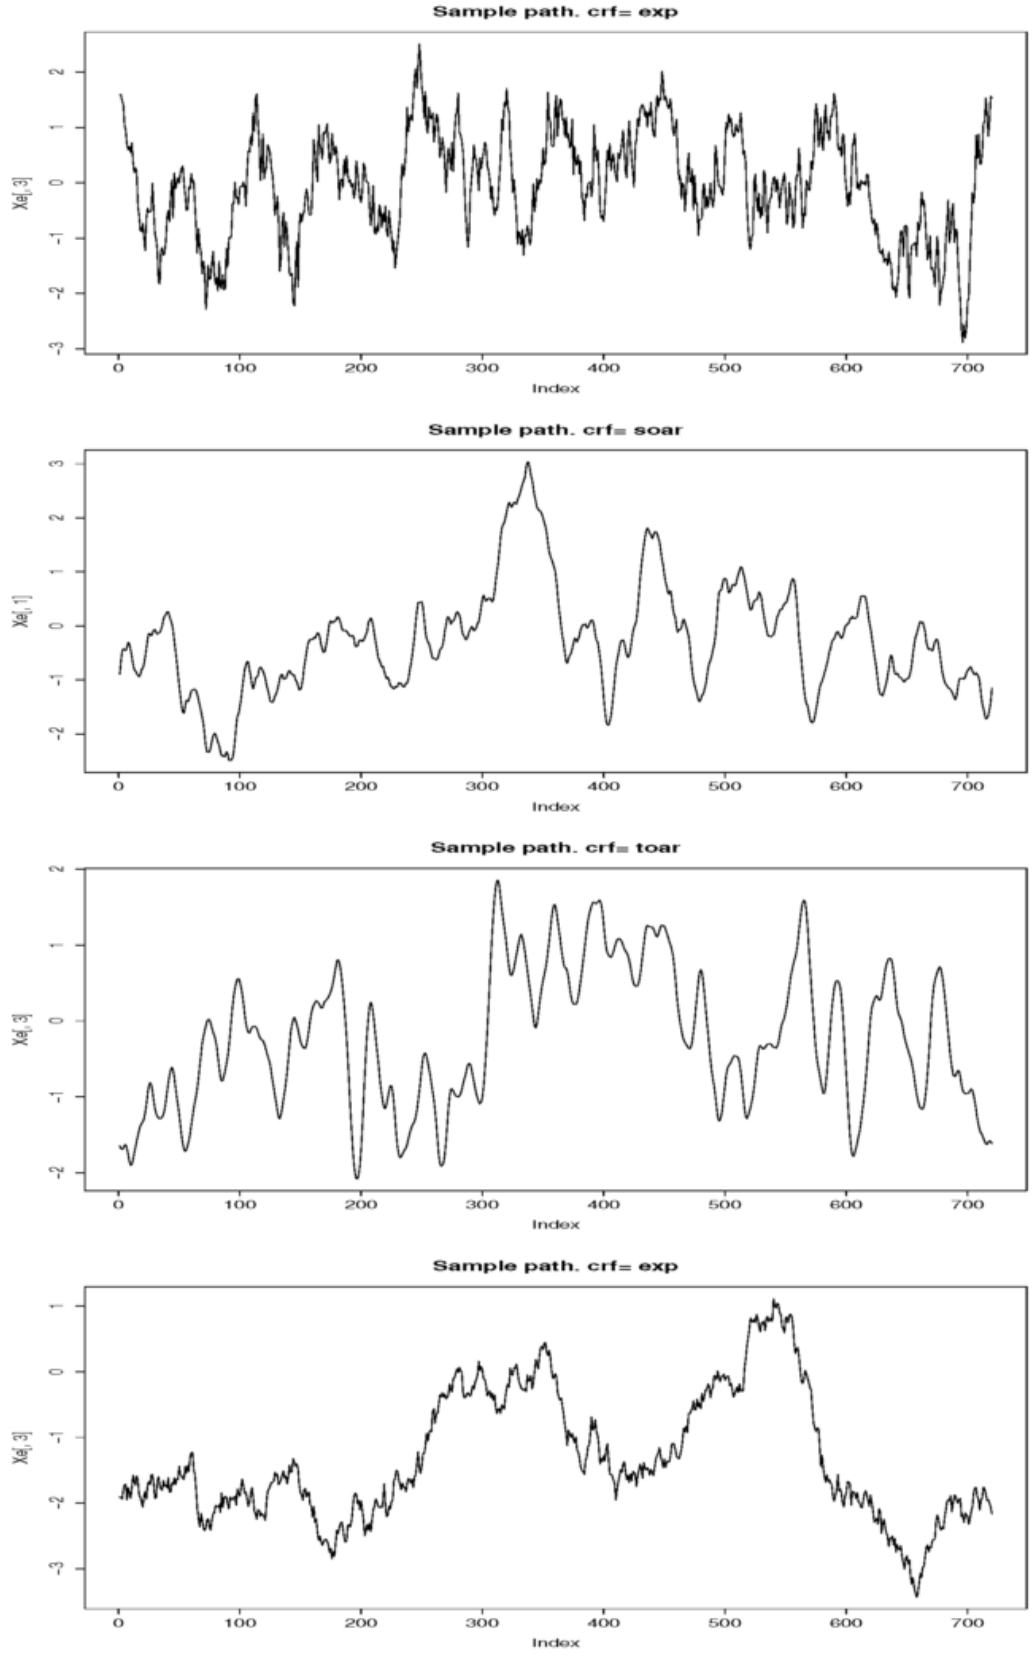

Figure 13: Sample paths for various ν and $L_{0.7}$. From the *top* to the *bottom*: $[\nu = \frac{1}{2}, L_{0.7} = 500]$, $[\nu = \frac{3}{2}, L_{0.7} = 500]$, $[\nu = \frac{5}{2}, L_{0.7} = 500]$, $[\nu = \frac{1}{2}, L_{0.7} = 1500]$

F Stationary statistics of a time discrete higher-order OSDE

Here, to simplify the exposition, we first examine the simplest first-order (i.e. with $p = 1$) OSDE and then give the results for the third-order OSDE used in the current version of the SPG.

F.1 First-order numerical scheme

Discretization of the Langevin Eq.(15) by an implicit scheme yields

$$\eta_i - \eta_{i-1} + a\eta_i \Delta t = \sigma \Delta W_i, \tag{100}$$

so that

$$\eta_i = \frac{\eta_{i-1} + \sigma \Delta W_i}{1 + a\Delta t}. \tag{101}$$

In the stationary regime, $\mathsf{Var}\,\eta_i = \mathsf{Var}\,\eta_{i-1}$, whence, bearing in mind that $\mathsf{Var}\,\Delta W_i = \Delta t$ and ΔW_i is independent on the values of η for all time moments up to and including the moment $i-1$, we apply the variance operator to both sides of Eq.(101) and obtain the stationary variance

$$V(\Delta t) := \lim_{i\to\infty} \mathsf{Var}\,\eta_i = \frac{\sigma^2}{2a + (g\Delta t)^2}. \tag{102}$$

Note that, as $\Delta t \to 0$, $V(\Delta t)$ tends to the continuous-time variance $\frac{\sigma^2}{2a}$, see Eq.(16).

F.2 Third-order numerical scheme

Consider the continuous-time OSDE, Eq.(91), with $p = 3$. The implicit scheme Eq.(62) we use to numerically solve it is reproduced here as

$$\eta_i = \frac{1}{\varkappa^3}\left[3\varkappa^2\eta_{i-1} - 3\varkappa\eta_{i-2} + \eta_{i-3} + \sigma(\Delta t)^2\,\Delta W_i\right], \tag{103}$$

where $\varkappa := 1 + a\Delta t$. Here, the goal is to find the stationary variance $V := \lim_{i\to\infty} \mathsf{Var}\,\eta_i$ along with lag-1 and lag-2 stationary covariances, $c_1 := \lim_{i\to\infty} \mathsf{E}\,\eta_i\eta_{i-1}$ and $c_2 := \lim_{i\to\infty} \mathsf{E}\,\eta_i\eta_{i-2}$, respectively. To reach this goal, we build three linear algebraic equations for the three unknowns, V, c_1, and c_2. The first equation is obtained by applying the variance operator to both sides of Eq.(103). The second and third equations are obtained by multiplying Eq.(103) by η_{i-1} and η_{i-2}, respectively, and applying the expectation operator to both sides of the resulting equations. Omitting the derivations, we write down the results:

$$V = \frac{\varkappa^4 + 4\varkappa^2 + 1}{(\varkappa^2 - 1)^5}\,(\Delta t)^5\sigma^2. \tag{104}$$

$$c_1 = \frac{3\varkappa(\varkappa^2 + 1)}{(\varkappa^2 - 1)^5}\,(\Delta t)^5\sigma^2, \qquad c_2 = \frac{6\varkappa^2}{(\varkappa^2 - 1)^5}\,(\Delta t)^5\sigma^2. \tag{105}$$

As in the first-order case, one can see that as $\Delta t \to 0$, V tends to the continuous-time variance $\frac{3}{16}\frac{\sigma^2}{a^5}$, see Table 2 in Appendix D.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

A Turbulence Kinetic Energy – Scalar Variance Turbulence Parameterization Scheme

Dmitrii V. Mironov[†] *and Ekaterina E. Machulskaya*

German Weather Service, Offenbach am Main, Germany

Abstract

A turbulence kinetic energy – scalar variance (TKESV) closure model (parameterization scheme) for moist atmosphere is developed. The scheme is formulated in terms of variables that are approximately conserved for phase changes in the absence of precipitation. These are the total water specific humidity and the liquid water potential temperature (or, if cloud ice is present, the ice-liquid water potential temperature). The scheme carries prognostic equations for the turbulence kinetic energy and for the variances and covariance of scalar quantities. The other second-moment equations, namely, the equations for the Reynolds stress and for the scalar fluxes, are reduced to the diagnostic algebraic expressions. In the present report, the set of governing equations of the TKESV scheme and parameterizations (closure assumptions) for the pressure-scrambling terms, the third-order transport (diffusion) terms, and the molecular destruction (dissipation) terms are discussed. Particular attention is paid to the pressure-scrambling terms in the Reynolds-stress and scalar-flux equations. The other issues that receive careful consideration are the effect of clouds on mixing (treated with the aid of statistical cloud schemes) and the interaction of the boundary layer with the underlying surface. Estimates of disposable parameters of the TKESV scheme are given.

1 Introduction

A turbulence parameterization scheme is an integral part of a physical parameterization package of any model of atmospheric circulation, including numerical weather prediction (NWP) and climate models. The importance of turbulence parameterization schemes will likely further increase as the resolution of the atmospheric models is refined. As the mesh size becomes small, quasi-organized flow structures, such as deep convective plumes that are chiefly responsible for non-local convective transport of momentum and scalars, are increasingly resolved. The focus of parameterizations of the sub-grid scale processes is then shifted towards motions at smaller scales and towards other issues, as e.g. the anisotropy of turbulence near the surface and in stably-stratified regions of the flow, and the interaction between boundary-layer turbulence and shallow clouds. Turbulence closure schemes based on truncated second-order moment equations are viable tools for describing these features.

There are many quite sophisticated and physically sound turbulence models (parameterization schemes) which proved to be very useful research tools. There is little chance, however, to use them in operational NWP and related applications for those schemes are computationally prohibitively expensive and are often specific to a particular mixing regime. A turbulence parameterization scheme should no doubt account for the essential physics of atmospheric turbulence. On the other hand, a usable scheme should be computationally efficient and should give a reasonably accurate solution for all mixing regimes (stably-stratified boundary layer, dry convective boundary layer, convective boundary layers capped by cumulus or stratus clouds, etc.) around the clock and at any point on the globe. Therefore, the key issue in developing turbulence parameterization schemes for NWP and related applications is to find the best compromise between physical realism and computational economy.

The so-called one-equation turbulence parameterizations schemes have been very popular in geophysical applications over several decades. Those schemes carry the turbulence kinetic energy (TKE) equation, including the time-rate-of-change (or substantial derivative if the TKE advection is included) and the third-order turbulent transport (diffusion) terms. All other second-moment equations, viz., the equations for the Reynolds stress, for the fluxes of scalar quantities (e.g. temperature and humidity), and for the scalar variances and scalar covariance, are reduced to diagnostic algebraic expressions. In spite of their numerous shortcomings (see a discussion in Mironov, 2009), one-equation TKE schemes (and even simpler algebraic schemes) have been and still are the draft horses of atmospheric turbulence modelling in NWP, climate studies, and related applications.

The present report describes a TKE – Scalar Variance (TKESV) turbulence parameterization scheme that is a natural step beyond one-equation TKE schemes. Apart from the TKE equation, the TKESV scheme carries prognostic transport equations for the scalar variances and covariance (see section 2 for the definition of quasi-conservative scalars utilized by the TKESV scheme). It is the authors' opinion that the level of complexity of the TKESV scheme is likely the minimum level of complexity that is required for NWP, climate modelling and related applications in terms of essential physics. A justification of this opinion is almost trivial. The key issue in modelling of any turbulent flow is an adequate description of the flow energy. In neutrally stratified flows, the kinetic energy of turbulence is a major concern. This explains why the one-equation schemes have been successfully used in modelling neutral flows. The situation is very different in flows where the buoyancy stratification is not neutral. In such flows, the turbulence potential energy (TPE) plays an important part along with the TKE. The TKE is spent to work against the gravity and is converted into the TPE in stably stratified flows. In convective flows, the TKE grows at the expense of the TPE. Since the atmospheric flows are virtually never hydrostatically neutral, and the TKE and the

TPE in stratified flows are equally important, it is difficult to adduce plausible arguments in favour of one form of energy over the other. Both energies possess equal rights and should be treated in a similar way. In the atmosphere, the TPE is characterized by the variances and covariance of the scalar quantities (see Appendix C). Hence, the scalar (co)variances should be treated as accurately as the TKE. An improved treatment of scalar (co)variances helps to improve the performance of atmospheric models in several respects. These are, for example, a consistent treatment of counter-gradient fluxes of scalars (which is not possible with the one-equation TKE schemes) and an improved representation of the fractional cloudiness. Furthermore, the TKESV scheme provides a framework for a consistent unified treatment of boundary-layer turbulence and shallow convection.

Examples of turbulence parameterization schemes that carry transport equations for both the TKE and the scalar variances are given in Kenjereš and Hanjalić (2002) (for the temperature-stratified atmosphere) and Nakanishi and Niino (2004) (for the moist atmosphere). Worthy of mention is a more complex scheme termed CLUBB (Cloud Layers Unified By Binormals), an assumed-PDF (probability distribution function) unified parameterization of turbulence and cloud processes in the Earth's atmosphere (numerous references and further information about CLUBB can be found at https://people.uwm.edu/vlarson/clubb/).

Interestingly enough, it was stated already by Mellor and Yamada in their popular 1974 paper (Mellor and Yamada, 1974) that the scheme (level 3 in their nomenclature) that carries transport equations for the TKE and for the potential-temperature variance is particularly attractive. The level 3 scheme outperforms an algebraic closure scheme, and little is gained if a more complex scheme that carries transport equations for all second-order moments involved is used. Thus the level 3 scheme represents an optimal choice. Mention should also be made of the analysis of the second-moment budgets in the cloud-topped boundary layers performed by Heinze et al. (2015) using large-eddy simulation (LES) data. It was found (among other things) that the third-order transport is of secondary importance in the Reynolds-stress and scalar-flux budgets but it plays a key role in maintaining the TKE and the scalar (co)variance budgets. These results support the design of the TKESV scheme.

In the present report, governing equations and closure assumptions (parameterizations) of the TKE–Scalar Variance scheme are formulated, and estimates of disposable parameters are given. In the remainder of this section, an outline of the report is given.

The TKESV scheme is formulated in terms of variables that are approximately conserved for phase changes in the absence of precipitation. These are the total water specific humidity and the liquid water potential temperature. If cloud ice is present, the ice-liquid water potential temperature is used. Quasi-conservative thermodynamic variables are introduced in section 2. Transport equations for the second-order moments of fluctuating velocity and scalar fields are given in section 3. The TKESV scheme carries "full" prognostic equations, i.e. the equations including the substantial derivative (that reduces to the time-rate-of-change in one-dimensional case, where the flow variables depend on the vertical coordinate only) and the third-order turbulent transport terms, for the TKE and for the variances and covariance of the scalar quantities. The equations for the Reynolds stress and for the scalar fluxes are reduced (truncated) to the diagnostic algebraic expressions by neglecting the substantial derivative and the third-order transport terms. The truncated Reynolds-stress and scalar-flux equations are presented in section 4.

The system of governing second-moment equations is not closed. There are four groups of terms that require parameterizations (closure assumptions). These are the pressure-scrambling terms in the Reynolds-stress and the scalar-flux equations, the third-order turbulent transport terms in the equations for the TKE and for the scalar variances and covariance, the dissipation rates of the TKE and of the scalar variances and covariance, and the buoy-

ancy terms (incorporating correlations of the velocity and scalars with the virtual potential temperature) in the Reynolds-stress, scalar-flux and TKE equations. Parameterizations of these terms are presented in sections 5 and 7. Particular attention is paid to the pressure-scrambling terms. Although parameterization of the pressure-scrambling effects is probably the most crucial issue in modelling atmospheric turbulence, this issue receives unduly little attention in the atmospheric modelling community. Formulations of the turbulence time and length scales are presented in section 6. An algebraic interpolation formula for the turbulence length scale that accounts for the limiting effect of stable density stratification is presented. A more advanced non-local length-scale formulation is also discussed. In section 7, we consider the effect of clouds on mixing intensity. The second-moment equations are coupled to a statistical cloud scheme, and parameterizations of the buoyancy terms in the Reynolds-stress, scalar-flux and TKE equations are developed with due regard for the presence of cloud condensate.

In section 8, the so-called boundary-layer approximation is invoked to obtain a one-dimensional version of the TKESV scheme. Note that in the majority of NWP models, including ICON and COSMO, one-dimensional schemes are used to parameterize turbulent mixing (unless these models are used in the LES mode). The so-called stability functions that appear in the algebraic formulations for the Reynolds stress and scalar fluxes (see e.g. Mellor and Yamada, 1974) are discussed in section 9 in much detail. The stability functions, resulting from the truncated Reynolds-stress and scalar-flux equations (where the third-order and the time-rate-of-change terms are neglected) with the linear parameterizations of the pressure-scrambling terms (linear in the second-order moments involved), are ill-behaved over a certain range of governing parameters (e.g. mean velocity shear and mean temperature gradient). Using rather plausible physical arguments, we develop regularized stability functions that are well-behaved in the entire range of governing parameters. The interaction of the boundary-layer flow with the underlying surface is discussed in section 10, where the focus is on the lower boundary conditions for the scalar variances and covariance.

The emphasis in sections 5 through 10 is on the baseline version of the TKESV scheme (TKESV-Bas). This somewhat simplified version of the scheme is based on the linear parameterizations of the pressure-scrambling terms, the simplest isotropic down-gradient parameterizations of the third-order transport terms, and the algebraic interpolation formula for the turbulence length scale. It utilizes an ad hoc correction to the Gaussian statistical cloud scheme to account for shallow cumuli (enhanced mixing due to clouds in spite of low fractional cloud cover). The lower boundary conditions for the scalar variances and covariance do not account for the heterogeneity of the underlying surface. It is the baseline version of the TKESV scheme in the boundary-layer approximation (i.e. the one-dimensional TKESV-Bas) that is intended for use within NWP models ICON and COSMO in the near future.

In the medium-term prospective, an extended version of the scheme (TKESV-Ext) can be used. TKESV-Ext incorporates advanced formulations of the pressure-scrambling terms and of the third-order transport terms, non-local formulation of the turbulence length scale, lower boundary conditions for the scalar (co)variances that are consistent with the tile approach to compute the surface fluxes over heterogeneous surfaces, and a statistical cloud scheme capable of describing cumulus regimes. These formulations are discussed in the respective sections under the heading ***Advanced Features***. The use of an advanced statistical cloud scheme, e.g. the scheme proposed by Naumann et al. (2013), requires knowledge of the triple correlations (skewness) of scalar quantities (more specifically, of linearized saturation deficit/excess). The scalar-skewness prognostic equation is developed in section 11.

Conclusions are given in section 12. The present report contains several Appendices. The aim

of the report is not only to present the governing equations and parameterization assumptions of the TKESV scheme, but also to elucidate their physical meaning and, importantly, their limitations. To this end, detailed derivations of at least some parameterizations should be presented (most notably, of the pressure-scrambling terms). Since the derivations are rather lengthy, they are given in Appendices. This allows to keep the main body of the text more concise.

2 Quasi-Conservative Variables

In order to account for the presence of cloud condensate, turbulence and shallow-convection models are formulated in terms of variables that are approximately conserved for phase changes in the absence of precipitation (Betts, 1973; Deardorff, 1976; Betts, 1986). One pair of moist quasi-conservative variables consists of the total water specific humidity q_t and the liquid water potential temperature θ_l defined as

$$q_t = q + q_l, \tag{1}$$

$$\theta_l = \theta - \frac{\theta}{T}\frac{L_v}{c_p} q_l. \tag{2}$$

Here, q is the water vapour specific humidity (the mass of water vapour per unit mass of moist air), q_l is the liquid water specific humidity (the mass of cloud water per unit mass of moist air), c_p is the specific heat of air at constant pressure, L_v is the heat of vapourization, θ is the potential temperature related to the absolute temperature T through $\theta = T(P_0/P)^{R_d/c_p}$, P and P_0 being the atmospheric pressure and its reference value, respectively, and R_d being the gas constant for dry air. No supersaturation is assumed, so that $q_l = q_t - q_s$ if $q_t > q_s$, where q_s is the saturation specific humidity, and $q_l = 0$ otherwise. Clearly, q_t and θ_l reduce to the dry variables q and θ, respectively, in unsaturated conditions. For the sake of simplicity the total water specific humidity and the liquid water potential temperature will also be referred to as simply humidity and temperature, respectively.

Advanced Features

The $q_t - \theta_l$ system outlined above can be extended to the case of three phases including cloud ice (Deardorff, 1976). To this end, the total water specific humidity is generalized to account for the presence of ice, and the ice-liquid water (i.e. total water) potential temperature is introduced:

$$q_t = q + q_l + q_i, \tag{3}$$

$$\theta_t = \theta - \frac{\theta}{T}\frac{L_v}{c_p} q_l - \frac{\theta}{T}\frac{L_i}{c_p} q_i, \tag{4}$$

where q_i is the solid water specific humidity (the mass of cloud ice per unit mass of moist air), and L_i is the heat of sublimation.

3 Transport Equations for Second-Order Moments

The basis for the development of second-order closure schemes is the set of transport equations for the second-order moments of fluctuating fields (e.g. Monin and Yaglom, 1971;

Mironov, 2009). For the moist atmosphere characterized by quasi-conservative variables θ_l and q_t, these are the equations for the Reynolds stress $\langle u_i' u_j' \rangle$, u_i being the velocity components[1], for the scalar fluxes $\langle u_i' \theta_l' \rangle$ and $\langle u_i' q_t' \rangle$, for the scalar variances $\langle \theta_l'^2 \rangle$ and $\langle q_t'^2 \rangle$, and for the scalar covariance $\langle \theta_l' q_t' \rangle$. The angle brackets denote mean quantities, and a prime denotes a turbulent fluctuation. Using the Boussinesq approximation and assuming that the Reynolds number is sufficiently high to neglect the molecular diffusion terms in the second-moment budget equations (a good approximation for the atmospheric flows), the equations read

$$\left(\frac{\partial}{\partial t} + \langle u_k \rangle \frac{\partial}{\partial x_k}\right) \langle u_i' u_j' \rangle =$$
$$- \left(\langle u_i' u_k' \rangle \frac{\partial \langle u_j \rangle}{\partial x_k} + \langle u_j' u_k' \rangle \frac{\partial \langle u_i \rangle}{\partial x_k} \right) - \left(\beta_i \langle u_j' \theta_v' \rangle + \beta_j \langle u_i' \theta_v' \rangle \right)$$
$$-2 \left(\epsilon_{imk} \Omega_m \langle u_k' u_j' \rangle + \epsilon_{jmk} \Omega_m \langle u_k' u_i' \rangle \right) + \left\langle p' \left(\frac{\partial u_i'}{\partial x_j} + \frac{\partial u_j'}{\partial x_i} \right) \right\rangle$$
$$- \frac{\partial}{\partial x_k} \left(\langle u_k' u_i' u_j' \rangle + \delta_{kj} \langle p' u_i' \rangle + \delta_{ki} \langle p' u_j' \rangle \right) - \epsilon_{ij}, \tag{5}$$

$$\left(\frac{\partial}{\partial t} + \langle u_k \rangle \frac{\partial}{\partial x_k}\right) \langle u_i' \theta_l' \rangle = - \langle u_k' \theta_l' \rangle \frac{\partial \langle u_i \rangle}{\partial x_k} - \langle u_i' u_k' \rangle \frac{\partial \langle \theta_l \rangle}{\partial x_k} - \beta_i \langle \theta_l' \theta_v' \rangle$$
$$-2 \epsilon_{imk} \Omega_m \langle u_k' \theta_l' \rangle - \left\langle \theta_l' \frac{\partial p'}{\partial x_i} \right\rangle - \frac{\partial}{\partial x_k} \langle u_k' u_i' \theta_l' \rangle - \epsilon_{\theta i}, \tag{6}$$

$$\left(\frac{\partial}{\partial t} + \langle u_k \rangle \frac{\partial}{\partial x_k}\right) \langle u_i' q_t' \rangle = - \langle u_k' q_t' \rangle \frac{\partial \langle u_i \rangle}{\partial x_k} - \langle u_i' u_k' \rangle \frac{\partial \langle q_t \rangle}{\partial x_k} - \beta_i \langle q_t' \theta_v' \rangle$$
$$-2 \epsilon_{imk} \Omega_m \langle u_k' q_t' \rangle - \left\langle q_t' \frac{\partial p'}{\partial x_i} \right\rangle - \frac{\partial}{\partial x_k} \langle u_k' u_i' q_t' \rangle - \epsilon_{qi}, \tag{7}$$

$$\frac{1}{2} \left(\frac{\partial}{\partial t} + \langle u_k \rangle \frac{\partial}{\partial x_k}\right) \langle \theta_l'^2 \rangle = - \langle u_k' \theta_l' \rangle \frac{\partial \langle \theta_l \rangle}{\partial x_k} - \frac{1}{2} \frac{\partial}{\partial x_k} \langle u_k' \theta_l'^2 \rangle - \epsilon_{\theta\theta}, \tag{8}$$

$$\frac{1}{2} \left(\frac{\partial}{\partial t} + \langle u_k \rangle \frac{\partial}{\partial x_k}\right) \langle q_t'^2 \rangle = - \langle u_k' q_t' \rangle \frac{\partial \langle q_t \rangle}{\partial x_k} - \frac{1}{2} \frac{\partial}{\partial x_k} \langle u_k' q_t'^2 \rangle - \epsilon_{qq}, \tag{9}$$

$$\left(\frac{\partial}{\partial t} + \langle u_k \rangle \frac{\partial}{\partial x_k}\right) \langle \theta_l' q_t' \rangle = - \langle u_k' q_t' \rangle \frac{\partial \langle \theta_l \rangle}{\partial x_k} - \langle u_k' \theta_l' \rangle \frac{\partial \langle q_t \rangle}{\partial x_k} - \frac{\partial}{\partial x_k} \langle u_k' \theta_l' q_t' \rangle - 2 \epsilon_{\theta q}. \tag{10}$$

Here, t is the time, x_i are the space coordinates, $\beta_i = g_i \alpha_T$ is the buoyancy parameter, g_i is the acceleration due to gravity, $\alpha_T = -\rho^{-1} \partial \rho / \partial T$ is the thermal expansion coefficient, ρ is the density, Ω_i is the angular velocity of the reference frame rotation, and p is the kinematic pressure (deviation of pressure from the hydrostatically balanced pressure divided by the reference density ρ_r). The Einstein summation convention for repeated indices is adopted. The last terms on the right-hand sides (r.h.s.) of Eqs. (5)–(10) are the molecular destruction (dissipation) rates of the Reynolds stress, of the scalar fluxes, and of the scalar variances and covariance. The quantity θ_v is the virtual potential temperature that is defined with due regard for the water loading effect (Lilly, 1968; Bannon, 2007),

$$\theta_v = \theta \left[1 + \left(\frac{R_v}{R_d} - 1 \right) q - q_l \right], \tag{11}$$

[1]The term "Reynolds stress" is used here in a somewhat loose way. Strictly speaking, the Reynolds stress tensor is $-\rho \langle u_i' u_j' \rangle$, where ρ is the fluid density. See e.g. Pope (2000).

where R_v is the gas constant for water vapour.

Setting $j = i$ in Eq. (5) yields the budget equation for the TKE, $e \equiv \frac{1}{2}\langle u_i'^2 \rangle$,

$$\frac{1}{2}\left(\frac{\partial}{\partial t} + \langle u_k \rangle \frac{\partial}{\partial x_k}\right)\langle u_i'^2 \rangle = -\langle u_i' u_k' \rangle \frac{\partial \langle u_i \rangle}{\partial x_k} - \beta_i \langle u_i' \theta_v' \rangle - \frac{\partial}{\partial x_k}\left(\frac{1}{2}\langle u_k' u_i'^2 \rangle + \langle u_k' p' \rangle\right) - \epsilon, \tag{12}$$

where the last term on the r.h.s. is the TKE dissipation rate, $\epsilon \equiv \frac{1}{2}\epsilon_{ii}$.

The pressure gradient-velocity covariance $\langle u_i' \partial p'/\partial x_j \rangle + \langle u_j' \partial p'/\partial x_i \rangle$ describes the combined effect of pressure transport and pressure scrambling in the Reynolds-stress equation. These are different physical processes that should be modelled in a different way. To this end, the pressure gradient-velocity covariance is decomposed to separate out the traceless part which does not alter the TKE but acts to redistribute the energy between the components, thus driving turbulence towards the isotropic state (hence the term "pressure scrambling"). The rest of the pressure gradient-velocity covariance describes the transport of the Reynolds stress in space by the fluctuating velocity and pressure fields. It should be mentioned that the decomposition of the pressure gradient-velocity covariance is not unique. Along with a somewhat more traditional decomposition into pressure-strain and pressure transport that is used in Eq. (5),

$$\left\langle u_i' \frac{\partial p'}{\partial x_j} \right\rangle + \left\langle u_j' \frac{\partial p'}{\partial x_i} \right\rangle = -\left\langle p' \left(\frac{\partial u_i'}{\partial x_j} + \frac{\partial u_j'}{\partial x_i}\right) \right\rangle + \left(\frac{\partial}{\partial x_j}\langle p' u_i' \rangle + \frac{\partial}{\partial x_i}\langle p' u_j' \rangle\right), \tag{13}$$

a decomposition into deviatoric and isotropic parts,

$$\left\langle u_i' \frac{\partial p'}{\partial x_j} \right\rangle + \left\langle u_j' \frac{\partial p'}{\partial x_i} \right\rangle = \left(\left\langle u_i' \frac{\partial p'}{\partial x_j} \right\rangle + \left\langle u_j' \frac{\partial p'}{\partial x_i} \right\rangle - \frac{2}{3}\delta_{ij}\frac{\partial}{\partial x_k}\langle u_k' p' \rangle\right) + \frac{2}{3}\delta_{ij}\frac{\partial}{\partial x_k}\langle u_k' p' \rangle, \tag{14}$$

has also been advocated (e.g. Speziale, 1985). The difference,

$$\frac{\partial}{\partial x_j}\langle p' u_i' \rangle + \frac{\partial}{\partial x_i}\langle p' u_j' \rangle - \frac{2}{3}\delta_{ij}\frac{\partial}{\partial x_k}\langle u_k' p' \rangle, \tag{15}$$

is both a transport term and a traceless term. Any fraction of this difference may be added to the pressure-strain and subtracted from the pressure transport, thus producing a new decomposition (Lumley, 1975).

The non-uniqueness of decomposition of the pressure gradient-velocity covariance does not matter much if a truncated equation for the Reynolds stress is used, where the third-order transport and pressure transport terms are neglected. No matter which approach is taken, the pressure-strain and the deviatoric part of the pressure gradient-velocity covariance are both traceless tensors that are modelled in the same way. Therefore, there is no general difference between the decompositions (13) and (14), or any other decomposition separating the traceless and the transport parts, as regards the pressure redistribution (the inter-component energy transfer)[2]. The two decompositions are essentially different as regards the pressure transport (Speziale, 1985). The pressure transport of the Reynolds stress is, however, neglected within the framework of the scheme considered here.

[2]Notice, however, that the way the traceless part of the pressure term is separated out does matter when data, e.g. large-eddy simulation or direct numerical simulation data, are used to evaluate disposable parameters in models (parameterizations) of the pressure redistribution terms.

Advanced Features

If cloud ice is considered, the virtual potential temperature is defined as

$$\theta_v = \theta \left[1 + \left(\frac{R_v}{R_d} - 1 \right) q - q_l - q_i \right]. \tag{16}$$

4 Truncated Reynolds-Stress and Scalar-Flux Equations

Within the framework of the TKESV scheme, the equations for the Reynolds stress and for the scalar fluxes are reduced (truncated) to the diagnostic algebraic expressions by neglecting the substantial derivatives, the third-order transport of $\langle u_i' u_j' \rangle$, $\langle u_i' \theta_l' \rangle$ and $\langle u_i' q_t' \rangle$, and the pressure transport of $\langle u_i' u_j' \rangle$. The resulting algebraic equations are conveniently recast in terms of the departure-from-isotropy tensor defined as

$$a_{ij} = \langle u_i' u_j' \rangle - \frac{2}{3} \delta_{ij} e. \tag{17}$$

Subtracting Eq. (12) times $\frac{2}{3}\delta_{ij}$ from Eq. (5) and neglecting the time-rate-of-change, advection by the mean flow, the third-order transport and the pressure transport, we obtain

$$\begin{aligned} &- \left[\frac{4}{3} e S_{ij} + \left(a_{ik} S_{jk} + a_{jk} S_{ik} - \frac{2}{3} \delta_{ij} a_{km} S_{km} \right) + \left(a_{ik} W_{jk} + a_{jk} W_{ik} \right) \right] \\ &- \left(\beta_i \langle u_j' \theta_v' \rangle + \beta_j \langle u_i' \theta_v' \rangle - \frac{2}{3} \delta_{ij} \beta_k \langle u_k' \theta_v' \rangle \right) - 2 \left(\epsilon_{imk} \Omega_m a_{kj} + \epsilon_{jmk} \Omega_m a_{ki} \right) \\ &- \Pi_{ij} - \epsilon_{ij}^d = 0, \end{aligned} \tag{18}$$

where $S_{ij} = \frac{1}{2} \left(\frac{\partial \langle u_i \rangle}{\partial x_j} + \frac{\partial \langle u_j \rangle}{\partial x_i} \right)$ and $W_{ij} = \frac{1}{2} \left(\frac{\partial \langle u_i \rangle}{\partial x_j} - \frac{\partial \langle u_j \rangle}{\partial x_i} \right)$ are the symmetric and the antisymmetric parts, respectively, of the mean-velocity gradient tensor, $\epsilon_{ij}^d = \epsilon_{ij} - \frac{2}{3}\delta_{ij}\epsilon$ is the deviatoric part of the Reynolds-stress dissipation tensor, and Π_{ij} is the traceless part of the pressure gradient-velocity covariance in the Reynolds-stress equation, see Eq. (13).

Neglecting the substantial derivative and the third-order transport terms in Eqs. (6) and (7), we obtain algebraic equations for the scalar fluxes $\langle u_i' \theta_l' \rangle$ and $\langle u_i' q_t' \rangle$. They read

$$\begin{aligned} &- \left(\frac{2}{3} e \delta_{ik} + a_{ik} \right) \frac{\partial \langle \theta_l \rangle}{\partial x_k} - \left(S_{ik} + W_{ik} \right) \langle u_k' \theta_l' \rangle - \beta_i \langle \theta_l' \theta_v' \rangle - 2 \epsilon_{imk} \Omega_m \langle u_k' \theta_l' \rangle \\ &- \Pi_{\theta i} - \epsilon_{\theta i} = 0, \end{aligned} \tag{19}$$

$$\begin{aligned} &- \left(\frac{2}{3} e \delta_{ik} + a_{ik} \right) \frac{\partial \langle q_t \rangle}{\partial x_k} - \left(S_{ik} + W_{ik} \right) \langle u_k' q_t' \rangle - \beta_i \langle q_t' \theta_v' \rangle - 2 \epsilon_{imk} \Omega_m \langle u_k' q_t' \rangle \\ &- \Pi_{qi} - \epsilon_{qi} = 0, \end{aligned} \tag{20}$$

where $\Pi_{\theta i}$ and Π_{qi} denote the pressure gradient-scalar covariances $\langle \theta_l' \partial p' / \partial x_i \rangle$ and $\langle q_t' \partial p' / \partial x_i \rangle$, respectively.

5 Parameterization of Pressure Scrambling, Third-Order Transport and Dissipation Effects

The second-moment equations (8), (9), (10), (12), (18), (19) and (20) are not closed. There are four groups of terms that should be parameterized. These are the pressure-scrambling terms, the third-order transport (diffusion) terms, the molecular destruction (dissipation) terms, and the buoyancy terms (incorporating correlations of the velocity and scalars with the virtual potential temperature). Parameterizations (closure assumptions) for the pressure-scrambling, third-order transport and dissipation terms are developed in sections 5.1, 5.2 and 5.3, respectively. The buoyancy terms are considered in section 7.

5.1 Pressure Scrambling

A common approach nowadays is to decompose the pressure-scrambling terms in the Reynolds-stress and scalar-flux equations into the contributions due to the non-linear turbulence interactions (that stem from the advection term in the equation of motion), mean velocity shear, buoyancy and the Coriolis effects, and to model (parameterize) these contributions separately (see e.g. Zeman, 1981; Mironov, 2001, 2009). Following this approach, we apply the return-to-isotropy parameterizations (Rotta, 1951; Monin, 1965) to the non-linear turbulence contributions to Π_{ij}, $\Pi_{\theta i}$ Π_{qi} (often referred to as slow parts of the pressure-scrambling terms) and utilize the simplest linear parameterizations of the mean velocity shear, buoyancy and Coriolis contributions (referred to as rapid parts of the pressure-scrambling terms). The following parameterizations of the pressure-scrambling terms are used in the TKESV-Bas scheme:

$$\begin{aligned}
\Pi_{ij} &= C_t^u \frac{a_{ij}}{\tau_{ru}} \\
&- C_{s1}^u S_{ij} e - C_{s2}^u \left(S_{ik} a_{kj} + S_{jk} a_{ki} - \frac{2}{3} \delta_{ij} S_{kl} a_{kl} \right) - C_{s3}^u \left(W_{ik} a_{kj} + W_{jk} a_{ki} \right) \\
&- C_b^u \left(\beta_i \left\langle u_j' \theta_v' \right\rangle + \beta_j \left\langle u_i' \theta_v' \right\rangle - \frac{2}{3} \delta_{ij} \beta_k \left\langle u_k' \theta_v' \right\rangle \right) \\
&- 2 C_c^u \left(\epsilon_{imk} \Omega_m a_{kj} + \epsilon_{jmk} \Omega_m a_{ki} \right), \qquad (21)
\end{aligned}$$

$$\Pi_{\theta i} = C_t^\theta \frac{\left\langle u_i' \theta_l' \right\rangle}{\tau_{r\theta}} - \left(C_{s1}^\theta S_{ij} + C_{s2}^\theta W_{ij} \right) \left\langle u_j' \theta_l' \right\rangle - C_b^\theta \beta_i \left\langle \theta_l' \theta_v' \right\rangle - 2 C_c^\theta \epsilon_{imj} \Omega_m \left\langle u_j' \theta_l' \right\rangle, \qquad (22)$$

$$\Pi_{qi} = C_t^q \frac{\left\langle u_i' q_t' \right\rangle}{\tau_{rq}} - \left(C_{s1}^q S_{ij} + C_{s2}^q W_{ij} \right) \left\langle u_j' q_t' \right\rangle - C_b^q \beta_i \left\langle q_t' \theta_v' \right\rangle - 2 C_c^q \epsilon_{imj} \Omega_m \left\langle u_j' q_t' \right\rangle, \qquad (23)$$

where $C_t^u = 1.8$, $C_{s1}^u = 4/5$, $C_{s2}^u = -6\alpha_5$, $C_{s3}^u = \frac{2}{3}(2 + 7\alpha_5)$, $C_b^u = 3/10$, $C_c^u = \frac{1}{3}(2 + 7\alpha_5)$, $C_t^\theta = C_t^q = 5.0$, $C_{s1}^\theta = C_{s1}^q = 3/5$, $C_{s2}^\theta = C_{s2}^q = 1$, $C_b^\theta = C_b^q = 1/3$ and $C_c^\theta = C_c^q = 1/2$ are dimensionless constants. An estimate of the yet undetermined disposable constant α_5 is obtained below. The return-to-isotropy time scales τ_{ru}, $\tau_{r\theta}$ and τ_{rq} in Eqs. (21)–(23) are taken to be proportional to the TKE dissipation time scale, $\tau_{ru} = \tau_{r\theta} = \tau_{rq} = \tau_\epsilon$, where $\tau_\epsilon = e/\epsilon$ and proportionality constants are set to one as they always occur in combination with the other constants. Parameterizations of the various time and length scales are discussed in section 6. A detailed derivation of Eqs. (21)–(23) is given in Appendix A. The properties of linear parameterizations of the pressure-scrambling terms, most notably their limitations, should be discussed in some detail.

It is readily seen that the linear parameterizations of the mean-velocity shear, buoyancy and Coriolis contributions to Π_{ij}, $\Pi_{\theta i}$ and Π_{qi} have the same form as the mean-velocity shear, buoyancy and Coriolis terms in the Reynolds-stress and scalar-flux equations (5)–(7) [or their truncated counterparts (18)–(20)]. Therefore, the effect of linear rapid parts of the pressure-scrambling terms, sometimes referred to as the implicit mean-velocity shear, buoyancy and Coriolis terms, is simply to partially offset the respective explicit terms already present in the Reynolds-stress and scalar-flux equations.

In the linear parameterizations of the pressure-scrambling terms, Eqs. (21)–(23), the numerical values of most dimensionless coefficients are fixed by mathematical constraints. In practice, however, those coefficients are often treated as disposable parameters whose values are adjusted to improve the overall performance of a turbulence model (parameterization scheme) in a particular flow regime. Although this approach may be considered legitimate in practical applications, caution must be exercised. Consider, for example, the coefficient C_b^θ in the buoyancy contribution to the pressure gradient-temperature covariance. As shown in Appendix A, the symmetry (A.11) and the normalization (A.13) constraints require that C_b^θ be equal to 1/3. This value corresponds to the isotropic limit and is consistent with the fact that the linear parameterizations of the pressure-scrambling terms are only valid for the flows where turbulence is not far from the isotropic state. The use of an empirical estimate of $C_b^\theta = 0.5$ advocated by a number of authors would improve the overall turbulence-scheme performance in the convective boundary layer driven by the surface buoyancy flux, but it would violate the isotropic constraint. One more important situation where the linear parameterizations fail is the so-called two-component limit (TCL). This is the limit that turbulence approaches when the velocity component in one direction vanishes. This occurs, for example, near the rigid boundary or in stably stratified layers, where the velocity component (both mean velocity and turbulent fluctuations) normal to the boundary or aligned with the vector of gravity, respectively, is suppressed. In order to satisfy the TCL constraint, C_b^θ should tend to one as the velocity component in one direction tends to zero (see Craft et al., 1996; Mironov, 2001, for details). Clearly, it is impossible to satisfy both the isotropic and the TCL constraints with one and the same value of C_b^θ. This shows a fundamental limitation of the linear parameterizations of the pressure-scrambling terms.

A consistent way out is to leave the coefficients of the linear terms intact, so that the isotropic limit is satisfied, and to include the non-linear terms, e.g. the terms non-linear in a_{ij} (e.g. Ristorcelli et al., 1995; Craft et al., 1996; Mironov, 2001). This would make the resulting turbulence model more flexible (capable of describing various flow regimes) and more suitable for strongly anisotropic flows. Non-linear parameterizations of the pressure-scrambling terms are inevitably complex, however. They are often inconvenient to use and are computationally expensive. It is therefore common in geophysical applications, including NWP, to put up with the shortcomings of linear parameterizations and apply Eqs. (21)–(23) without non-linear extensions. Another practically useful (albeit mathematically inconsistent) approach is to keep the functional form of Eqs. (21)–(23) but to replace some dimensionless constants with dimensionless functions of the flow governing parameters. Those functions should be constructed in such a way as to satisfy a number of limits. An approximation of $C_b^\theta(Ri)$, Ri being the gradient Richardson number, that satisfies that TCL constraint (a large positive Ri) and yields $C_b^\theta = 0.5$ at $Ri \leq 0$ (best-fit value for convective boundary layer) was proposed by Wyngaard (1975).

The TKESV-Bas scheme utilizes Eqs. (21)–(23) with the estimates of dimensionless constants given above. The estimates of the coefficients C_t^u, C_t^θ and C_t^q in the slow (return-to-isotropy) parts of the pressure-scrambling terms may require some fine tuning in order to improve the overall performance of the TKESV scheme. Most other dimensionless coefficients are fixed by mathematical constraints. We utilize their values given above, keeping in mind that these

values are actually suitable for nearly isotropic turbulence and may not be the best estimates for other flow regimes. The only remaining disposable coefficient α_5 should be determined by satisfying an additional constraint deemed important in terms of essential physics and/or practical significance. We determine α_5 so that the resulting equations of the TKESV scheme yield the classical logarithmic velocity profile in the vicinity of the underlying surface. The way this constraint is applied is described in Appendix A. The following expression for α_5 is obtained:

$$\alpha_5 = \frac{1}{22}\left[1-(1+11C_\alpha^*)^{1/2}\right], \qquad C_\alpha^* = 1+\frac{9C_t^u}{4}\left(\frac{4}{3}-C_{s1}^u\right)-\frac{9}{2}\left(\frac{C_t^u}{C_e}\right)^2, \tag{24}$$

where C_e is the dimensionless constant in the expression [third member of Eq. (A.30)] that relates the values of the TKE and of the friction velocity in the near-surface log-layer. Using $C_{s1}^u = 4/5$, $C_t^u = 1.8$ and $C_e = 3.33$, we obtain an estimate of $\alpha_5 = -0.164$. Optionally, the value of $\alpha_5 = -1/10$ can be used [see Eq. (26) and the subsequent text at the end of this section and Appendix B].

Advanced Features

Craft et al. (1996) proposed advanced parameterizations of the pressure-scrambling terms that satisfy both the isotropic limit and the strongly anisotropic two-component limit. Those parameterizations are rather complex and can hardly be used in NWP and related applications, at least in the short-term prospects. However, the TCL parameterizations of the buoyancy contributions $\Pi_{\theta i}^b$ and Π_{qi}^b to the pressure gradient-scalar covariances can be utilized within the framework of the TKESV scheme without making the scheme unduly complex and computationally expensive. Extending the formulation presented in Craft et al. (1996) to the case of moist air, we obtain

$$\Pi_{\theta i}^b = -\beta_j\left(\frac{1}{3}\delta_{ij}-a_{ij}\right)\langle\theta_l'\theta_v'\rangle, \qquad \Pi_{qi}^b = -\beta_j\left(\frac{1}{3}\delta_{ij}-a_{ij}\right)\langle q_t'\theta_v'\rangle. \tag{25}$$

In the isotropic limit, $a_{ij} = 0$ and the expressions (25) coincide with the third terms on the r.h.s. of Eqs. (22) and (23), respectively, where $C_b^\theta = C_b^q = 1/3$. In the two-component limit, the buoyancy contributions to the pressure-scrambling terms given by (25) cancel the buoyancy terms in the scalar-flux equations (19) and (20). The use of Eq. (25) helps to avoid spurious generation of scalar fluxes by the buoyancy forces in stably stratified regions of the flow, where the vertical velocity is suppressed and turbulence is driven towards the two-component state.

One point should be stressed in relation to Eq. (25). As discussed in section 7, the covariances $\langle\theta_l'\theta_v'\rangle$ and $\langle q_t'\theta_v'\rangle$ involving virtual potential temperature are parameterized in terms of linear combinations of $\langle\theta_l'^2\rangle$, $\langle q_t'^2\rangle$ and $\langle\theta_l'q_t'\rangle$. Since the TKESV scheme carries prognostic transport equations for the variances and covariance of scalar quantities, diagnostic equations (18)–(20) with due regard for the parameterizations (21)–(23), where the third terms on the r.h.s. of Eqs. (22) and (23) are replaced with the TCL formulations (25), remain linear in a_{ij} (and hence in $\langle u_i'u_j'\rangle$), $\langle u_i'\theta_l'\rangle$ and $\langle u_i'q_t'\rangle$. Then, the system of linear equations is readily solved, resulting in explicit diagnostic formulations for the Reynolds-stress and scalar-flux components (see section 9). This is not the case for one-equation TKE schemes, where diagnostic equations for the scalar variances and covariance are used [these are obtained from Eqs. (8)–(10) by neglecting the substantial derivative and the third-order transport terms]. Then, the use of Eq. (25) results in non-linear equations for a_{ij}, $\langle u_i'\theta_l'\rangle$, $\langle u_i'q_t'\rangle$, $\langle\theta_l'^2\rangle$, $\langle q_t'^2\rangle$ and $\langle\theta_l'q_t\rangle$.

As mentioned above, TKESV-Bas utilizes a constant value of dimensionless parameter α_5.

A more sophisticated approximation was proposed by Shih and Lumley (1985),

$$\alpha_5 = -\frac{1}{10}\left(1 + \frac{4}{5}F_l^{1/2}\right), \tag{26}$$

where $F_l = 1 - \frac{9}{8}(A_2 - A_3)$ is the so-called flatness parameter, and $A_2 = \hat{a}_{ij}\hat{a}_{ij}$ and $A_3 = \hat{a}_{ij}\hat{a}_{jk}\hat{a}_{ki}$ are the second and the third invariants, respectively, of the dimensionless departure-from-isotropy tensor $\hat{a}_{ij} = e^{-1}a_{ij}$. Although the use of Eq. (26) results in non-linear equations for a_{ij}, $\langle u_i'\theta_l'\rangle$ and $\langle u_i'q_t'\rangle$, the non-linearity can be treated in an approximate way, e.g. by evaluating F_l at the previous time step(s) during the integration of turbulence-moment equations in time. It should be mentioned that a constant value of $\alpha_5 = -1/10$ was adopted in a number of studies (e.g. Shih, 1996; Hanjalić, 1999). The value of $\alpha_5 = -1/10$ corresponds to $F_l = 0$, i.e. to the one-component or two-component limit of strongly anisotropic turbulence.

5.2 Third-Order Transport

The second group of terms that require closure assumptions includes turbulent transport (diffusion) terms. These terms enter the equations for the turbulence moments in the divergence form. They describe the transport of the quantity in question by the fluctuating velocity and the fluctuating pressure. Numerous formulations for the third-order turbulent transport have been proposed, ranging from the simplest down-gradient approximations to very complex formulations based on a sophisticated treatment of transport equations for the high-order turbulence moments. Simple isotropic down-gradient formulations have been very popular in various applications.

In the TKESV-Bas scheme, the simplest isotropic down-gradient parameterizations for the third-order transport terms in the TKE, scalar-variance and scalar-covariance equations are used. They read

$$\frac{1}{2}\left\langle u_i' u_k'^2\right\rangle + \left\langle u_i' p'\right\rangle = -C_e^d \tau_\epsilon e \frac{\partial e}{\partial x_i}, \tag{27}$$

$$\left\langle u_i'\theta_l'^2\right\rangle = -C_{\theta\theta}^d \tau_\epsilon e \frac{\partial\left\langle\theta_l'^2\right\rangle}{\partial x_i}, \qquad \left\langle u_i' q_t'^2\right\rangle = -C_{qq}^d \tau_\epsilon e \frac{\partial\left\langle q_t'^2\right\rangle}{\partial x_i},$$
$$\left\langle u_i'\theta_l q_t'\right\rangle = -C_{\theta q}^d \tau_\epsilon e \frac{\partial\left\langle\theta_l' q_t'\right\rangle}{\partial x_i}, \tag{28}$$

where C_e^d, $C_{\theta\theta}^d$, C_{qq}^d and $C_{\theta q}^d$ are dimensionless coefficients set equal to 0.1. Somewhat higher values of these coefficients may be used as needed. For example, an estimate of $C_{\theta\theta}^d = 0.3$ was advocated by Otić et al. (2005).

Advanced Features

The isotropic down-gradient diffusion formulations often perform poorly in strongly anisotropic flows, e.g. in the flows dominated by the effects of stratification and/or rotation. Generalized down-gradient diffusion approximations (Daly and Harlow, 1970) are somewhat more appropriate for such flows. The formulations for the diffusion terms in the TKE, scalar-variance and scalar-covariance equations read

$$\frac{1}{2}\left\langle u_i' u_k'^2\right\rangle + \left\langle u_i' p'\right\rangle = -C_e^{dg} \tau_\epsilon \left\langle u_i' u_k'\right\rangle \frac{\partial e}{\partial x_k}, \tag{29}$$

$$\langle u_i'\theta_l'^2\rangle = -C_{\theta\theta}^{dg}\tau_\epsilon \langle u_i'u_k'\rangle \frac{\partial \langle \theta_l'^2\rangle}{\partial x_k}, \qquad \langle u_i'q_t'^2\rangle = -C_{qq}^{dg}\tau_\epsilon \langle u_i'u_k'\rangle \frac{\partial \langle q_t'^2\rangle}{\partial x_k},$$
$$\langle u_i'\theta_l'q_t'\rangle = -C_{\theta q}^{dg}\tau_\epsilon \langle u_i'u_k'\rangle \frac{\partial \langle \theta_l'q_t'\rangle}{\partial x_k}, \tag{30}$$

where C_e^{dg}, $C_{\theta\theta}^{dg}$, C_{qq}^{dg} and $C_{\theta q}^{dg}$ are dimensionless coefficients set equal to 0.15. Higher values have also been proposed, e.g. $C_{\theta\theta}^{dg} = 0.22$ (Jones and Musogne, 1988; Hanjalić, 1999; Otić et al., 2005). Equations (29) and (30) reduce to Eqs. (27) and (28), respectively, if the Reynolds-stress anisotropy is neglected, i.e. a_{ij} is set to zero in the expression $\langle u_i'u_k'\rangle = a_{ik} + \frac{2}{3}\delta_{ik}e$.

5.3 Dissipation

Molecular destruction (dissipation) rates of the TKE and of the scalar variances and covariance can be determined from their own transport equations. The dissipation-rate equations are very complex, however. They contain a number of terms whose physical nature is poorly understood. In fact, all terms in the dissipation-rate equations that describe production, destruction and turbulent transport of the dissipation rates should be parameterized, and the validity of those parameterizations is uncertain. It has often been questioned whether prognostic transport equations for the dissipation rates are really necessary, or diagnostic expressions are sufficient, at least for flows in relatively simple geometries. The latter viewpoint is commonly held in geophysical applications.

In the TKESV scheme, the TKE dissipation rate is parameterized in terms of the TKE dissipation time scale τ_ϵ through the following algebraic expression:

$$\epsilon = \frac{e}{\tau_\epsilon}. \tag{31}$$

The dissipation rates of the scalar variances and the scalar covariance are parameterized as

$$\epsilon_{\theta\theta} = \frac{\langle \theta_l'^2\rangle}{2\tau_{\theta\theta}}, \qquad \epsilon_{qq} = \frac{\langle q_t'^2\rangle}{2\tau_{qq}}, \qquad \epsilon_{\theta q} = \frac{\langle \theta_l'q_t'\rangle}{2\tau_{\theta q}}, \tag{32}$$

where $\tau_{\theta\theta}$, τ_{qq} and $\tau_{\theta q}$ are the dissipation times scales of the scalar variances and the scalar covariance. These time scales are taken to be proportional to the TKE dissipation time scale (see the next section).

The deviatoric part ϵ_{ij}^d of the Reynolds-stress dissipation tensor is either neglected (on the assumption of local isotropy at small scales) or incorporated into a parameterization of the slow part Π_{ij}^t of the pressure redistribution term. Likewise, the temperature-flux and the humidity-flux dissipation rates, $\epsilon_{\theta i}$ and ϵ_{qi}, are incorporated into parameterizations of $\Pi_{\theta i}^t$ and Π_{qi}^t, respectively.

6 Time and Length Scales

The return-to-isotropy time scales in Eqs. (21)–(23) are taken to be proportional to the TKE dissipation time scale:

$$\tau_{ru} = \tau_{r\theta} = \tau_{rq} = \tau_\epsilon, \tag{33}$$

where proportionality constants between the various time scales are set to one as they always occur in combination with the other constants. Likewise, the dissipation time scales of the

scalar variances and the scalar covariance, Eq. (32), are taken to be proportional to the TKE dissipation time scale:

$$\tau_{\theta\theta} = \tau_{qq} = \tau_{\theta q} = R_\tau \tau_\epsilon, \tag{34}$$

where R_τ is the ratio of the scalar-variance/scalar-covariance dissipation time scale to the TKE dissipation time scale [e.g. $R_\tau = \tau_{\theta\theta}/\tau_\epsilon = \langle \theta_l'^2 \rangle \, \epsilon / (2e\epsilon_{\theta\theta})$ for the temperature variance]. The same value of R_τ is used for $\tau_{\theta\theta}$, τ_{qq} and $\tau_{\theta q}$. The estimates of R_τ given in the literature range from 0.3 to 1.0 (e.g. Dol et al., 1997). Following Kenjereš and Hanjalić (1995, 2000) and Hanjalić (2002), the value of $R_\tau = 0.5$ is utilized.

The TKE dissipation time scale is expressed in terms of the turbulence length scale l:

$$\tau_\epsilon = \frac{1}{C_\epsilon} \frac{l}{e^{1/2}}, \tag{35}$$

where $C_\epsilon = C_e^{-3/2}$, and C_e is a constant in the expression that relates the TKE and the friction velocity in the neutrally-stratified near-surface layer characterized by the logarithmic mean-velocity profile [see Eq. (A.30) in Appendix A]. We utilize an estimate of $C_e = 3.33$ (Umlauf and Burchard, 2003; Umlauf et al., 2003). The following interpolation formula is used in the TKESV-Bas scheme to compute the turbulence length scale:

$$\frac{1}{l} = \frac{1}{\kappa x_n} + \frac{1}{l_\infty} + \mathrm{H}\left(N^2\right) \frac{N}{C_{lb} e^{1/2}}, \tag{36}$$

where κ is the von Kármán constant, x_n is the distance normal to the surface, l_∞ is the length scale characteristic of the flow far away from the underlying surface, N is the buoyancy frequency, $\mathrm{H}(\zeta)$ is the Heaviside step function (equal to 1 if $\zeta \geq 0$, and to 0 if $\zeta < 0$), and C_{lb} is a dimensionless constant. If the last term on the r.h.s. is neglected, Eq. (36) reduces to the well-known Blackadar's formula (Blackadar, 1962) that yields the logarithmic velocity profile close to the underlying surface and prevents l from growing without bound far away from the surface. A conventional value of $\kappa = 0.4$ is utilized, and the l_∞ is set to a constant value of 200 m. The last term on the r.h.s. of Eq. (36) limits the length scale in stably stratified layers (where N^2 is positive) by the buoyancy length scale $l_b = C_{lb} N^{-1} e^{1/2}$ (e.g. Stull, 1973; Zeman and Tennekes, 1977; Brost and Wyngaard, 1978; Zilitinkevich and Mironov, 1992). An estimate of $C_{lb} = 1.0$ is used. The buoyancy frequency N is computed with due regard for the effect of cloud condensate on the static stability (see section 9).

Advanced Features

As an alternative to setting the time-scale ratio in Eq. (34) to a constant value, R_τ can be computed as a function of the scalar-flux correlation coefficient. The following expression was proposed by Craft et al. (1996):

$$R_\tau = \frac{2}{3\left(1 + A_{u\theta}\right)}, \qquad A_{u\theta} = \frac{\langle u_i' \theta' \rangle \, \langle u_i' \theta' \rangle}{e \, \langle \theta'^2 \rangle}, \tag{37}$$

where $A_{u\theta}$ is the heat-flux correlation coefficient. In the case of moist air, the time-scale ratio for the temperature variance, $R_\tau^{\theta\theta}$, and for the humidity variance, R_τ^{qq}, can be computed from Eq. (37) where θ is replaced with θ_l and q_t, respectively. The time scale ratio for the temperature-humidity covariance is then computed as $R_\tau^{\theta q} = \frac{1}{2}\left(R_\tau^{\theta\theta} + R_\tau^{qq}\right)$.

Following Bougeault and André (1986), Bougeault and Lacarrère (1989), Bechtold et al. (1992), Lappen and Randall (2001) and Golaz et al. (2002), an advanced non-local formulation for the turbulence length scale can be used instead of Eq. (36). The turbulence length scale is computed from the following relations:

$$e\left(x_i\right) = \int_{x_i}^{x_i + l_{up}} \beta_i \left[\theta_v^{par}\left(x_i, x_i'\right) - \theta_v^{env}\left(x_i'\right)\right] dx_i', \tag{38}$$

$$e\left(x_i\right) = \int_{x_i - l_{do}}^{x_i} \beta_i \left[\theta_v^{env}\left(x_i'\right) - \theta_v^{par}\left(x_i, x_i'\right)\right] dx_i', \tag{39}$$

$$\frac{1}{l} = \frac{1}{\kappa x_n} + \left(\frac{2}{l_{up} l_{do}}\right)^{1/2}. \tag{40}$$

The physical meaning of Eqs. (38)–(40) can be elucidates as follows. Consider a flat horizontal surface. The x_3-axis is aligned with the vector of gravity $(0, 0, -g_3)$ and is positive upward. The quantity l_{up} (l_{do}) is an estimate of the distance that an air parcel originating at the level x_3 travels upward (downward) until its energy $e\left(x_3\right)$ is spent working against gravity (l_{do} is limited by the distance to the surface). The virtual potential temperature $\theta_v^{par}\left(x_3, x_3'\right)$ of an ascending/descending air parcel is computed with due regard for the condensation/evaporation. As an air parcel is displaced from the level x_3 to the level x_3', the liquid water potential temperature $\theta_l^{par}\left(x_3'\right)$ and the total water specific humidity $q_t^{par}\left(x_3'\right)$ of the parcel are conserved, i.e. they remain equal to the values $\theta_l^{par}\left(x_3\right)$ and $q_t^{par}\left(x_3\right)$, respectively. However, the potential temperature θ^{par}, the specific humidity q^{par} and the liquid water specific humidity q_l^{par}, and hence the virtual potential temperature θ_v^{par}, are not conserved (because of phase changes) and are therefore re-computed at each level x_3' during the parcel ascend/descent. Note that the quantity $2^{-1/2}\left(l_{up} l_{do}\right)^{1/2}$, where l_{up} and l_{do} are computed from Eqs.(38) and (39), respectively, yields the buoyancy length scale $l_b = C_{lb} N^{-1} e^{1/2}$ with $C_{lb} = 1.0$ in stably stratified fluid characterized by a constant buoyancy frequency N. The first term on the r.h.s. of the interpolation formula (40) is required to recover the logarithmic velocity profile close to the underlying surface.

7 Effect of Clouds on Mixing

The thermodynamic structure of the atmosphere is heavily complicated by the presence of clouds. Clouds produce precipitation and interact with atmospheric radiation, strongly affecting the atmosphere energy budget. They also change the buoyancy of air parcels. As far as the parameterization of turbulence is concerned, the primary goal is to account for the effect of latent heat release/consumption on the buoyancy production/destruction of the Reynolds stress (including its trace, the TKE) and of the scalar fluxes. To this end, the buoyancy terms (the terms with β_i) in Eqs. (12), (18), (19) and (20) should be parameterized with due regard for the presence of cloud condensate. The problem essentially amounts to modelling the virtual potential temperature flux $\left\langle u_i' \theta_v' \right\rangle$ and the scalar-virtual potential temperature covariances $\left\langle \theta_l' \theta_v' \right\rangle$ and $\left\langle q_t' \theta_v' \right\rangle$ in terms of other moments that include fluctuations of u_i, θ_l and q_t.

Using the definition of the virtual potential temperature (11), the covariances incorporating θ_v' are represented as

$$\begin{aligned} \left\langle f' \theta_v' \right\rangle &= \left[1 + (R-1)\left\langle q_t \right\rangle - R\left\langle q_l \right\rangle\right] \left\langle f' \theta_l' \right\rangle + (R-1)\left\langle \theta \right\rangle \left\langle f' q_t' \right\rangle \\ &+ \left\{ \frac{\left\langle \theta \right\rangle}{\left\langle T \right\rangle} \frac{L_v}{c_p} \left[1 + (R-1)\left\langle q_t \right\rangle - R\left\langle q_l \right\rangle\right] - R\left\langle \theta \right\rangle \right\} \left\langle f' q_l' \right\rangle, \end{aligned} \tag{41}$$

where $R = R_v / R_d$, and a generic variable f stands for u_i, θ_l or q_t. In order to obtain Eq. (41), the third-order covariances and the pressure fluctuations are neglected. The latter assumption yields $\theta_l = \theta - \dfrac{\left\langle \theta \right\rangle}{\left\langle T \right\rangle} \dfrac{L_v}{c_p} q_l$. In the "dry" limit, where a given atmospheric-model

grid box is cloud free (but the water vapour may be present), Eq. (41) reduces to

$$\left\langle f'\theta'_v \right\rangle_d = \left[1 + (R-1)\left\langle q_t \right\rangle\right] \left\langle f'\theta'_l \right\rangle + (R-1)\left\langle \theta \right\rangle \left\langle f'q'_t \right\rangle, \tag{42}$$

where θ_l and q_t coincide with θ and q, respectively, as $q_l = 0$. In the "wet" limit, the entire atmospheric-model grid box is saturated, i.e. $q_l = q_t - q_s > 0$ at each point of the grid box. Then, $\langle f'\theta'_v \rangle$ can be expressed, to a good approximation, in terms of $\langle f'\theta'_l \rangle$ and $\langle f'q'_t \rangle$ as follows:

$$\begin{aligned} \left\langle f'\theta'_v \right\rangle_w &= \left[1 + (R-1)\left\langle q_t \right\rangle - R\left\langle q_l \right\rangle\right] \left\langle f'\theta'_l \right\rangle + (R-1)\left\langle \theta \right\rangle \left\langle f'q'_t \right\rangle \\ &+ \left[-\frac{\mathcal{A}\mathcal{P}}{\mathcal{Q}} \left\langle f'\theta'_l \right\rangle + \frac{\mathcal{A}}{\mathcal{Q}} \left\langle f'q'_t \right\rangle \right]. \end{aligned} \tag{43}$$

Here, $\mathcal{A} = \dfrac{\langle\theta\rangle}{\langle T\rangle}\dfrac{L_v}{c_p}\left[1 + (R-1)\langle q_t\rangle - R\langle q_l\rangle\right] - R\langle\theta\rangle$, $\mathcal{P} = \dfrac{\langle T\rangle}{\langle\theta\rangle}\langle q_{sl,T}\rangle$, $\mathcal{Q} = 1 + \dfrac{L_v}{c_p}\langle q_{sl,T}\rangle$, and $\langle q_{sl,T}\rangle \equiv \left.\dfrac{\partial q_s}{\partial T}\right|_{T=\langle T_l\rangle}$, T_l being the liquid water absolute temperature, is computed from the Clausius-Clapeyron equation, $\dfrac{\partial q_s}{\partial T} = \dfrac{L_v q_s}{R_v T^2}$. A first-order Taylor expansion of the saturation specific humidity $q_s(T)$ about $T = \langle T_l \rangle$ is used to express $\langle f'q'_l \rangle$ in terms of $\langle f'\theta'_l \rangle$ and $\langle f'q'_t \rangle$ [the last terms in brackets on the r.h.s. of Eq. (43)]. An expression is needed that is valid not only in the dry and wet limits, but also in the general case of fractional cloudiness. To this end, the following interpolation formula is used:

$$\begin{aligned} \left\langle f'\theta'_v \right\rangle &= \left[1 + (R-1)\left\langle q_t \right\rangle - R\left\langle q_l \right\rangle\right] \left\langle f'\theta'_l \right\rangle + (R-1)\left\langle \theta \right\rangle \left\langle f'q'_t \right\rangle \\ &+ \hat{\mathcal{R}} \left[-\frac{\mathcal{A}\mathcal{P}}{\mathcal{Q}} \left\langle f'\theta'_l \right\rangle + \frac{\mathcal{A}}{\mathcal{Q}} \left\langle f'q'_t \right\rangle \right]. \end{aligned} \tag{44}$$

where $\hat{\mathcal{R}}$ is the interpolation variable satisfying $0 \le \hat{\mathcal{R}} \le 1$. Equation (44) reduces to Eq. (42) and to Eq. (43) in the dry ($\hat{\mathcal{R}} = 0$) and wet ($\hat{\mathcal{R}} = 1$) limits, respectively.

The simplest way to determine $\hat{\mathcal{R}}$ is to set it equal to the fractional cloud cover $\hat{\mathcal{C}}$. This parameterization is used within the framework of one-equation TKE turbulence scheme of COSMO and ICON (see Raschendorfer, 1999, 2001; Baldauf et al., 2011). In order to compute the fractional cloud cover, a Gaussian statistical cloud scheme is used that is very similar to the scheme proposed by Sommeria and Deardorff (1977) (see also Mellor, 1977). Recall that statistical cloud schemes make use of probability distribution functions of the sub-grid scale (SGS) humidity and temperature (and possibly velocity) fluctuations. Once the PDF is specified, the fractional cloud cover is simply the integral over a saturated part of the PDF. The COSMO/ICON statistical cloud scheme is formulated in terms of s variable (Mellor, 1977) defined as $s = \mathcal{Q}^{-1}\left(\langle q_t\rangle - \langle q_{sl}\rangle + q'_t - \mathcal{P}\theta'_l\right)$, where $\langle q_{sl}\rangle = q_s(\langle T_l\rangle)$. The variable s accounts for the combined effect of humidity and temperature fluctuations (the latter ones change the local saturation vapour pressure). It is a measure of local oversaturation/undersaturation. A positive s is nothing but a local value of the liquid water specific humidity q_l computed with respect to the linearized saturation specific humidity curve[3]. Assuming that no supersaturation occurs, the fractional cloud cover is given by $\hat{\mathcal{C}} = \displaystyle\int_0^\infty G(s)ds$, where $G(s)$ is the PDF of s. The grid-box mean liquid water specific humidity is given by $\langle q_l \rangle = \displaystyle\int_0^\infty sG(s)ds$. Partial or full PDF moments of higher order can be computed in a similar manner. Following

[3]In fact, the quantity s has already been used above to express $\langle f'q'_l \rangle$ through $\langle f'q'_t \rangle$ and $\langle f'\theta'_l \rangle$ in Eq. (41), leading to Eq. (43)

Sommeria and Deardorff (1977) and Mellor (1977), a Gaussian PDF is utilized within the framework of the COSMO/ICON TKE turbulence scheme. The following relations hold:

$$\hat{\mathcal{C}} = \frac{1}{2}\left[1 + \mathrm{erf}\left(\frac{\langle s\rangle}{\sqrt{2}\sigma_s}\right)\right], \qquad \langle q_l\rangle = \hat{\mathcal{C}}\,\langle s\rangle + \frac{\sigma_s}{\sqrt{2\pi}}\exp\left(-\frac{\langle s\rangle^2}{2\sigma_s^2}\right), \tag{45}$$

where erf is the error function, $\langle s\rangle = \mathcal{Q}^{-1}\left(\langle q_t\rangle - \langle q_{sl}\rangle\right)$ is the mean value of s, and $\sigma_s \equiv \left\langle s'^2\right\rangle^{1/2} = \mathcal{Q}^{-1}\left(\left\langle q_t'^2\right\rangle + \mathcal{P}^2\left\langle \theta_l'^2\right\rangle - 2\mathcal{P}\left\langle q_t'\theta_l'\right\rangle\right)^{1/2}$ is its standard deviation. Note that σ_s depends on the variances of q_t and θ_l and on their covariance, providing an important link between the cloud cover and the dynamics of SGS motions. Within the framework of the one-equation TKE turbulence scheme, $\left\langle q_t'^2\right\rangle$, $\left\langle \theta_l'^2\right\rangle$ and $\left\langle q_t'\theta_l'\right\rangle$, and hence σ_s, are computed diagnostically through the down-gradient algebraic formulations. This is different from the TKESV scheme that carries prognostic equations for the scalar variances and covariance with due regard for the third-order transport. It is also worth noting that approximations of Eqs. (45) through piecewise polynomial (linear and quadratic) functions are used in COSMO/ICON to compute $\hat{\mathcal{C}}$ and $\langle q_l\rangle$ [see Eqs. (22) and (25) in Sommeria and Deardorff (1977) and Eqs. (47) below].

The use of $\hat{\mathcal{R}} = \hat{\mathcal{C}}$ in Eq. (44) along with the Gaussian formulations for $\hat{\mathcal{C}}$ and $\langle q_l\rangle$ may result in large errors in the determination of the buoyancy terms in the Reynolds-stress and scalar-flux equations. A prominent example is the convective boundary layer with shallow cumuli, where the PDFs of cloud-related variables are highly skewed. In the shallow cumulus regime, the atmospheric-model grid box is undersaturated in the mean and the fractional cloud cover is typically small (certainly, this holds if the horizontal model resolution is not too high and shallow cumulus clouds remain unresolved). However, these highly localized cumulus clouds account for much of the buoyancy terms in the Reynolds-stress, scalar-flux and TKE equations, and $\langle f'\theta_v'\rangle$ is closer to $\langle f'\theta_v'\rangle_w$ than to $\langle f'\theta_v'\rangle_d$. Then, $\hat{\mathcal{R}}$ in Eq. (44) is (considerably) larger than $\hat{\mathcal{C}}$ (see e.g. Lewellen and Lewellen, 2004).

In order to account for the skewed nature of convective motions associated with shallow cumuli, the following parameterization that interpolates between the Gaussian and the exponential formulations (Bougeault, 1981; Bechtold et al., 1995) is used within the framework of the TKESV-Bas scheme:

$$f = \begin{cases} f_{Gauss} & \text{at} \quad \tilde{s} \geq 0 \\ 0.5\left[(2+\tilde{s})\, f_{Gauss} - \tilde{s} f_{exp}\right] & \text{at} \quad -2 \leq \tilde{s} \leq 0 \\ f_{exp} & \text{at} \quad \tilde{s} \leq -2, \end{cases} \tag{46}$$

where $\tilde{s} = \langle s\rangle / \sigma_s$, and f stands either for the fractional cloud cover $\hat{\mathcal{C}}$ or for the grid-box mean liquid water specific humidity $\langle q_l\rangle$. The Gaussian formulations are given by

$$\begin{aligned} \hat{\mathcal{C}}_{Gauss} &= \begin{cases} 1 & \text{at} \quad \tilde{s} \geq 1.6 \\ 0.5\,(1+\tilde{s}/1.6) & \text{at} \quad -1.6 \leq \tilde{s} \leq 1.6 \\ 0 & \text{at} \quad \tilde{s} \leq -1.6, \end{cases} \\ \frac{\langle q_l\rangle_{Gauss}}{\sigma_s} &= \begin{cases} \tilde{s} & \text{at} \quad \tilde{s} \geq 1.6 \\ (\tilde{s}+1.6)^2/6.4 & \text{at} \quad -1.6 \leq \tilde{s} \leq 1.6 \\ 0 & \text{at} \quad \tilde{s} \leq -1.6. \end{cases} \end{aligned} \tag{47}$$

Equations (47) are the piecewise polynomial approximations of Eqs. (45). The exponential formulations are given by

$$\hat{\mathcal{C}}_{exp} = \exp\left(\tilde{s}-1\right), \qquad \langle q_l\rangle_{exp} = \sigma_s \exp\left(\tilde{s}-1\right). \tag{48}$$

At large negative $\tilde{s}$, the Gaussian relations (45) give a very small fractional cloud cover, and the approximations (47) give no clouds at all. A relatively thick exponential tail (as

compared to a Gaussian tail) is introduced to account, in an approximate way, for non-zero fractional cloud cover in the shallow cumulus regime. The buoyancy terms in the Reynolds-stress and scalar-flux equations are computed from Eq. (44), where the interpolation variable $\hat{\mathcal{R}}$ is given by

$$\frac{\hat{\mathcal{R}}}{\hat{\mathcal{C}}} = \begin{cases} 1 & \text{at} \quad \tilde{s} \geq 0 \\ 1 - 1.5\tilde{s} & \text{at} \quad -2 \leq \tilde{s} \leq 0 \\ 2 - \tilde{s} & \text{at} \quad \tilde{s} \leq -2. \end{cases} \tag{49}$$

Note that Eq. (49) may underestimate $\hat{\mathcal{R}}$ (perhaps quite considerably) at large negative $\tilde{s}$. Thus the above formulations with the exponential tail can only be considered as the first-order corrections to the Gaussian formulations. Note further that $\hat{\mathcal{C}}$, $\langle q_l \rangle$, and $\hat{\mathcal{R}}$ given by Eqs. (46)–(49) depend on the mean and the variance of s but do not explicitly depend on higher-order moments such as skewness. That is, the skewed nature of shallow cumulus clouds is accounted for implicitly in a rather ad hoc manner.

It should be recognized that the use of the interpolation formula (44) to determine the buoyancy terms in the Reynolds-stress and the scalar-flux equations can be avoided. If a cloud scheme employs a joint PDF for the scalars q_t and θ_l and for the vertical velocity u_3, all quantities $\langle f' q_l' \rangle$ including the liquid water specific humidity are determined in a straightforward way by means of integration over the saturated part of the PDF. In other words, the problem reduces to the determination of a number of partial moments using an assumed PDF. This approach is taken within the framework of CLUBB (Cloud Layers Unified By Binormals), an assumed-PDF unified parameterization of turbulence and cloud processes in the Earth's atmosphere (see references at https://people.uwm.edu/vlarson/papers/). Apart from its numerous advantages, the approach has shortcomings. For example, the cloud schemes based on a joint PDF require a large number of statistical moments of fluctuating scalar and velocity fields as an input. Furthermore, the joint-PDF schemes may place rather stringent requirements upon the input quality, i.e. a large number of irreducible moments of second, third and possibly higher order should be determined accurately. Comprehensive discussions of various issues related to the parameterization of clouds and cloud-turbulence interaction in atmospheric models are given in Tompkins (2003, 2005) and Machulskaya (2015). A cloud parameterization based on a joint scalar-velocity PDF may be incorporated into the TKESV scheme in the future. The TKESV-Bas scheme employs an interpolation formula (44) with $\hat{\mathcal{C}}$, $\langle q_l \rangle$, and $\hat{\mathcal{R}}$ determined through the approximations (46)–(49).

Advanced Features

Following Larson et al. (2001), Naumann et al. (2013) developed a statistical cloud scheme based on a double-Gaussian PDF of s,

$$\begin{aligned} G(s) &= aG_1(s) + (1-a)\,G_2(s) \\ &= \frac{a}{\sqrt{2\pi}\sigma_{s1}} \exp\left[-\frac{1}{2}\left(\frac{s-s_1}{\sigma_{s1}}\right)^2\right] + \frac{1-a}{\sqrt{2\pi}\sigma_{s2}} \exp\left[-\frac{1}{2}\left(\frac{s-s_2}{\sigma_{s2}}\right)^2\right]. \end{aligned} \tag{50}$$

Here, a and $1-a$ are the relative weights of the two Gaussian curves G_1 and G_2, respectively, and s_1 and s_2 and σ_{s1} and σ_{s2} are, respectively, their means and standard deviations. The PDF given by Eq. (50) is a five-parameter PDF. That is, five irreducible moments of s, e.g. five first moments, should be provided as input arguments to specify a, s_1, s_2, σ_{s1} and σ_{s2}. In order to reduce the number of input arguments, Naumann et al. (2013) used observational and numerical LES data to express σ_{s1} and σ_{s2} through the standard deviation σ_s and the skewness $S_s \equiv \langle s'^3 \rangle / \langle s'^2 \rangle^{3/2}$ of s. The following relations are proposed by Naumann et al.

(2013) (cf. Larson et al., 2001):

$$\begin{aligned}
\frac{\sigma_{s1}}{\sigma_s} &= \begin{cases} 1+\gamma_3\dfrac{S_s}{(\alpha+S_s^2)^{1/2}} & \text{at} \quad S_s \le 0 \\ 1+\gamma_1\dfrac{S_s}{\alpha^{1/2}} & \text{at} \quad S_s \ge 0, \end{cases} \\
\frac{\sigma_{s2}}{\sigma_s} &= \begin{cases} 1-\gamma_4\dfrac{S_s}{(\alpha+S_s^2)^{1/2}} & \text{at} \quad S_s \le 0 \\ 1-\gamma_2\dfrac{S_s}{(\alpha+S_s^2)^{1/2}} & \text{at} \quad S_s \ge 0, \end{cases}
\end{aligned} \tag{51}$$

where $\alpha = 2.0$, $\gamma_1 = 0.73$, $\gamma_2 = 0.46$, $\gamma_3 = 0.78$ and $\gamma_4 = 0.73$ are dimensionless constants (the notation used in Naumann et al., 2013, is retained).

With due regard for (51), only three irreducible moments of s should be provided, viz., $\langle s \rangle$, σ_s and S_s. The mean value of s is provided by the host atmospheric model. The variances and the covariance of the scalar quantities required to compute σ_s are determined within the framework of the TKESV scheme from the scalar (co)variance transport equations. The skewness of s is required to close the problem. The way to determine S_s is discussed in section 11. A cloud scheme based on Eqs. (50) and (51) represents a good compromise between physical realism and computational economy and is a viable choice for the extended version of the TKESV scheme. On the one hand, a double-Gaussian distribution (50) is very flexible and is capable of describing both symmetric and skewed PDFs, the latter one is required to describe the cumulus regime. On the other hand, the use of Eqs. (51) reduces the number of PDF input arguments to three (mean, variance, and skewness), making the cloud scheme reasonably inexpensive from the computational viewpoint.

Given the estimates of $\langle s \rangle$, σ_s and S_s, the weighting factor a is determined as a solution to the following equation:

$$\begin{aligned}
&S_s - \left\{ a\,(1-a) \left[1 - a \left(\frac{\sigma_{s1}}{\sigma_s} \right)^2 - (1-a) \left(\frac{\sigma_{s2}}{\sigma_s} \right)^2 \right] \right\}^{1/2} \\
&\times \left\{ 3 \left(\frac{\sigma_{s1}}{\sigma_s} \right)^2 - 3 \left(\frac{\sigma_{s2}}{\sigma_s} \right)^2 + \frac{1-2a}{a\,(1-a)} \left[1 - a \left(\frac{\sigma_{s1}}{\sigma_s} \right)^2 - (1-a) \left(\frac{\sigma_{s2}}{\sigma_s} \right)^2 \right] \right\} = 0,
\end{aligned} \tag{52}$$

where σ_{s1}/σ_s are σ_{s2}/σ_s are given by Eqs. (51). The mean values s_1 and s_2 are computed from

$$\begin{aligned}
\frac{s_1 - \langle s \rangle}{\sigma_s} &= \left(\frac{1-a}{a} \right)^{1/2} \left[1 - a \left(\frac{\sigma_{s1}}{\sigma_s} \right)^2 - (1-a) \left(\frac{\sigma_{s2}}{\sigma_s} \right)^2 \right]^{1/2}, \\
\frac{s_2 - \langle s \rangle}{\sigma_s} &= \left(\frac{a}{1-a} \right)^{1/2} \left[1 - a \left(\frac{\sigma_{s1}}{\sigma_s} \right)^2 - (1-a) \left(\frac{\sigma_{s2}}{\sigma_s} \right)^2 \right]^{1/2}.
\end{aligned} \tag{53}$$

Then, the fractional cloud cover and the grid-box mean liquid water specific humidity are computed from the following relations:

$$\begin{aligned}
\hat{\mathcal{C}} &= \frac{a}{2} \left[1 + \operatorname{erf} \left(\frac{s_1}{\sqrt{2}\sigma_{s1}} \right) \right] + \frac{1-a}{2} \left[1 + \operatorname{erf} \left(\frac{s_2}{\sqrt{2}\sigma_{s2}} \right) \right], \\
\langle q_l \rangle &= s_1 \frac{a}{2} \left[1 + \operatorname{erf} \left(\frac{s_1}{\sqrt{2}\sigma_{s1}} \right) \right] + s_2 \frac{1-a}{2} \left[1 + \operatorname{erf} \left(\frac{s_2}{\sqrt{2}\sigma_{s2}} \right) \right] \\
&+ \sigma_{s1} \frac{a}{\sqrt{2\pi}} \exp \left(-\frac{s_1^2}{2\sigma_{s1}^2} \right) + \sigma_{s2} \frac{1-a}{\sqrt{2\pi}} \exp \left(-\frac{s_2^2}{2\sigma_{s2}^2} \right).
\end{aligned} \tag{54}$$

The buoyancy terms in the Reynolds-stress and scalar-flux equations are computed from Eq. (44), where the interpolation variable $\hat{\mathcal{R}}$ is given by

$$\frac{\hat{\mathcal{R}}}{\hat{\mathcal{C}}} = \begin{cases} 1 & \text{at} \quad \tilde{s} \geq 0 \\ 1 + 1.5\tilde{s}^2 \exp\left(0.25 S_s\right) & \text{at} \quad \tilde{s} \leq 0. \end{cases} \tag{55}$$

It is significant that $\hat{\mathcal{R}}$ depends on the skewness of s in an explicit manner. This is different from Eq. (49), where $\hat{\mathcal{R}}$ explicitly depends on $\langle s \rangle$ and σ_s (via $\tilde{s} = \langle s \rangle / \sigma_s$) but there is no explicit dependence on S_s.

In order to obtain the weighting factor a, Eq. (52) with due regard for Eqs. (51) should be solved numerically at each atmospheric-model time step. Since the left-hand side (l.h.s.) of Eq. (52) is the seventh-order polynomial in a, in general no analytical solution $a\left(S_s\right)$ exists. In order to save computational resources, an approximate solution is used that interpolates between analytical asymptotic solutions valid at $S_s \to \pm\infty$ and $S_s \to \pm 0$. The asymptotic solutions are

$$\begin{aligned} a_{-\infty} &= 1 - \frac{C_{-\infty}}{S_s^2} && \text{at} \quad S_s \to -\infty \\ a_{-0} &= 1 + C_{-0} S_s && \text{at} \quad S_s \to -0 \\ a_{+0} &= C_{+0} S_s && \text{at} \quad S_s \to +0 \\ a_{+\infty} &= \frac{C_{+\infty}}{S_s^2} && \text{at} \quad S_s \to +\infty, \end{aligned} \tag{56}$$

where $C_{-\infty} = \gamma_3^3 \left(2 - \gamma_3\right)^3 \approx 0.862$, $C_{-0} = 8\alpha^{-3/2}\gamma_3^3 \approx 1.342$, $C_{+0} = 8\alpha^{-3/2}\gamma_2^3 \approx 0.275$, and $C_{+\infty} \approx 0.570$ are dimensionless constants. The value of $C_{+\infty}$ is a root of the cubic equation $\frac{4\gamma_1^6}{\alpha^3} C_{+\infty}^3 + \left[1 - \frac{3\gamma_1^2}{\alpha}\gamma_2^2 \left(2 - \gamma_2\right)^2\right] C_{+\infty} - \gamma_2^3 \left(2 - \gamma_2\right)^3 = 0$. Using (56), the weighting factor is computed from the following interpolation formulae:

$$\begin{aligned} \frac{1}{\left(1 - a\right)^n} &= \frac{1}{\left(1 - a_{-0}\right)^n} + \frac{1}{\left(1 - a_{-\infty}\right)^n} && \text{at} \quad S_s < 0 \\ a &= \frac{1}{2} && \text{at} \quad S_s = 0 \\ \frac{1}{a^m} &= \frac{1}{a_{+0}^m} + \frac{1}{a_{+\infty}^m} && \text{at} \quad S_s > 0, \end{aligned} \tag{57}$$

where the exponents n and m are tuning parameters estimated at 0.52 and 0.75, respectively.

As seen from Fig. 1, Eqs. (56) and (57) approximate the exact solution of Eqs. (51) and (52) very accurately at $S_s > 0$. A positive (and possibly large) skewness of s is characteristic of shallow cumulus regime that presents major difficulties in terms of modelling the effect of clouds on turbulent mixing. The agreement between the approximation and the exact solution is less favourable in the range of S_s from ca. -1 to ca. -4. This is not crucial, however. A negative S_s is characteristic of the stratus or stratocumulus clouds, but large negative values of S_s are rarely encountered. In the stratus (stratocumulus) regime, the atmospheric-model grid box is oversaturated in the mean ($\langle s \rangle > 0$), the fractional cloud cover is typically large, and the effect of clouds on mixing can be accounted for with the aid of relatively simple parameterization schemes. For example, assuming $\hat{\mathcal{R}} = \hat{\mathcal{C}}$, as in Eq. (55), does not lead to large uncertainties in the determination of the buoyancy terms in the Reynolds-stress and scalar-flux equations. Note that the error in a caused by the use of Eqs. (56) and (57) instead of the exact solution to Eqs. (51) and (52) does not exceed a few percent. This error is tolerable in the stratus regime.

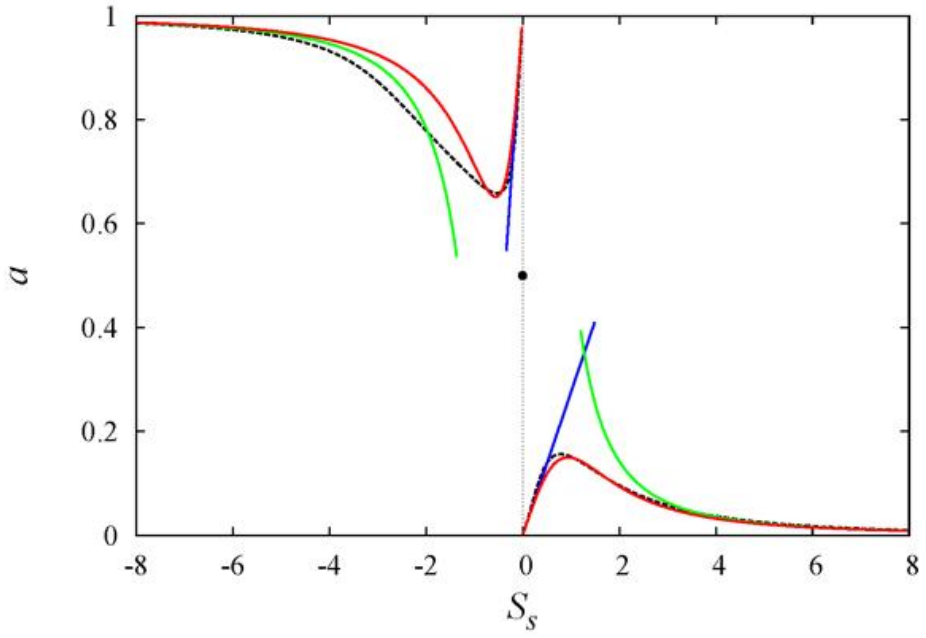

Figure 1: The weighting factor a as function of skewness S_s. Black dashed curves and black dot show numerical solution of Eqs. (51) and (52). Solid curves show the interpolation formulation given by Eqs. (56) and (57) – red, and the asymptotes a_{-0} and a_{+0} – blue, and $a_{-\infty}$ and $a_{+\infty}$ – green.

In order to account for the presence of cloud ice, a generalized total water specific humidity q_t and the ice-liquid (total) water potential temperature θ_t defined through Eqs. (3) and (4), respectively, should be utilized. The use of the $q_t - \theta_t$ system raises various tricky issues. A comprehensive discussion of those issues is beyond the scope of the present report. Here, a way to account for the cloud ice in a very approximate manner is briefly outlined.

Local saturation adjustment is performed in terms of the total cloud condensate $q_c = q_l + q_i$ computed as $q_c = q_t - q_s$ if $q_t > q_s$, and $q_c = 0$ if $q_t \leq q_s$. The saturation specific humidity is specified with respect to the water-ice mixed phase. The following parameterization of the mixed-phase q_s is used:

$$q_{sc} = (1 - F_i)\, q_{sl} + F_i q_{si}, \tag{58}$$

where $F_i = q_i / (q_l + q_i)$ is the cloud-ice fraction of the total cloud condensate, and q_{sl} and q_{si} are the saturation specific humidity for the vapour-liquid equilibrium and for the vapour-ice equilibrium, respectively. If cloud ice and cloud water are allowed to co-exist over a certain temperature range, a simple (e.g. polynomial) function of temperature can be used to determine F_i. A more attractive alternative is to employ a rate equation for F_i (see e.g. Deardorff, 1976):

$$\frac{dF_i}{dt} = -\mathrm{H}\,(T_{li} - T)\,\frac{(F_i - 1)}{\tau_{li}} - \mathrm{H}\,(T - T_{il})\,\frac{F_i}{\tau_{il}}, \tag{59}$$

where H is the Heaviside step function, τ_{li} and τ_{il} are the e-folding time scales of the liquid water to ice and ice to liquid water conversion, respectively, T_{li} is a threshold temperature, below which the conversion of liquid water to ice is assumed to occur, and T_{il} a threshold temperature, above which the cloud ice melting takes place (T_{il} may be set equal to the

fresh-water freezing point). In the quantities $\mathcal{A}$, $\mathcal{P}$ and $\mathcal{Q}$ that enter Eqs. (43) and (44), $\langle q_l \rangle$ should be replaced with $\langle q_c \rangle = \langle q_l \rangle + \langle q_i \rangle$, q_{sl} should be replaced with q_{sc}, and L_v should be replaced with the effective heat of vapourization-sublimation L_c. The latter quantity may be approximated through an interpolation formula similar to Eq. (58), that is $L_c = (1 - F_i)\, L_v + F_i L_i$.

A method to account for the effect of cloud ice described above is rather crude and can only be considered as a zero-order approximation. It should still be advantageous within a parameterization scheme of shallow clouds.

8 Boundary-Layer Approximation

A simplification typically made in geophysical applications, including NWP, is the so-called boundary-layer approximation. This approximation is fairly accurate for large-scale and meso-scale atmospheric models whose grid-box aspect ratio (the ratio of the horizontal grid size to the vertical grid size) is large. Within the framework of the boundary-layer approximation, all derivatives in the x_1 and x_2 horizontal directions in the second-moment equations are neglected and the grid-box mean vertical velocity $\langle u_3 \rangle$ is zero in the second-moment equations (but not in the equations for the mean fields). The equations become one-dimensional, i.e. the flow variables depend on the x_3 vertical coordinate only.

Equations (60)–(67) presented below are obtained using the baseline parameterizations of the third-order transport, dissipation and pressure-scrambling terms in the second-moment equations. The incorporation of more advanced formulations, given in the preceeding sections under the heading ***Advanced Features***, is fairly straightforward.

With due regard for the (baseline) parameterizations of the third-order transport and the dissipation terms given in sections 5.2, 5.3 and 6, the equations for the TKE and for the scalar variances and covariance in the boundary-layer approximation are

$$\begin{aligned} \frac{\partial e}{\partial t} = & - \left(\langle u_1' u_3' \rangle \frac{\partial \langle u_1 \rangle}{\partial x_3} + \langle u_2' u_3' \rangle \frac{\partial \langle u_2 \rangle}{\partial x_3} \right) - \beta_3 \langle u_3' \theta_v' \rangle \\ & + \frac{\partial}{\partial x_3} \left(C_e^d \tau_\epsilon e \frac{\partial e}{\partial x_3} \right) - \frac{e}{\tau_\epsilon}, \end{aligned} \tag{60}$$

$$\frac{1}{2} \frac{\partial \langle \theta_l'^2 \rangle}{\partial t} = - \langle u_3' \theta_l' \rangle \frac{\partial \langle \theta_l \rangle}{\partial x_3} + \frac{1}{2} \frac{\partial}{\partial x_3} \left(C_{\theta\theta}^d \tau_\epsilon e \frac{\partial \langle \theta_l'^2 \rangle}{\partial x_3} \right) - \frac{\langle \theta_l'^2 \rangle}{2 R_\tau \tau_\epsilon}, \tag{61}$$

$$\frac{1}{2} \frac{\partial \langle q_t'^2 \rangle}{\partial t} = - \langle u_3' q_t' \rangle \frac{\partial \langle q_t \rangle}{\partial x_3} + \frac{1}{2} \frac{\partial}{\partial x_3} \left(C_{qq}^d \tau_\epsilon e \frac{\partial \langle q_t'^2 \rangle}{\partial x_3} \right) - \frac{\langle q_t'^2 \rangle}{2 R_\tau \tau_\epsilon}, \tag{62}$$

$$\frac{\partial \langle \theta_l' q_t' \rangle}{\partial t} = - \langle u_3' q_t' \rangle \frac{\partial \langle \theta_l \rangle}{\partial x_3} - \langle u_3' \theta_l' \rangle \frac{\partial \langle q_t \rangle}{\partial x_3} + \frac{\partial}{\partial x_3} \left(C_{\theta q}^d \tau_\epsilon e \frac{\partial \langle \theta_l' q_t' \rangle}{\partial x_3} \right) - \frac{\langle \theta_l' q_t' \rangle}{R_\tau \tau_\epsilon}, \tag{63}$$

where the vertical x_3 axis is aligned with the vector of gravity so that the only non-zero component of the buoyancy parameter is β_3. The virtual potential temperature flux $\langle u_i' \theta_v' \rangle$ is expressed through the fluxes of liquid water potential temperature, $\langle u_i' \theta_l' \rangle$, and the total water specific humidity, $\langle u_i' q_t' \rangle$, using Eq. (44), and the interpolation variable $\hat{\mathcal{R}}$ is computed from Eqs. (46)–(49). The TKE dissipation time scale τ_ϵ is computed from

$$\tau_\epsilon = \frac{1}{C_\epsilon} \frac{l}{e^{1/2}}, \qquad \frac{1}{l} = \frac{1}{\kappa x_3} + \frac{1}{l_\infty} + \mathrm{H}\left(N^2\right) \frac{N}{C_{lb} e^{1/2}}. \tag{64}$$

In the atmospheric flows, the Coriolis terms in the Reynolds-stress and scalar-flux equations are typically small and can safely be neglected. With due regard for the (baseline) parameterizations of pressure-scrambling terms given in section 5.1 (the deviatoric part of the Reynolds-stress dissipation rate and the dissipation rates of temperature and humidity fluxes are incorporated into the slow parts of the respective pressure-scrambling terms), the algebraic equations for the departure-from-isotropy tensor (and hence for the Reynolds stress) and for the scalar fluxes in the boundary-layer approximation are

$$\begin{aligned}
&C_t^u a_{ij} + (1 - C_{s2}^u)\,\tau_\epsilon \left(a_{ik}S_{jk} + a_{jk}S_{ik} - \frac{2}{3}\delta_{ij}a_{km}S_{km} \right) \\
&+ (1 - C_{s3}^u)\,\tau_\epsilon \left(a_{ik}W_{jk} + a_{jk}W_{ik} \right) \\
&+ (1 - C_b^u)\,\tau_\epsilon \left(\delta_{i3}\beta_3 \left\langle u_j'\theta_v' \right\rangle + \delta_{j3}\beta_3 \left\langle u_i'\theta_v' \right\rangle - \frac{2}{3}\delta_{ij}\beta_3 \left\langle u_3'\theta_v' \right\rangle \right) \\
&= -\left(\frac{4}{3} - C_{s1}^u \right) \tau_\epsilon e S_{ij},
\end{aligned} \tag{65}$$

$$\begin{aligned}
&C_t^\theta \left\langle u_i'\theta_l' \right\rangle + a_{i3}\tau_\epsilon \frac{\partial \left\langle \theta_l \right\rangle}{\partial x_3} + \tau_\epsilon \left[\left(1 - C_{s1}^\theta \right) S_{ik} + \left(1 - C_{s2}^\theta \right) W_{ik} \right] \left\langle u_k'\theta_l' \right\rangle \\
&= -\frac{2}{3}\tau_\epsilon e \delta_{i3} \frac{\partial \left\langle \theta_l \right\rangle}{\partial x_3} - \left(1 - C_b^\theta \right) \tau_\epsilon \delta_{i3}\beta_3 \left\langle \theta_l'\theta_v' \right\rangle,
\end{aligned} \tag{66}$$

$$\begin{aligned}
&C_t^q \left\langle u_i'q_t' \right\rangle + a_{i3}\tau_\epsilon \frac{\partial \left\langle q_t \right\rangle}{\partial x_3} + \tau_\epsilon \left[(1 - C_{s1}^q) S_{ik} + (1 - C_{s2}^q) W_{ik} \right] \left\langle u_k'q_t' \right\rangle \\
&= -\frac{2}{3}\tau_\epsilon e \delta_{i3} \frac{\partial \left\langle q_t \right\rangle}{\partial x_3} - \left(1 - C_b^q \right) \tau_\epsilon \delta_{i3}\beta_3 \left\langle q_t'\theta_v' \right\rangle,
\end{aligned} \tag{67}$$

where the covariances $\langle u_i'\theta_v' \rangle$, $\langle \theta_l'\theta_v' \rangle$ and $\langle q_t'\theta_v' \rangle$ incorporating the virtual potential temperature are expressed through $\langle u_i'\theta_l' \rangle$ and $\langle u_i'q_t' \rangle$, $\langle \theta_l'^2 \rangle$ and $\langle \theta_l'q_t' \rangle$, and $\langle q_t'^2 \rangle$ and $\langle \theta_l'q_t' \rangle$, respectively, using Eq. (44). Within the framework of the boundary-layer approximation, $S_{13} = S_{31} = W_{13} = -W_{31} = \frac{1}{2}\partial \langle u_1 \rangle / \partial x_3$, $S_{23} = S_{32} = W_{23} = -W_{32} = \frac{1}{2}\partial \langle u_2 \rangle / \partial x_3$, and other components of S_{ij} and W_{ij} are zero. Estimates of disposable constants and parameters of TKESV-Bas are summarized in Appendix B.

Equations (65)–(67) constitute a system of 12 linear equations for a_{ij} (six independent components), $\langle u_i'\theta_l' \rangle$ (three independent components), and $\langle u_i'q_t' \rangle$ (three independent components). This system is readily solved, yielding explicit expressions for the Reynolds stress and scalar fluxes. Unfortunately, the solution to Eqs. (65)–(67) is non-realizable. That is, it yields physically meaningless values of a_{ij} (and hence of $\langle u_i'u_j' \rangle$), $\langle u_i'\theta_l' \rangle$ and $\langle u_i'q_t' \rangle$, such as infinite scalar fluxes or negative velocity variances, over a certain range of governing parameters (e.g. mean velocity shear and mean temperature gradient). A plausible way to circumvent these difficulties is considered in the next section.

9 The (So-Called) Stability Functions

The system of linear equations (65)–(67) yields explicit expressions for the Reynolds-stress and scalar-flux components. The expressions for $\langle u_3'u_1' \rangle$ and $\langle u_3'u_2' \rangle$ (components of the vertical flux of horizontal momentum) have the following down-gradient form:

$$\left\langle u_3'u_1' \right\rangle = -\mathcal{F}_{\mathrm{M}}\tau_\epsilon e \frac{\partial \left\langle u_1 \right\rangle}{\partial x_3}, \qquad \left\langle u_3'u_2' \right\rangle = -\mathcal{F}_{\mathrm{M}}\tau_\epsilon e \frac{\partial \left\langle u_2 \right\rangle}{\partial x_3}. \tag{68}$$

The expressions for the vertical scalar fluxes contain both the down-gradient terms and the non-gradient terms that describe the generation of scalar fluxes by buoyancy:

$$\left\langle u_3'\theta_l'\right\rangle = -\mathcal{F}_{\mathrm{H1}}\tau_\epsilon e\frac{\partial\left\langle\theta_l\right\rangle}{\partial x_3} - \mathcal{F}_{\mathrm{H2}}\tau_\epsilon\beta_3\left\langle\theta_l'\theta_v'\right\rangle, \tag{69}$$

$$\left\langle u_3'q_t'\right\rangle = -\mathcal{F}_{\mathrm{H1}}\tau_\epsilon e\frac{\partial\left\langle q_t\right\rangle}{\partial x_3} - \mathcal{F}_{\mathrm{H2}}\tau_\epsilon\beta_3\left\langle q_t'\theta_v'\right\rangle, \tag{70}$$

where the covariances $\langle\theta_l'\theta_v'\rangle$ and $\langle q_t'\theta_v'\rangle$ are expressed through $\langle\theta_l'^2\rangle$ and $\langle\theta_l'q_t'\rangle$ and $\langle q_t'^2\rangle$ and $\langle\theta_l'q_t'\rangle$, respectively, using Eq. (44). The quantities $\mathcal{F}_{\mathrm{M}}$, $\mathcal{F}_{\mathrm{H1}}$ and $\mathcal{F}_{\mathrm{H2}}$ are referred to as the "stability functions" (Mellor and Yamada, 1974). It should be emphasized at once that the stability functions are merely the notation introduced to represent the formulations of fluxes in a compact from. Basically, $\mathcal{F}_{\mathrm{M}}$, $\mathcal{F}_{\mathrm{H1}}$ and $\mathcal{F}_{\mathrm{H2}}$ reflect the parameterization assumptions invoked to arrive at the algebraic Reynolds-stress and scalar-flux equations, first of all, the parameterizations of the pressure-scrambling terms.

The functions $\mathcal{F}_{\mathrm{M}}$ and $\mathcal{F}_{\mathrm{H1}}$ that appear in the down-gradient terms in Eqs. (68)–(70) are functions of three dimensionless parameters. These are the squared dimensionless shear $(\tau_\epsilon S)^2$, the squared dimensionless buoyancy frequency $(\tau_\epsilon N)^2$, and the potential to kinetic energy ratio P/e. Here, S^2, N^2 and P are given by

$$S^2 = \left(\frac{\partial\left\langle u_1\right\rangle}{\partial x_3}\right)^2 + \left(\frac{\partial\left\langle u_2\right\rangle}{\partial x_3}\right)^2, \tag{71}$$

$$N^2 = -\beta_3\left(\mathcal{I}_\theta\frac{\partial\left\langle\theta_l\right\rangle}{\partial x_3} + \mathcal{I}_q\frac{\partial\left\langle q_t\right\rangle}{\partial x_3}\right), \tag{72}$$

$$P = \tau_\epsilon^2\beta_3^2\left[\mathcal{I}_\theta\left(\mathcal{I}_\theta\left\langle\theta_l'^2\right\rangle + \mathcal{I}_q\left\langle\theta_l'q_t'\right\rangle\right) + \mathcal{I}_q\left(\mathcal{I}_q\left\langle q_t'^2\right\rangle + \mathcal{I}_\theta\left\langle\theta_l'q_t'\right\rangle\right)\right], \tag{73}$$

$$\mathcal{I}_\theta = 1 + (R-1)\left\langle q_t\right\rangle - R\left\langle q_l\right\rangle - \hat{\mathcal{R}}\frac{\mathcal{A}\mathcal{P}}{\mathcal{Q}}, \qquad \mathcal{I}_q = (R-1)\left\langle\theta\right\rangle + \hat{\mathcal{R}}\frac{\mathcal{A}}{\mathcal{Q}}, \tag{74}$$

where $\mathcal{A}$, $\mathcal{P}$, $\mathcal{Q}$ and $\hat{\mathcal{R}}$ are defined in section 7. The quantity P characterizes potential energy of the turbulent flow and may be referred to as the turbulence potential energy[4]. Note that the buoyancy frequency and the TPE appear to depend on the interpolation variable $\hat{\mathcal{R}}$ and hence on the fractional cloud cover. As discussed in section 7, the covariances incorporating fluctuation of the virtual potential temperature cannot be computed exactly in the general case of fractional cloudiness. It is the use of the interpolation formula (44) to determine $\langle u_i'\theta_v'\rangle$, $\langle\theta_l'\theta_v'\rangle$ and $\langle q_t'\theta_v'\rangle$ that leads to the interpolation formulae (72) and (73) for N^2 and P, respectively. Instead of $(\tau_\epsilon S)^2$ and $(\tau_\epsilon N)^2$, $\mathcal{F}_{\mathrm{M}}$ and $\mathcal{F}_{\mathrm{H1}}$ can be presented in terms of $(\tau_\epsilon S)^2$ [or $(\tau_\epsilon N)^2$] and the gradient Richardson number $Ri = N^2/S^2$. The stability function $\mathcal{F}_{\mathrm{H2}}$ that appears in the non-gradient terms in Eqs. (69) and (70) depends on $(\tau_\epsilon S)^2$ and $(\tau_\epsilon N)^2$, or, alternatively, on $(\tau_\epsilon S)^2$ [or $(\tau_\epsilon N)^2$] and Ri, but does not depend on P/e.

The stability functions resulting from Eqs. (68)–(70) are ill-behaved over a certain range of governing parameters. Figure 2 shows $\mathcal{F}_{\mathrm{M}}$ and $\mathcal{F}_{\mathrm{H1}}$ as dependent on Ri and $(\tau_\epsilon S)^2$ at a fixed value of P/e. As seen from the figure, the stability functions have physically meaningless values, i.e. they tend to infinity or become negative over a part of their parameter

[4]Other definitions of TPE have also been used in the analyses of atmospheric turbulence, see Appendix C for a brief discussion.

space. The scalar-flux stability function $\mathcal{F}_{\mathrm{H2}}$ (not shown) is well-behaved and poses no complications. The expressions of $\mathcal{F}_{\mathrm{M}}$, $\mathcal{F}_{\mathrm{H1}}$ and $\mathcal{F}_{\mathrm{H2}}$ are rather lengthy and are not presented in this section. However, those expressions are drastically simplified in the case of shear-free (and rotation-free) flow, and the ill-behaviour of the stability functions can be easily demonstrated analytically. The analysis is presented in Appendix D.

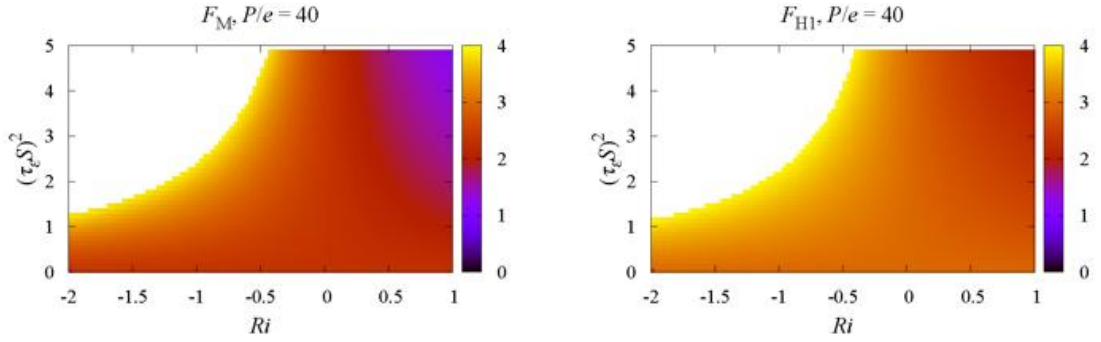

Figure 2: The momentum-flux $\mathcal{F}_{\mathrm{M}}$ (left panel) and the scalar-flux $\mathcal{F}_{\mathrm{H1}}$ (right panel) stability functions of the TKESV scheme as dependent on Ri and $(\tau_\epsilon S)^2$ at a fixed value of $P/e = 40$. The functions are computed with the estimates of dimensionless constants given in Table 1 (Appendix B), where the estimates of $C^u_{s2} = 3/5$ and $C^u_{s3} = 13/15$ are used. The values of $\mathcal{F}_{\mathrm{M}}$ and $\mathcal{F}_{\mathrm{H1}}$ are indicated by the colour scale. The white area is a part of the parameter space where the stability functions are ill-behaved.

In order to obtain the Reynolds-stress and scalar-flux formulations that remain in force over the entire parameter space, the stability functions should be modified (regularized) in one way or the other. A straightforward approach is to simply impose the upper and lower bounds on the stability functions themselves. Alternatively, realizability constraints may be imposed on the arguments, e.g. on $(\tau_\epsilon S)^2$ and $(\tau_\epsilon N)^2$, so that the stability functions cannot become infinite or negative (see e.g. Mellor and Yamada, 1982; Hassid and Galperin, 1994). These methods applied within the framework a one-equation TKE scheme may lead to either the model blow-up or to physically implausible solutions (Helfand and Labraga, 1988). One more method is to replace the ill-behaved stability functions with more simple functions that reveal no pathological behaviour. For example, the stability functions of the algebraic turbulence parameterization scheme, where all second-moment equations (including the TKE equation) are reduced to the diagnostic algebraic formulations, are well-behaved over their entire parameter space. The use of the algebraic-scheme stability functions within the one-equation TKE scheme yields regular solutions. However, the adjustment of the TKE towards the production-dissipation equilibrium state occurs on a too short time scale. In other words, turbulence responds too quickly to changes in the shear and buoyancy forcing. A more detailed discussion of the above (and some other) regularization methods is given in Helfand and Labraga (1988) (see also Hanjalić and Launder, 2011; Lazeroms et al., 2013, 2015, 2016).

An appealing way to tackle the problem was proposed by Helfand and Labraga (1988) (see also du Vachat, 1989; Helfand and Labraga, 1989). These authors analyzed the stability functions of the one-equation TKE scheme. Using rather plausible physical arguments, they developed regularized functions that reveal no pathological behaviour over their entire parameter space. In what follows, we extend the approach of Helfand and Labraga to the

TKESV scheme[5]. Following Helfand and Labraga (1988), we adhere to the Mellor and Yamada terminology (Mellor and Yamada, 1974, 1982; Yamada, 1977). The level 3 refers to the TKESV-like schemes that carry transport equations for the TKE and for the scalar variances and covariance, and the level 2 refers to the schemes, where all second-moment equations are reduced to the diagnostic algebraic formulations. One-equation TKE schemes are referred to as the level 2.5 schemes.

Within the framework of the level 2.5 scheme, the scalar-variance and scalar-covariance transport equations are truncated to the diagnostic expressions reflecting the steady-state balance between the mean-gradient production and the dissipation. The vertical scalar fluxes are given by the following down-gradient formulations:

$$\left\langle u_3' \theta_l' \right\rangle = -\mathcal{F}_{\mathrm{H}}^{2.5} \tau_\epsilon e \frac{\partial \left\langle \theta_l \right\rangle}{\partial x_3}, \qquad \left\langle u_3' q_t' \right\rangle = -\mathcal{F}_{\mathrm{H}}^{2.5} \tau_\epsilon e \frac{\partial \left\langle q_t \right\rangle}{\partial x_3}, \tag{75}$$

where $\mathcal{F}_{\mathrm{H}}^{2.5}$ is the level 2.5 scalar-flux stability function. The momentum-flux components $\langle u_3' u_1' \rangle$ and $\langle u_3' u_2' \rangle$ are given by Eqs. (68), where $\mathcal{F}_{\mathrm{M}}$ is replaced with the level 2.5 stability function $\mathcal{F}_{\mathrm{M}}^{2.5}$. The level 2.5 stability functions depend on $(\tau_\epsilon S)^2$ and $(\tau_\epsilon N)^2$, or, alternatively, on $(\tau_\epsilon S)^2$ [or $(\tau_\epsilon N)^2$] and Ri. The level 2.5 functions suffer from the same deficiencies as the level 3 functions, i.e. they are ill-behaved over a part of their parameter space.

Helfand and Labraga (1988) recast the functions $\mathcal{F}_{\mathrm{M}}^{2.5}\left(Ri, \tau_\epsilon^2 S^2\right)$ and $\mathcal{F}_{\mathrm{H}}^{2.5}\left(Ri, \tau_\epsilon^2 S^2\right)$ in terms of Ri and the ratio e/e_e of the actual TKE $e = e_{2.5}$ of the level 2.5 scheme (hence the subscript) to the equilibrium value of the TKE $e_e = e_2$ of the level 2 scheme. Within the framework of the level 2 scheme, all second-moment transport equations, including the TKE equation, are truncated to the diagnostic expressions by neglecting the time-rate-of-change, advection and third-order transport terms. That is, all second-order moments, including the TKE, are in the state of local production-destruction equilibrium. In order to change the variables $\left(Ri, \tau_\epsilon^2 S^2\right)$ to the variables $(Ri, e/e_e)$, the equality $\tau_\epsilon^2 S^2 = \left(\tau_\epsilon/\tau_{\epsilon e}\right)^2 \tau_{\epsilon e}^2 S^2 = \left(e_e/e\right) \tau_{\epsilon e}^2 S^2$ is used, where $\tau_{\epsilon e}$ is the equilibrium TKE dissipation time scale, i.e. τ_ϵ computed with e_e. The value of e_e, and hence of $\tau_{\epsilon e}^2 S^2$, for a given Ri is found by solving the equilibrium TKE equation of the level 2 scheme, which is a quadratic equation in e_e (in $\tau_{\epsilon e}^2 S^2$). Since the stability functions $\mathcal{F}_{\mathrm{M}}^2$ and $\mathcal{F}_{\mathrm{H}}^2$ are well-behaved over their entire parameter space (any value of Ri), a physically meaningful solution $e_e = e_2$ can always be found. Helfand and Labraga (1988) noticed that $\mathcal{F}_{\mathrm{M}}^{2.5}$ and $\mathcal{F}_{\mathrm{H}}^{2.5}$ become pathological in the case of growing turbulence, $e/e_e < 1$, where the TKE production (locally) dominates over the TKE dissipation. Figure 3 illustrates the pathological behaviour of the level 2.5 stability functions on the $Ri \times e/e_e$ plane. Note that $\mathcal{F}_{\mathrm{M}}^{2.5}$ and $\mathcal{F}_{\mathrm{H}}^{2.5}$ are computed with the estimates of dimensionless constants of TKESV-Bas (where $C_{s2}^u = 3/5$ and $C_{s3}^u = 13/15$), which are somewhat different from the estimates used by Helfand and Labraga (1988). As seen from the figure, $\mathcal{F}_{\mathrm{M}}^{2.5}$ and $\mathcal{F}_{\mathrm{H}}^{2.5}$ are well-behaved in the case of equilibrium or decaying turbulence, $e/e_e \geq 1$, but become pathological at $e/e_e < 1$.

The failure of the level 2.5 scheme is attributed to the closure assumptions used to develop the scheme, namely, (i) the neglect of the substantial derivative and the third order transport of the Reynolds stress, scalar fluxes and scalar variances and covariance, and (ii) the use of linear formulations of the pressure-scrambling terms in the Reynolds-stress and scalar-flux equations (see further discussion at the end of the present section). These closure assumptions are valid for the flows where turbulence is not far from the stationary, homogeneous, and isotropic state. Helfand and Labraga (1988) argue that it is precisely in the regime of growing TKE, where $e/e_e < 1$, that the turbulence becomes strongly anisotropic (also

[5]Helfand and Labraga (1988) considered dry atmosphere, where θ is the only thermodynamic variable that affects buoyancy. Our analysis deals with the moist atmosphere, using thermodynamic variables θ_l and q_t.

non-stationary and possibly non-homogeneous) and the above assumptions are too crude, leading to the ill-behaviour of the stability functions and to non-realizability of the turbulence closure scheme. In order to remedy the situation, Helfand and Labraga proposed to account, in an approximate way, for the effects of time-rate-of-change, advection and diffusion in those truncated second-moment equations in which these effects have been neglected. In other words, the idea is to restore to the second-moment equations some information that has been lost because of truncation. The following approximation was proposed:

$$\frac{d\mathcal{M}/dt + \mathcal{D}_\mathcal{M}}{\mathcal{G}_\mathcal{M}} = \frac{de/dt + \mathcal{D}_e}{\mathcal{G}_e}. \tag{76}$$

Here, $\mathcal{M}$ stands for the Reynolds stress, scalar fluxes, and (within the framework of the level 2.5 scheme) scalar variances and covariance, d/dt is the substantial derivative that coincides with $\partial/\partial t$ within the framework of the boundary-layer approximation, $\mathcal{D}$ is the diffusion rate of the respective second-order moment, and $\mathcal{G}$ is its production (generation) rate. The production rate $\mathcal{G}_\mathcal{M}$ includes the terms due to mean velocity shear and buoyancy (in the Reynolds-stress and scalar-flux equations), and due to mean scalar gradients (in the scalar-flux, scalar-variance and scalar-covariance equations). It should be mentioned that within the framework of the Helfand and Labraga approach the production rate is defined with due regard for the rapid parts of the pressure-scrambling terms. Equation (76) states that the ratio of the tendency of the second-order moment $\mathcal{M}$ due to d/dt and $\mathcal{D}$ to the production rate of $\mathcal{M}$ is the same as the respective ratio for the TKE.

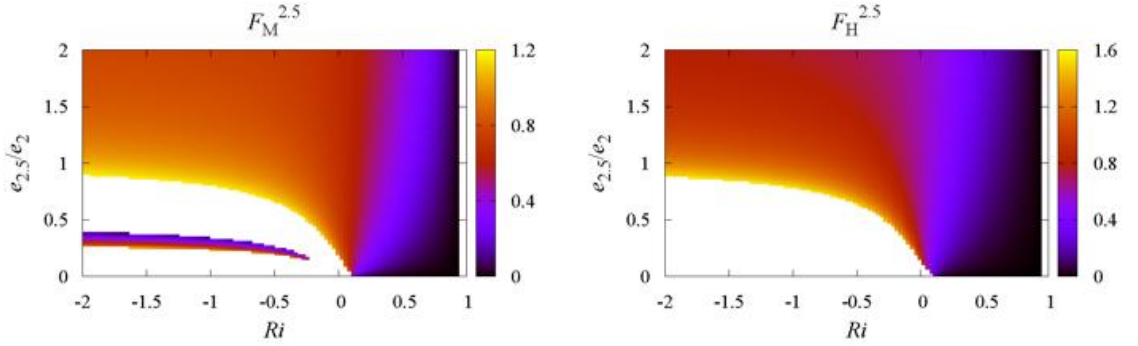

Figure 3: The stability functions of the level 2.5 scheme as dependent on Ri and $e/e_e = e_{2.5}/e_2$. The values of $\mathcal{F}_\mathrm{M}^{2.5}$ and $\mathcal{F}_\mathrm{H}^{2.5}$ are indicated by the colour scale. The white area is a part of the parameter space where the stability functions are ill-behaved.

Some comments on the validity of Eq. (76) are in order. Equation (76) is obviously exact in the regime of production-destruction equilibrium. In this regime, the production rate of any moment $\mathcal{M}$, including the TKE, is balanced by the destruction rate of $\mathcal{M}$ due to return-to-isotropy ($\mathcal{M}$ stands for the Reynolds stress or scalar flux) or viscous dissipation ($\mathcal{M}$ stands for the scalar variance, scalar covariance, or TKE). In the regime of production-destruction equilibrium, both the r.h.s. and the l.h.s. of Eq. (76) are zero. Equation (76) is also valid asymptotically if the production rate of the moment $\mathcal{M}$ strongly dominates over its destruction rate. A transport equation for $\mathcal{M}$ can be written in the following form:

$$\frac{d\mathcal{M}/dt + \mathcal{D}_\mathcal{M}}{\mathcal{G}_\mathcal{M}} = 1 - \frac{\epsilon_\mathcal{M}}{\mathcal{G}_\mathcal{M}}, \tag{77}$$

where $\epsilon_{\mathcal{M}}$ denotes the destruction rate of the moment $\mathcal{M}$. The r.h.s. of Eq. (77) approaches one as the ratio $\epsilon_{\mathcal{M}}/\mathcal{G}_{\mathcal{M}}$ tends to zero. If the ratio $\epsilon/\mathcal{G}_e$ for the TKE also tends to zero, both the r.h.s. and the l.h.s. of Eq. (76) approach one. In the real-world flows, this never holds exactly. However, $\epsilon_{\mathcal{M}}/\mathcal{G}_{\mathcal{M}} \ll 1$ may hold approximately following a rapid increase of forcing (by mean scalar gradient, mean velocity shear, or buoyancy), i.e. precisely in the regime of growing turbulence.

Using Eq. (76), the truncated, algebraic equations of the level 2.5 scheme can be modified to approximately account for (mimic) the effects of the time-rate-of-change and turbulent diffusion. To this end, approximations $d\mathcal{M}/dt + \mathcal{D}_{\mathcal{M}} = \alpha_e \mathcal{G}_{\mathcal{M}}$, where $\alpha_e = (de/dt + \mathcal{D}_e)/\mathcal{G}_e$ is known from the solution of the TKE equation, are added to the Reynolds-stress, scalar-flux and scalar-variance equations (recall that $d/dt = \partial/\partial t$ within the framework of the boundary-layer approximation). In substance, these modifications amount to multiplying the production terms in the algebraic equations by a factor $1 - \alpha_e$. The resulting system of the Reynolds-stress, scalar-flux and scalar-variance equations remains algebraic and linear. It is readily solved (see Helfand and Labraga, 1988, for details), giving the following expressions for the stability functions of the level 2.5 scheme:

$$\mathcal{F}_{\mathrm{M}}^{2.5} = \mathcal{F}_{\mathrm{Mr}}^{2.5} = \mathcal{F}_{\mathrm{M}}^{2} \left(\frac{e_{2.5}}{e_2} \right)^{1/2}, \qquad \mathcal{F}_{\mathrm{H}}^{2.5} = \mathcal{F}_{\mathrm{Hr}}^{2.5} = \mathcal{F}_{\mathrm{H}}^{2} \left(\frac{e_{2.5}}{e_2} \right)^{1/2}, \tag{78}$$

where the subscript "r" indicates the modified (regularized) stability functions. The regularized functions given by Eq. (78) are used in the case of growing turbulence, when the actual value of TKE $e_{2.5}$ of the level 2.5 scheme is less than the equilibrium TKE e_2 of the level 2 scheme. In the case of equilibrium or decaying turbulence, the original, non-modified stability functions of the level 2.5 scheme are used that are well-behaved at $e_{2.5}/e_2 \geq 1$ and pose no problem. Recall that the stability functions $\mathcal{F}_{\mathrm{M}}^2$ and $\mathcal{F}_{\mathrm{H}}^2$ of the level 2 algebraic scheme are well-behaved over their entire parameter space, and e_2 is found by solving the equilibrium TKE equation (a quadratic equation in e_2 that always has a physically meaningful solution). Figure 4 illustrates the regularized stability functions of the level 2.5 scheme that reveal no pathological behaviour.

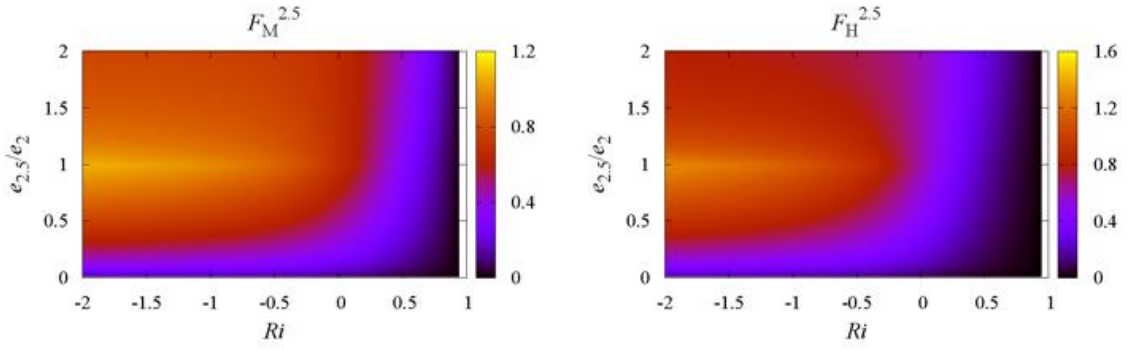

Figure 4: The regularized stability functions of the level 2.5 scheme as dependent on Ri and $e/e_e = e_{2.5}/e_2$. The values of $\mathcal{F}_{\mathrm{M}}^{2.5}$ and $\mathcal{F}_{\mathrm{H}}^{2.5}$ are indicated by the colour scale. In the case of growing turbulence, $e_{2.5}/e_2 < 1$, the stability functions are computed from Eq. (78).

The regularization method of Helfand and Labraga (1988) is now applied to the TKESV (level 3) scheme. Using Eq. (76), the Reynolds-stress and scalar-flux equations are modified, and the resulting system of algebraic equations for a_{ij}, $\langle u_i' \theta_l' \rangle$ and $\langle u_i' q_l' \rangle$ is solved (the

derivations are rather cumbersome and are omitted here). The following expressions of the stability functions $\mathcal{F}_{\mathrm{M}} = \mathcal{F}^3_{\mathrm{M}}$ and $\mathcal{F}_{\mathrm{H1}} = \mathcal{F}^3_{\mathrm{H1}}$ in Eqs. (68)–(70) are obtained (index "3" refers to the level 3, i.e. to the TKESV, scheme):

$$\mathcal{F}^3_{\mathrm{M}} = \mathcal{F}^3_{\mathrm{Mr}} = \mathcal{F}^{2.p}_{\mathrm{M}} \left(\frac{e_3}{e_{2.p}} \right)^{1/2}, \qquad \mathcal{F}^3_{\mathrm{H1}} = \mathcal{F}^3_{\mathrm{H1r}} = \mathcal{F}^{2.p}_{\mathrm{H1}} \left(\frac{e_3}{e_{2.p}} \right)^{1/2}, \tag{79}$$

where the subscript "r" indicates the regularized stability functions. In Eq. (79), the index "2.p" refers to the scheme that utilizes the equilibrium TKE equation but carries transport equations for the scalar variances and scalar covariance. That is, the TKE is determined diagnostically using the steady-state production-dissipation balance, whereas the scalar variances and covariance (and hence the TPE) are determined prognostically with due regard for the third-order turbulent transport[6]. The stability functions $\mathcal{F}^{2.p}_{\mathrm{M}}$ and $\mathcal{F}^{2.p}_{\mathrm{H1}}$ of the level 2.p scheme are well-behaved over their entire parameter space. The equilibrium TKE $e_e = e_{2.p}$ is found by solving the equilibrium TKE equation of the level 2.p scheme, which is a cubic equation in e_e. The regularized stability functions given by Eq. (79) are used in the case of growing turbulence, when $e_3/e_{2.p} < 1$. In the case of equilibrium or decaying turbulence, the original, non-modified stability functions of the level 3 (TKESV) scheme are used which are well-behaved at $e_3/e_{2.p} \geq 1$ and pose no problem.

Figure 5 shows the original, non-modified stability functions of the TKESV (level 3) scheme on the $Ri \times e_3/e_{2.p}$ plane at a fixed value of P/e_3. The stability functions are well-behaved in the case of equilibrium or decaying turbulence, $e_3/e_{2.p} \geq 1$, but become pathological in the case of growing turbulence, $e_3/e_{2.p} < 1$. Figure 6 shows the regularized stability functions of the TKESV (level 3) scheme. As seen from the figure, the stability functions reveal no pathological behaviour.

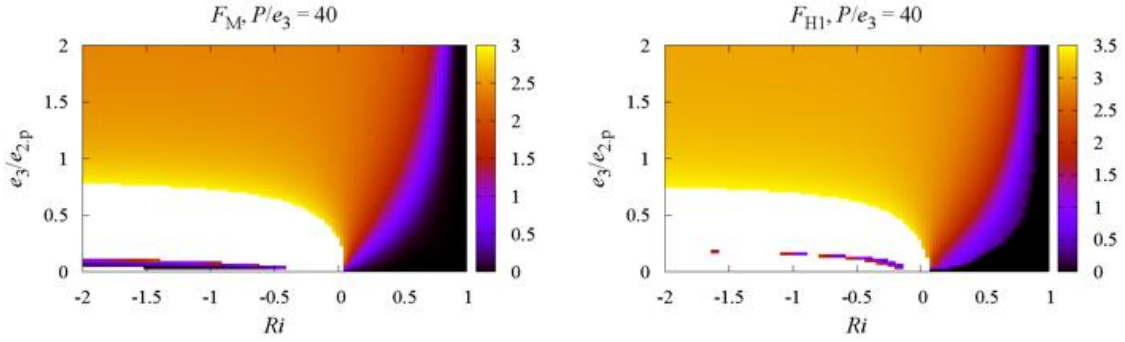

Figure 5: The original, non-regularized momentum-flux $\mathcal{F}_{\mathrm{M}} = \mathcal{F}^3_{\mathrm{M}}$ (left panel) and scalar-flux $\mathcal{F}_{\mathrm{H1}} = \mathcal{F}^3_{\mathrm{H1}}$ (right panel) stability functions of the TKESV (level 3) scheme as dependent on Ri and $e_3/e_{2.p}$ at a fixed value of $P/e_3 = 40$. The values of stability functions are indicated by the colour scale. The white area is a part of the parameter space where the stability functions are ill-behaved.

It is interesting to draw analogies between Eq. (78) and Eq. (79). As Eq. (78) shows, the regularized level 2.5 stability functions are expressed in terms of the level 2 stability

[6]The letter "p" in the label "2.p" is used to indicate potential energy. In a similar spirit, the level 2.5 scheme may be referred to as the "level 2.k" scheme, where "k" indicates kinetic energy, or, alternatively, the "level 2.e" scheme, where "e" is a conventional notation for the TKE.

functions. For the level 2.5 scheme, the level 2 scheme is the nearest lower-level realizable scheme whose stability functions are well-behaved over the entire parameter space. Likewise, for the level 3 scheme, the level 2.p scheme is the nearest lower-level realizable scheme. The level 2 and the level 2.p schemes differ significantly in the way they treat the scalar variances and covariance. However, both the level 2 and the level 2.p schemes utilize a steady-state equilibrium TKE equation, suggesting that it is the use of the TKE transport equation in combination with the algebraic formulations of the Reynolds stress and scalar fluxes that causes non-realizability of truncated turbulence closure schemes.

Note an important factor $(e_3/e_{2.p})^{1/2}$ in the expressions of the regularized level 3 stability functions, Eq. (79). It is this factor that takes care of a gradual transition of the TKE towards the production-dissipation equilibrium. Dropping the factor $(e_3/e_{2.p})^{1/2}$ in Eq. (79) would result in a too quick response of turbulence to changes in the forcing and in overestimation of momentum and scalar fluxes in the regime of growing TKE. The factor $(e_{2.5}/e_2)^{1/2}$ in Eq. (78) has a similar effect on the behaviour of the level 2.5 scheme.

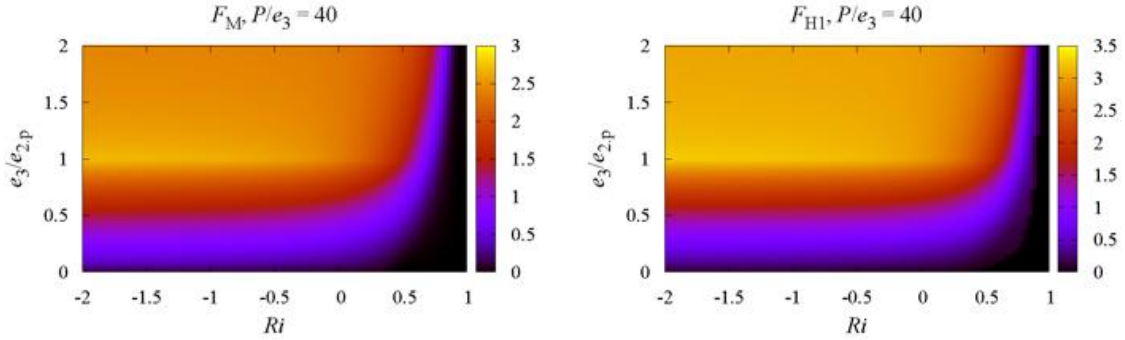

Figure 6: The regularized momentum-flux $\mathcal{F}_{\rm M} = \mathcal{F}^3_{{\rm M}r}$ (left panel) and scalar-flux $\mathcal{F}_{\rm H1} = \mathcal{F}^3_{{\rm H1}r}$ (right panel) stability functions of the TKESV (level 3) scheme as dependent on Ri and $e/e_e = e_3/e_{2.p}$ at a fixed value of $P/e_3 = 40$. The values of stability functions are indicated by the colour scale. In the case of growing turbulence, $e_3/e_{2.p} < 1$, the stability functions are computed from Eq. (79).

The idea of the regularization method of Helfand and Labraga (1988) is to restore to the second-moment equations some information that has been lost because of truncation. Equation (76) is used to approximately account for (mimic) the effects of the time-rate-of-change and turbulent diffusion in the Reynolds-stress and scalar-flux (and, in the case of level 2.5 scheme, in the scalar-variance and scalar-covariance) equations. An alternative interpretation can be suggested, however. As discussed above, the use Eq. (76) amounts to multiplying the production terms in the truncated equations by a factor $1-\alpha_e$, where $\alpha_e = (de/dt + \mathcal{D}_e)/\mathcal{G}_e$ depends on time t and vertical coordinate x_3. Consider, for example, the buoyancy production term in the liquid water potential temperature flux equation (66),

$$-\left(1 - C_b^\theta\right) \tau_\epsilon \beta_3 \left\langle \theta_l' \theta_v' \right\rangle , \tag{80}$$

where C_b^θ is a constant that stems from a linear model of the buoyancy contribution to the pressure-scrambling term in the temperature-flux equation. Recall that the use of linear parameterizations of the pressure-scrambling terms is identified as one reason for the failure

of truncated second-order schemes. If Eq. (76) is utilized, the buoyancy production term in the temperature-flux equation becomes

$$-\left[1-\alpha_e\left(t,x_3\right)\right]\left(1-C_b^\theta\right)\tau_\epsilon\beta_3\left\langle\theta_l'\theta_v'\right\rangle=-\left[1-C_{b*}^\theta\left(t,x_3\right)\right]\tau_\epsilon\beta_3\left\langle\theta_l'\theta_v'\right\rangle, \tag{81}$$

where $C_{b*}^\theta=C_b^\theta+\alpha_e\left(1-C_b^\theta\right)$ is no longer a constant, but a function of t and x_3. Note that $C_{b*}^\theta=C_b^\theta$ if $\alpha_e=0$, and the original, non-regularized formulation is recovered. If $\alpha_e=1$, then $C_{b*}^\theta=1$, which effectively satisfies the two-component limit constraint of strongly anisotropic turbulence. As discussed in section 5.1, it is not possible to satisfy the TCL constraint within the framework of a linear model of the pressure-scrambling terms if the value of C_b^θ is chosen so that to satisfy the isotropic limit. If Eq. (76) is utilized to modify the truncated temperature-flux equation, both the isotropic and the TCL constraints can be satisfied. Then, the Helfand and Labraga regularization procedure can be viewed as being conceptually similar to the use of non-linear parameterizations of the pressure-scrambling effects.

To conclude this section, we note that the regularized expressions have been obtained for all components of the Reynolds stress and scalar fluxes, not only for $\langle u_3'u_1'\rangle$, $\langle u_3'u_2'\rangle$, $\langle u_3'\theta_l'\rangle$, and $\langle u_3'q_t'\rangle$. Those regularized formulations are not presented here.

10 Interaction with the Underlying Surface

In order to describe the interaction of the boundary-layer turbulence with the underlying surface, the surface fluxes of momentum, heat and moisture should be specified and the boundary conditions for the TKE, scalar variances and scalar covariance should be imposed. The surface fluxes are assumed to be provided by the host atmospheric model (e.g. COSMO or ICON). A consideration of the surface flux calculation procedures is beyond the scope of the present report.

For the TKE, scalar-variance and scalar-covariance, the following boundary conditions at the underlying surface are used in the TKESV-Bas scheme:

$$-C_e^d\tau_\epsilon e\frac{\partial e}{\partial x_3}=0, \tag{82}$$

$$-C_{\theta\theta}^d\tau_\epsilon e\frac{\partial\left\langle\theta_l'^2\right\rangle}{\partial x_3}=0,\qquad -C_{qq}^d\tau_\epsilon e\frac{\partial\left\langle q_t'^2\right\rangle}{\partial x_3}=0,\qquad -C_{\theta q}^d\tau_\epsilon e\frac{\partial\left\langle\theta_l'q_t'\right\rangle}{\partial x_3}=0. \tag{83}$$

Equations (82) and (83) state that the fluxes of TKE, scalar variances and scalar covariance at the underlying surface are zero. That is, e, $\left\langle\theta_l'^2\right\rangle$, $\left\langle q_t'^2\right\rangle$ and $\left\langle\theta_l'q_t'\right\rangle$ are height-constant within the layer immediately adjacent to the underlying surface. This is consistent with the surface-layer similarity (cf. the log-layer relationships given in Appendix A). Notice, however, that the surface-layer relationships (the Monin-Obukhov similarity theory) are applicable to continuous turbulence over a homogeneous surface, and it is, strictly speaking, incorrect to apply the surface-layer similarity relationships over heterogeneous surfaces. Then, the boundary conditions (82) and (83) become inaccurate if a tile approach is used to compute the grid-box mean surface fluxes.

Advanced Features

In order to develop the surface boundary conditions for the scalar variances and covariance that are consistent with the tiled surface schemes, we make use of the following triple

decomposition:

$$f = \langle \overline{f} \rangle + \overline{f}'' + f^s, \tag{84}$$

where f is a generic variable. The angle brackets denote the quantity averaged horizontally over a grid box of a host model. An overbar denotes a mean over a tile, and a double prime denotes a fluctuation of a tile mean quantity about a grid-box mean quantity. The superscript "s" denotes a sub-tile fluctuation. By definition, $\left\langle \overline{f}'' \right\rangle = 0$. To simplify the discussion, we take $\overline{f^s} = 0$, although this assumption is not necessary (cf. Mironov and Sullivan, 2016).

Using Eq. (84), we obtain the following expression for the triple-correlation of the vertical velocity, u_3, and the two scalars, θ_l and q_t:

$$\begin{aligned} \langle u_3' \theta_l' q_t' \rangle &= \left\langle \overline{\left(\overline{u_3}'' + u_3^s\right)\left(\overline{\theta_l}'' + \theta_l^s\right)\left(\overline{q_t}'' + q_t^s\right)} \right\rangle \\ &= \left\langle \overline{u_3}''\overline{\theta_l}''\overline{q_t}'' \right\rangle + \left\langle \overline{u_3}''\overline{\theta_l^s q_t^s}'' \right\rangle + \left\langle \overline{\theta_l}''\overline{u_3^s q_t^s}'' \right\rangle + \left\langle \overline{q_t}''\overline{u_3^s \theta_l^s}'' \right\rangle + \langle \overline{u_3^s \theta_l^s q_t^s} \rangle . \end{aligned} \tag{85}$$

The first two terms on the r.h.s. of Eq. (85) are zero at the surface because of zero vertical velocity $\overline{u_3}$. The last term on the r.h.s. cannot be estimated unless a high-order closure model is applied to individual tiles. This is usually not the case. The third and the fourth terms on the r.h.s. of Eq. (85) are zero if the grid box of the host model is horizontally homogeneous. If the grid box is heterogeneous, the temperature $\overline{\theta_l}$ and humidity $\overline{q_t}$ differ between the tiles and so do the temperature and humidity fluxes, $\overline{u_3^s \theta_l^s}$ and $\overline{u_3^s q_t^s}$. Then, the third-order velocity-scalar covariance $\langle u_3' \theta_l' q_t' \rangle$, i.e. the flux of temperature-humidity covariance, is generally non-zero at the surface. The expressions for $\langle u_3' \theta_l'^2 \rangle$ and $\langle u_3' q_t'^2 \rangle$ are obtained from Eq. (85) by replacing q_t with θ_l and θ_l with q_t, respectively.

Notice a close analogy between the above analysis and the analysis of Mironov and Sullivan (2016). These authors used large-eddy simulation to explore the second-moment budgets in the stably stratified planetary boundary layer (PBL) over thermally homogeneous and thermally heterogeneous surfaces. Importantly, the LES-based second-moment budgets were estimated with due regard for the sub-grid scale contributions. Taking account of the SGS contributions revealed that the third-order velocity-scalar covariances are non-zero at the heterogeneous surfaces and are crucial for the maintenance of second-moment budgets in the heterogeneous PBL. That finding helped explain the enhanced vertical mixing in the stably-stratified PBL over thermally heterogeneous surfaces.

Based upon the above considerations, we propose the following surface boundary conditions for the scalar variances and scalar covariance that are consistent with the tiled surface schemes:

$$\begin{aligned} -C_{\theta\theta}^d \tau_\epsilon e \frac{\partial \langle \theta_l'^2 \rangle}{\partial x_3} = 2 \left\langle \overline{\theta_l}''\overline{u_3^s \theta_l^s}'' \right\rangle , \qquad -C_{qq}^d \tau_\epsilon e \frac{\partial \langle q_t'^2 \rangle}{\partial x_3} = 2 \left\langle \overline{q_t}''\overline{u_3^s q_t^s}'' \right\rangle , \\ -C_{\theta q}^d \tau_\epsilon e \frac{\partial \langle \theta_l' q_t' \rangle}{\partial x_3} = \left\langle \overline{\theta_l}''\overline{u_3^s q_t^s}'' \right\rangle + \left\langle \overline{q_t}''\overline{u_3^s \theta_l^s}'' \right\rangle . \end{aligned} \tag{86}$$

Note that the surface boundary condition (82) for the TKE remains in force, even though the tile approach may be used. This is readily shown by setting $\theta_l = u_i$ and $q_t = u_i$ in Eq. (85) (summation over repeated indices) and invoking the no-slip boundary condition for the flow velocity, $\overline{u_i} = 0$, at the underlying surface. Note that the term $\langle \overline{u_3^s u_i^s u_i^s} \rangle$ is not necessarily zero at the surface. It cannot be estimated, however, unless a high-order closure model is applied to individual tiles.

The surface boundary conditions given by Eqs. (86) provide an intimate coupling of the scalar variances and covariance with many other quantities characterizing the atmosphere and the soil. In order to illustrate this coupling, consider the moisture and heat balance equations at the underlying surface for individual tiles. The moisture balance equation reads

$$\overline{PP} + \rho\overline{u_3^s q_t^s} = \overline{G_q}, \tag{87}$$

where G_q is the ground moisture flux at the surface, and PP denotes the sum of all forms of precipitation, including (relatively slow) sedimentation of water droplets and ice crystals. Subtracting from Eq. (87) its horizontal mean, multiplying the result with $\overline{q_t}''$ and averaging horizontally, we obtain

$$\left\langle \overline{q_t}''\overline{u_3^s q_t^s}'' \right\rangle = \rho^{-1}\left[\left\langle \overline{q_t}''\overline{G_q}'' \right\rangle - \left\langle \overline{q_t}''\overline{PP}'' \right\rangle\right]. \tag{88}$$

The first term in brackets on the r.h.s. of Eq. (88) is generally non-zero since over heterogeneous surfaces both the total water content and the ground moisture flux vary between the tiles and are likely correlated. There is no good reason to assume that rain, snow, or hail falls differently onto some tiles than onto the others. However, if PP includes sedimentation of water droplets and ice crystals, then the difference between the tiles may be substantial and the covariance $\left\langle \overline{q_t}''\overline{PP}'' \right\rangle$ may appear to be different from zero. For example, if there is fog over some tiles but not over the other tiles, $\overline{PP}'' \neq 0$. Rain or snow falling through the fog layers may amplify the influence of fog via seeder-feeder effect.

Consideration of the heat balance of the underlying surface yields the following expression:

$$\left\langle \overline{\theta_l}''\overline{w^s\theta_l^s}'' \right\rangle =$$
$$(\rho c_p)^{-1}\left[\left\langle \overline{\theta_l}''\overline{G_\theta}'' \right\rangle - \left\langle \overline{\theta_l}''\overline{R_s}'' \right\rangle - \left\langle \overline{\theta_l}''\overline{R_l}'' \right\rangle - L_v\left(\left\langle \overline{\theta_l}''\overline{G_q}'' \right\rangle - \left\langle \overline{\theta_l}''\overline{PP}'' \right\rangle\right)\right]. \tag{89}$$

Here, G_θ is the ground heat flux at the surface, R_s is the solar radiation balance at the surface, and R_l is the net long-wave radiation at the surface. All terms on the r.h.s. of Eq. (89) are generally non-zero. The solar radiation balance varies between the tiles because of the difference in the tile albedo, and the long-wave radiation balance varies because of the difference in the tile temperature.

For the flux of temperature-humidity covariance, the following expression holds:

$$\left\langle \overline{\theta_l}''\overline{w^s q_t^s}'' \right\rangle + \left\langle \overline{q_t}''\overline{w^s\theta_l^s}'' \right\rangle = \rho^{-1}\left[\left\langle \overline{\theta_l}''\overline{G_q}'' \right\rangle - \left\langle \overline{\theta_l}''\overline{PP}'' \right\rangle\right]$$
$$(\rho c_p)^{-1}\left[\left\langle \overline{q_t}''\overline{G_\theta}'' \right\rangle - \left\langle \overline{q_t}''\overline{R_s}'' \right\rangle - \left\langle \overline{q_t}''\overline{R_l}'' \right\rangle - L_v\left(\left\langle \overline{q_t}''\overline{G_q}'' \right\rangle - \left\langle \overline{q_t}''\overline{PP}'' \right\rangle\right)\right], \tag{90}$$

where all terms on the r.h.s. of Eq. (90) are generally non-zero over heterogeneous surfaces. If ice is taken into account, a generalized formulation of q_t should be used, θ_l should be replaced with the total water potential temperature, and L_c should be replaced with an effective heat of vapourization-sublimation (see sections 2 and 7).

11 Equation for Scalar Skewness

In this section, a transport equation for the skewness (triple correlation) of the scalar variable s is developed. The s-skewness is required to utilize the double-Gaussian statistical cloud scheme proposed by Naumann et al. (2013) and is only used within the framework of the

extended version of the TKESV scheme. Thus this section discusses ***Advanced Features*** that are not used within the framework of TKESV-Bas.

Recall that the s variable defined as $s = \mathcal{Q}^{-1}\left(\langle q_t\rangle - \langle q_{sl}\rangle + q_t' - \mathcal{P}\theta_l'\right)$ accounts for the combined effect of humidity and temperature fluctuations, and is a measure of local oversaturation/undersaturation (see section 7 for details). A positive s is merely a local value of q_l computed with respect to the linearized saturation specific humidity curve. In order to determine the s skewness, $S_s \equiv \langle s'^3\rangle / \langle s'^2\rangle^{3/2}$, the variance of s, $\langle s'^2\rangle$, and its triple correlation, $\langle s'^3\rangle$, should be computed. The variance of s is given by

$$\langle s'^2\rangle = \mathcal{Q}^{-2}\left(\langle q_t'^2\rangle - 2\mathcal{P}\langle q_t'\theta_l'\rangle + \mathcal{P}^2\langle \theta_l'^2\rangle\right). \tag{91}$$

It can be computed in a straightforward way using the values of $\langle q_t'^2\rangle$, $\langle q_t'\theta_l'\rangle$ and $\langle \theta_l'^2\rangle$ determined within the framework of the TKESV scheme from the scalar (co)variance equations. The triple correlation of s is given by

$$\langle s'^3\rangle = \mathcal{Q}^{-3}\left(\langle q_t'^3\rangle - 3\mathcal{P}\langle q_t'^2\theta_l'\rangle + 3\mathcal{P}^2\langle q_t'\theta_l'^2\rangle - \mathcal{P}^3\langle \theta_l'^3\rangle\right). \tag{92}$$

As Eq. (92) suggests, the determination of $\langle s'^3\rangle$ requires knowledge of the four third-order scalar correlations. These correlations can be computed from their transport equations, where closure assumptions are required for a number of terms (third-order and fourth-order velocity-scalar correlations and molecular destruction terms). This would make the TKESV scheme unduly complex and computationally expensive. We therefore take a different, more simple approach. We combine the transport equations for $\langle q_t'^3\rangle$, $\langle q_t'^2\theta_l'\rangle$, $\langle q_t'\theta_l'^2\rangle$ and $\langle \theta_l'^3\rangle$ with due regard for Eq. (92) to formulate a single transport equation for $\langle s'^3\rangle$. To this end, we neglect the derivatives of $\mathcal{P}$ and $\mathcal{Q}$ with respect to time and space. Although an exact equation for the s-variable triple correlation can easily be derived, this is not required. The exact equation for $\langle s'^3\rangle$, including time and space derivatives of $\mathcal{P}$ and $\mathcal{Q}$, is cumbersome. Since $\mathcal{P}$ and $\mathcal{Q}$ depend on the grid-box mean quantities only, the uncertainties associated with neglect of the derivatives of $\mathcal{P}$ and $\mathcal{Q}$ are typically small unless the mean quantities change faster in space and time than higher-order moments (an unlikely situation). Note also that the skewness of s only serves to help determine the fractional cloud cover and its effect on the buoyancy production of the Reynolds stress and scalar fluxes. Then, $\langle s'^3\rangle$ is in a sense an auxiliary quantity, and it is legitimate to keep the $\langle s'^3\rangle$ equation reasonably simple at the expense of slightly reduced accuracy.

Combining transport equations for the four third-order moments on the r.h.s. of Eq. (92) and neglecting the derivatives of $\mathcal{P}$ and $\mathcal{Q}$ with respect to t and x_i, we obtain the following equation for the s-variable triple correlation:

$$\frac{1}{3}\left(\frac{\partial}{\partial t} + \langle u_i\rangle\frac{\partial}{\partial x_i}\right)\langle s'^3\rangle = -\langle u_i's'^2\rangle\frac{\partial\langle s\rangle}{\partial x_i} + \langle s'^2\rangle\frac{\partial\langle u_i's'\rangle}{\partial x_i} - \frac{1}{3}\frac{\partial\langle u_i's'^3\rangle}{\partial x_i} - \epsilon_{s3}, \tag{93}$$

where $\langle s\rangle = \mathcal{Q}^{-1}\left(\langle q_t\rangle - \langle q_{sl}\rangle\right)$. The terms on the r.h.s. of Eq. (93) represent production/destruction due to the mean scalar gradient and due to the scalar-flux divergence, fourth-order turbulent transport, and molecular destruction (dissipation), respectively. In order to close Eq. (93), parameterizations of the third-order, $\langle u_i's'^2\rangle$, and fourth-order, $\langle u_i's'^3\rangle$, velocity-scalar correlations and of the dissipation term, ϵ_{s3}, should be developed.

The dissipation rate of $\langle s'^3\rangle$ is parameterized through the following algebraic expression:

$$\epsilon_{s3} = \frac{\langle s'^3\rangle}{3R_{\tau s}\tau_\epsilon}, \tag{94}$$

where $R_{\tau s} = \tau_{s3}/\tau_\epsilon = \langle s'^3\rangle\,\epsilon/\left(3e\epsilon_{s3}\right)$ is the ratio of the $\langle s'^3\rangle$ dissipation time scale to the TKE dissipation time scale.

We adopt the following parameterization of the third-order velocity-scalar correlation:

$$\left\langle u_i' s'^2 \right\rangle = -C_{us2}^d \tau_\epsilon e \frac{\partial \left\langle s'^2 \right\rangle}{\partial x_i} + S_s \left\langle s'^2 \right\rangle^{1/2} \left\langle u_i' s' \right\rangle, \tag{95}$$

where C_{us2}^d is a dimensionless constant. In the case of nearly isotropic turbulence, the skewness S_s is small and Eq. (95) reduces to the down-gradient diffusion formulation. In the limiting case of strongly skewed PDF of s, the second term on the r.h.s of Eq. (95) becomes dominant. Then, Eq. (95) reduces to the form suggested by the top-hat representation of fluctuating quantities that is fundamental to the mass-flux approach widely used to parameterize cumulus convection in numerical models of the atmosphere. The simplest top-hat mass-flux model is formulated in terms of fractional areas of updraughts, a_u, and downdraughts, $a_d = 1 - a_u$. Alternatively, a PDF can be used which consists of only two Dirac delta functions, i.e. the probabilities of motions to be either updraughts or downdraughts are P_u and P_d, respectively, and $P_u + P_d = 1$. The second term on the r.h.s. of Eq. (95) is basically the mass-flux formulation recast in terms of the quantities used within the second-order closure framework (see Mironov, 2009, for a detailed discussion of the analogies between the mass-flux and the ensemble-mean second-order modelling frameworks). A skewness-dependent parameterization for the flux of potential-temperature variance [given by the second term on the r.h.s. of Eq. (95), where s is replaced with θ] was formulated in Mironov et al. (1999), Abdella and McFarlane (1999) and Abdella and Petersen (2000). An interpolation formula that incorporates both the down-gradient and the skewness-dependent terms was presented in Gryanik and Hartmann (2002). As different from previous studies, we apply these parameterization ideas to the scalar quantity s that accounts for the combined effect of temperature and humidity fluctuations.

The following parameterization of the fourth-order velocity-scalar correlation is adopted:

$$\left\langle u_i' s'^3 \right\rangle = 3 \left(1 + \frac{1}{3} S_s^2 \right) \left\langle s'^2 \right\rangle \left\langle u_i' s' \right\rangle - C_{us3}^d \tau_\epsilon e \frac{\partial \left\langle s'^3 \right\rangle}{\partial x_i}, \tag{96}$$

where C_{us3}^d is a dimensionless constant. The first term on the r.h.s. of Eq. (96) represents a generalization of the Millionshchikov hypothesis formulated in Gryanik and Hartmann (2002) and Gryanik et al. (2005) for convective boundary-layer turbulence. In the case of isotropic turbulence, S_s vanishes and the first term on the r.h.s. reduces to the classical Millionshchikov (1941) formulation. It states that the fourth-order moments can be considered as Gaussian, even though the third-order moments are nonzero. In the limiting case of very skewed turbulence, S_s is large and the first term on the r.h.s. of Eq. (96) takes on the form suggested by the top-hat mass-flux approach (cf. the formulation of $\left\langle u_i' s'^2 \right\rangle$). The expression $3 \left(1 + \frac{1}{3} S_s^2 \right) = 3 + S_s^2$ amounts to the simplest linear interpolation between the two limiting cases, where dimensionless coefficients 3 and 1 are chosen so that the limiting cases are satisfied exactly. The down-gradient diffusion term, the last term on the r.h.s. of Eq. (96), can be viewed as the smoothing operator that is added to the parameterization of the fourth-order turbulent transport term for numerical reasons. The use of the diffusion term can also be justified on physical grounds. To this end, one needs to consider the transport equation for the fourth-order term $\left\langle u_i' s'^3 \right\rangle$ and invoke a number of simplifying assumptions (e.g. use the Rotta-type closure for the pressure-scrambling terms and neglect turbulence anisotropy in the formulations of the mean-gradient terms).

Substituting Eqs. (94), (95) and (96) into Eq. (93) and using the boundary-layer approxi-

mation, we obtain the following equation for the s-variable triple correlation:

$$\frac{1}{3}\frac{\partial\left\langle s'^3\right\rangle}{\partial t} = -\left(S_s\left\langle s'^2\right\rangle^{1/2}\left\langle u_3's'\right\rangle - C^d_{us2}\tau_\epsilon e\frac{\partial\left\langle s'^2\right\rangle}{\partial x_3}\right)\frac{\partial\left\langle s\right\rangle}{\partial x_3} - \left\langle u_3's'\right\rangle\frac{\partial\left\langle s'^2\right\rangle}{\partial x_3}$$
$$+\frac{1}{3}\frac{\partial}{\partial x_3}\left(C^d_{us3}\tau_\epsilon e\frac{\partial\left\langle s'^3\right\rangle}{\partial x_3} - S_s^2\left\langle s'^2\right\rangle\left\langle u_3's'\right\rangle\right) - \frac{\left\langle s'^3\right\rangle}{3R_{\tau s}\tau_\epsilon}. \tag{97}$$

The following (tentative) estimates of disposable parameters are utilized: $C^d_{us2} = 0.1$, $C^d_{us3} = 0.1$, and $R_{\tau s} = 0.1$.

The surface boundary condition for $\left\langle s'^3\right\rangle$ should be specified that is applicable over both homogeneous and heterogeneous surfaces and is consistent with the tiled surface schemes. To this end, we make use of the triple decomposition (84) and express the fourth-order velocity-scalar covariance as follows:

$$\begin{aligned}\left\langle u_3's'^3\right\rangle &= \left\langle\overline{\left(\overline{u_3}'' + u_3^s\right)\left(\overline{s}'' + s^s\right)^3}\right\rangle \\ &= \left\langle\overline{u_3}''\overline{s}''^3\right\rangle + 3\left\langle\overline{u_3}''\overline{s}''\overline{s^{s2}}\right\rangle + \left\langle\overline{u_3}''\overline{s^{s3}}''\right\rangle \\ &+ 3\left\langle\overline{s}''^2\right\rangle\left\langle\overline{u_3^s s^s}\right\rangle + 3\left\langle\overline{s}''^2\overline{u_3^s s^s}''\right\rangle + 3\left\langle\overline{s}''\overline{u_3^s s^{s2}}''\right\rangle + \left\langle\overline{u_3^s s^{s3}}\right\rangle.\end{aligned} \tag{98}$$

The first three terms on the r.h.s. of Eq. (98) are zero at the surface because of zero vertical velocity $\overline{u_3}$. The last two terms on the r.h.s. cannot be estimated unless a high-order closure model is applied to individual tiles. The remaining two terms are generally non-zero over heterogeneous surfaces.

Using Eq. (98), we propose the following surface boundary condition for $\left\langle s'^3\right\rangle$:

$$3\left(1+\frac{1}{3}S_s^2\right)\left\langle s'^2\right\rangle\left\langle u_3's'\right\rangle - C^d_{us3}\tau_\epsilon e\frac{\partial\left\langle s'^3\right\rangle}{\partial x_3} = 3\left\langle\overline{s}''^2\right\rangle\left\langle\overline{u_3^s s^s}\right\rangle + 3\left\langle\overline{s}''^2\overline{u_3^s s^s}''\right\rangle. \tag{99}$$

Note that Eq. (99) represents the so-called Robin boundary condition, also referred to as the impedance boundary condition, or convective boundary condition. It is a weighted combination of Dirichlet and Neumann boundary conditions that relates the quantity in question ($\left\langle s'^3\right\rangle$ in our case) and its derivative normal to the domain boundary.

12 Conclusions

A turbulence kinetic energy – scalar variance (TKESV) turbulence parameterization scheme is developed. The scheme is formulated in terms of two scalars that are approximately conserved for phase changes in the absence of precipitation. These are the total water specific humidity and the liquid water potential temperature. The TKESV scheme carries prognostic transport equations (including the time-rate-of-change and the third-order turbulent transport terms) for the TKE, for the variances of scalar quantities, and for the scalar covariance. The other second-order moments, namely, the Reynolds stress and the scalar fluxes, are determined through the diagnostic algebraic expressions obtained by neglecting the time-rate-of-change and the triple correlations terms in the respective transport equations.

The focus of the present report is on the baseline version of the TKESV scheme (TKESV-Bas). TKESV-Bas is based on the linear (in the second-order moments involved) parameterizations of the pressure-scrambling terms in the Reynolds-stress and scalar-flux equations, the isotropic down-gradient parameterizations of the third-order transport terms in the TKE

and scalar (co)variance equations, and the algebraic interpolation formula for the turbulence length scale that incorporates a correction term due to stable density stratification. The various time scales, namely, the dissipation time scales in the TKE and the scalar (co)variance equations and the return-to-isotropy time scales in the Reynolds-stress and scalar-flux equations, are set proportional to each other and are expressed in terms of turbulence length scale and the TKE. The simplified boundary conditions for the scalar variances and covariance at the underlying surface are used that do not account for the surface heterogeneity within a grid box of a host atmospheric model. The effect of latent heat release/consumption on the buoyancy production/destruction of the Reynolds stress (including half of its trace, the TKE) and of the scalar fluxes is taken into account through the use of a statistical cloud scheme. The cloud scheme makes use of a combination of Gaussian and exponential PDFs of linearized saturation deficit/excess (s variable). The exponential PDF is used at strong grid-box mean undersaturation and is designed to account, in a rather approximate way, for the shallow cumulus regime. In that regime, mixing is known to be dominated by convective plumes although the fractional cloud cover is typically low. The so-called stability functions that appear in the algebraic formulations for the Reynolds stress and scalar fluxes are considered in much detail. The stability functions resulting from the truncated Reynolds-stress and scalar-flux equations (where the third-order and the time-rate-of-change terms are neglected) with the linear parameterizations of the pressure-scrambling terms are ill-behaved over a certain range of governing parameters (e.g. mean velocity shear and mean buoyancy gradient). Using plausible physical arguments, regularized stability functions are developed that are well-behaved over their entire parameter space and cause no pathological behaviour of the Reynolds stress and scalar fluxes.

It is the baseline version of the TKESV scheme in the boundary-layer approximation (i.e. the one-dimensional TKESV-Bas) that is intended for use in NWP models ICON and COSMO in the near future. In the medium-term prospective, an extended version of the scheme (TKESV-Ext) can be used. TKESV-Ext incorporates a number of advanced features discussed in the respective sections of the present report. These include improved formulations of the pressure-scrambling terms and of the third-order transport terms, non-local formulation of the turbulence length scale, lower boundary conditions for the scalar (co)variances that account for the surface heterogeneity and are consistent with the tile approach to compute surface fluxes, allowance for cloud ice through the use of the ice-liquid water potential temperature, and a statistical cloud scheme capable of describing cumulus regimes. The utilization of an advanced statistical cloud scheme, e.g. the scheme proposed by Naumann et al. (2013), requires knowledge of the scalar skewness. A prognostic transport equation for the skewness (triple correlation) of the s variable that accounts for the combined effect of humidity and temperature fluctuations is derived in section 11.

The TKESV-Bas scheme is implemented into the NWP models ICON and COSMO. Testing of TKESV-Bas is underway. Details of the implementation and results from numerical experiments will be reported in subsequent publications. Results of testing of an earlier version of the TKESV scheme through off-line single-column numerical experiments and through parallel experiments with the full-fledged COSMO model (including the entire data assimilation cycle) are reported in Machulskaya and Mironov (2013).

Appendix A. Modelling Pressure-Scrambling Terms in the Reynolds-Stress and Scalar-Flux Equations

In this section, we demonstrate how models (parameterizations) of the pressure-scrambling terms in the Reynolds-stress and the scalar-flux equations are developed. By way of illustration, the formulation for the potential temperature θ is considered. Other scalar quantities, e.g. θ_l and q_t, are treated in the same way. We restrict our consideration to the parameterizations of Π_{ij} and $\Pi_{\theta i}$ which are linear in terms of the second-order moments of fluctuating fields. Some non-linear parameterizations of the pressure-scrambling terms are briefly discussed in section 5.1.

Decomposition

Taking the divergence of the transport equation for the fluctuating velocity, a Poisson equation for the fluctuating pressure is obtained. It reads

$$\frac{\partial^2 p'}{\partial x_k^2} = -\frac{\partial^2}{\partial x_k \partial x_l}\left(u_k' u_l' - \langle u_k' u_l' \rangle\right) - \beta_k \frac{\partial \theta'}{\partial x_k} - 2\epsilon_{kml}\Omega_m \frac{\partial u_l'}{\partial x_k} - 2\frac{\partial \langle u_k \rangle}{\partial x_l}\frac{\partial u_l'}{\partial x_k}. \tag{A.1}$$

The fluctuating pressure is decomposed into the contributions due to the non-linear turbulence interactions (denoted by the subscript t), buoyancy (subscript b), the Coriolis effects (subscript c), and mean-velocity shear (subscript s),

$$p' = p_t' + p_b' + p_c' + p_s', \tag{A.2}$$

which are found by solving the following set of Poisson equations:

$$\frac{\partial^2 p_t'}{\partial x_k^2} = -\frac{\partial^2}{\partial x_k \partial x_l}\left(u_k' u_l' - \langle u_k' u_l' \rangle\right), \qquad \frac{\partial^2 p_b'}{\partial x_k^2} = -\beta_k \frac{\partial \theta'}{\partial x_k},$$

$$\frac{\partial^2 p_c'}{\partial x_k^2} = -2\epsilon_{kml}\Omega_m \frac{\partial u_l'}{\partial x_k}, \qquad \frac{\partial^2 p_s'}{\partial x_k^2} = -2\frac{\partial \langle u_k \rangle}{\partial x_l}\frac{\partial u_l'}{\partial x_k}. \tag{A.3}$$

The (formal) solutions to Eqs. (A.3) read (Chou, 1945; Ristorcelli et al., 1995; Shih, 1996)

$$p_t = \frac{1}{4\pi}\int_{Vol}\left(\frac{\partial^2 u_k'' u_l''}{\partial x_k'' \partial x_l''} - \frac{\partial^2 \langle u_k u_l \rangle''}{\partial x_k'' \partial x_l''}\right)\frac{dVol}{|\mathbf{x}-\mathbf{x}''|}, \qquad p_b = \frac{1}{4\pi}\int_{Vol}\beta_k''\frac{\partial \theta''}{\partial x_k''}\frac{dVol}{|\mathbf{x}-\mathbf{x}''|},$$

$$p_c = \frac{1}{4\pi}\int_{Vol} 2\epsilon_{kml}\Omega_m \frac{\partial u_l''}{\partial x_k''}\frac{dVol}{|\mathbf{x}-\mathbf{x}''|}, \qquad p_s = \frac{1}{4\pi}\int_{Vol} 2\frac{\partial U_k''}{\partial x_l''}\frac{\partial u_l''}{\partial x_k''}\frac{dVol}{|\mathbf{x}-\mathbf{x}''|}, \tag{A.4}$$

where double-primed quantities are evaluated as functions of the integration variable. Small letters denote turbulent fluctuations, and capital letters denote mean quantities (this notation is used temporarily to avoid confusion between primed and double-primed quantities).

Using (A.2), the pressure-scrambling terms Π_{ij} and $\Pi_{\theta i}$ are decomposed into the contributions due to the non-linear turbulence interactions (superscript t), buoyancy (superscript b), the Coriolis effects (superscript c), and mean-velocity shear (superscript s),

$$\Pi_{ij} = \Pi_{ij}^t + \Pi_{ij}^b + \Pi_{ij}^c + \Pi_{ij}^s, \qquad \Pi_{\theta i} = \Pi_{\theta i}^t + \Pi_{\theta i}^b + \Pi_{\theta i}^c + \Pi_{\theta i}^s. \tag{A.5}$$

With due regard for Eqs. (A.4) these contributions are given by

$$\Pi_{ij}^{t} = -\left\langle p_t \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \right\rangle = \frac{1}{4\pi} \int_{Vol} \left(\frac{\partial^3 \langle u_k'' u_l'' u_i \rangle}{\partial x_k'' \partial x_l'' \partial x_j''} + \frac{\partial^3 \langle u_k'' u_l'' u_j \rangle}{\partial x_k'' \partial x_l'' \partial x_i''} \right) \frac{dVol}{|\mathbf{x} - \mathbf{x}''|},$$

$$\Pi_{ij}^{b} = -\left\langle p_b \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \right\rangle = \frac{1}{4\pi} \int_{Vol} \beta_k'' \left(\frac{\partial^2 \langle \theta'' u_i \rangle}{\partial x_k'' \partial x_j''} + \frac{\partial^2 \langle \theta'' u_j \rangle}{\partial x_k'' \partial x_i''} \right) \frac{dVol}{|\mathbf{x} - \mathbf{x}''|},$$

$$\Pi_{ij}^{c} = -\left\langle p_c \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \right\rangle = \frac{1}{4\pi} \int_{Vol} 2\epsilon_{kml}\Omega_m \left(\frac{\partial^2 \langle u_l'' u_i \rangle}{\partial x_k'' \partial x_j''} + \frac{\partial^2 \langle u_l'' u_j \rangle}{\partial x_k'' \partial x_i''} \right) \frac{dVol}{|\mathbf{x} - \mathbf{x}''|},$$

$$\Pi_{ij}^{s} = -\left\langle p_s \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right) \right\rangle = \frac{1}{4\pi} \int_{Vol} 2\frac{\partial U_k''}{\partial x_l''} \left(\frac{\partial^2 \langle u_l'' u_i \rangle}{\partial x_k'' \partial x_j''} + \frac{\partial^2 \langle u_l'' u_j \rangle}{\partial x_k'' \partial x_i''} \right) \frac{dVol}{|\mathbf{x} - \mathbf{x}''|}, \quad \text{(A.6)}$$

and

$$\Pi_{\theta i}^{t} = \left\langle \theta \frac{\partial p_t}{\partial x_i} \right\rangle = \frac{1}{4\pi} \int_{Vol} \frac{\partial^3 \langle u_k'' u_l'' \theta \rangle}{\partial x_k'' \partial x_l'' \partial x_i''} \frac{dVol}{|\mathbf{x} - \mathbf{x}''|},$$

$$\Pi_{\theta i}^{b} = \left\langle \theta \frac{\partial p_b}{\partial x_i} \right\rangle = \frac{1}{4\pi} \int_{Vol} \beta_k'' \frac{\partial^2 \langle \theta'' \theta \rangle}{\partial x_k'' \partial x_i''} \frac{dVol}{|\mathbf{x} - \mathbf{x}''|},$$

$$\Pi_{\theta i}^{c} = \left\langle \theta \frac{\partial p_c}{\partial x_i} \right\rangle = \frac{1}{4\pi} \int_{Vol} 2\epsilon_{kml}\Omega_m \frac{\partial^2 \langle u_l'' \theta \rangle}{\partial x_k'' \partial x_i''} \frac{dVol}{|\mathbf{x} - \mathbf{x}''|},$$

$$\Pi_{\theta i}^{s} = \left\langle \theta \frac{\partial p_s}{\partial x_i} \right\rangle = \frac{1}{4\pi} \int_{Vol} 2\frac{\partial U_k''}{\partial x_l''} \frac{\partial^2 \langle u_l'' \theta \rangle}{\partial x_k'' \partial x_i''} \frac{dVol}{|\mathbf{x} - \mathbf{x}''|}, \quad \text{(A.7)}$$

where quantities without double primes are evaluated at the point where Π_{ij} and $\Pi_{\theta i}$ are determined. The Π_{ij}^{t} and $\Pi_{\theta i}^{t}$ contributions are often referred to as slow parts and Π_{ij}^{b}, Π_{ij}^{c}, Π_{ij}^{s}, $\Pi_{\theta i}^{b}$, $\Pi_{\theta i}^{c}$ and $\Pi_{\theta i}^{s}$ as rapid parts, respectively, of the pressure-scrambling terms.

The integrals in Eqs. (A.6) and (A.7) are taken over the entire flow domain. In practice, however, the two-point correlations are assumed to diminish rapidly with distance from the point where the pressure terms are evaluated. Then, the volume of integration is reduced to a small region in the immediate vicinity of that point, and Π_{ij} and $\Pi_{\theta i}$ are modelled in terms of local quantities.

Slow Parts of Π_{ij} and $\Pi_{\theta i}$

We utilize the return-to-isotropy parameterizations (Rotta, 1951; Monin, 1965) for the slow (return-to-isotropy) contributions to the pressure-scrambling terms. They read

$$\Pi_{ij}^{t} = C_t^u \frac{\langle u_i u_j \rangle - \frac{2}{3}\delta_{ij} e}{\tau_{ru}} = C_t^u \frac{a_{ij}}{\tau_{ru}}, \qquad \Pi_{\theta i}^{t} = C_t^\theta \frac{\langle u_i \theta \rangle}{\tau_{r\theta}}, \quad \text{(A.8)}$$

where τ_{ru} and $\tau_{r\theta}$ are the relaxation return-to-isotropy time scales, and C_t^u and C_t^θ are dimensionless constants.

It is customary in geophysical and engineering applications to take the relaxation time scales τ_{ru} and $\tau_{r\theta}$ to be proportional to the TKE dissipation time scale $\tau_\epsilon = e/\epsilon$, that is $\tau_{ru} = \tau_{r\theta} = \tau_\epsilon$, where dimensionless proportionality constants are set to one as they always occur in combination with the other constants. Estimates of C_t^u and C_t^θ vary over a wide range. Values of C_t^u from 1 to 3 and of C_t^θ from 2 to 10 have been proposed (see e.g. Launder et al., 1975; Zeman and Tennekes, 1975; Zeman and Lumley, 1976; Dakos and Gibson, 1987; Speziale et al., 1991; Kenjereš and Hanjalić, 1995; Hanjalić et al., 1996; Craft et al., 1996; Dol et al., 1997; Hanjalić, 1999; Girimaji, 2000; Mironov, 2001; Hanjalić, 2002; Umlauf and Burchard, 2005). We adopt the estimates of $C_t^u = 1.8$ and $C_t^\theta = 5.0$, keeping in mind that some tuning may appear to be necessary. In particular, the estimate of $C_t^\theta = 3.0$ is found by a number of authors to be more appropriate for (mostly) buoyancy-driven flows.

Buoyancy Contributions to Π_{ij} and $\Pi_{\theta i}$

The formal expressions for the buoyancy, the Coriolis and the mean-velocity shear contributions (the so-called rapid contributions) to the pressure-scrambling terms are given by the second, the third and the fourth members of Eqs. (A.6) and (A.7), respectively. Assuming that the mean fields are approximately homogeneous over a distance of the order of the integral turbulence length scale, β_k can be taken outside the integrals (the same is true for $2\partial U_k/\partial x_l$ in the expressions for the mean-velocity shear contributions to the pressure-scrambling terms considered below). Then, the buoyancy contributions to the pressure-scrambling terms can be represented in the form (see e.g. Shih, 1996)

$$\Pi_{ij}^b = -\beta_k \left(X_{kij}^b + X_{kji}^b \right), \qquad \Pi_{\theta i}^b = -\beta_k Y_{ki}^b. \tag{A.9}$$

where, in view of the second members of Eqs. (A.6) and (A.7),

$$X_{kij}^b = -\frac{1}{4\pi} \int_{Vol} \frac{\partial^2 \langle \theta'' u_i \rangle}{\partial x_k'' \partial x_j''} \frac{dVol}{|\mathbf{x} - \mathbf{x}''|}, \qquad Y_{ki}^b = -\frac{1}{4\pi} \int_{Vol} \frac{\partial^2 \langle \theta'' \theta \rangle}{\partial x_k'' \partial x_i''} \frac{dVol}{|\mathbf{x} - \mathbf{x}''|}. \tag{A.10}$$

The tensors X_{kij} and Y_{ki} satisfy the following constraints:

$$\text{symmetry} \qquad X_{kij}^b = X_{jik}^b, \quad Y_{ki}^b = Y_{ik}^b, \tag{A.11}$$

$$\text{continuity} \qquad X_{kii}^b = 0, \tag{A.12}$$

$$\text{normalization} \qquad X_{kik}^b = \langle u_i \theta \rangle, \quad Y_{kk}^b = \langle \theta^2 \rangle. \tag{A.13}$$

Within the limits of linear approximations (in the second-order moments of fluctuating fields, i.e. in $\langle u_i u_j \rangle$, $\langle u_i \theta \rangle$ and $\langle \theta^2 \rangle$), the most general forms of X_{kij}^b and Y_{ki}^b that satisfy the symmetry constraints (A.11) are the following tensor polynomials:

$$X_{kij}^b = \alpha_1 \delta_{kj} \langle u_i \theta \rangle + \alpha_2 \left(\delta_{ki} \langle u_j \theta \rangle + \delta_{ji} \langle u_k \theta \rangle \right), \qquad Y_{ki}^b = \gamma_1 \delta_{ki} \langle \theta^2 \rangle. \tag{A.14}$$

Satisfying the continuity (A.12) and the normalization (A.13) constraints, we obtain $\alpha_1 = 2/5$, $\alpha_2 = -1/10$ and $\gamma_1 = 1/3$. With these estimates, Eqs. (A.9) and (A.14) yield the following formulations:

$$\Pi_{ij}^b = -\frac{3}{10} \left(\beta_i \langle u_j \theta \rangle + \beta_j \langle u_i \theta \rangle - \frac{2}{3} \delta_{ij} \beta_k \langle u_k \theta \rangle \right), \qquad \Pi_{\theta i}^b = -\frac{1}{3} \beta_i \langle \theta^2 \rangle. \tag{A.15}$$

Note that Eq. (A.15) contains no free parameters; the numerical values of all dimensionless coefficients in the expressions for Π_{ij}^b and $\Pi_{\theta i}^b$ are fixed by mathematical constraints.

Coriolis Contributions to Π_{ij} and $\Pi_{\theta i}$

Parameterizations of the Coriolis contributions to the pressure-scrambling terms are developed analogously to parameterizations of the buoyancy contributions. The Coriolis contributions are represented as

$$\Pi^c_{ij} = -2\epsilon_{kml}\Omega_m \left(X^c_{klij} + X^c_{klji}\right), \qquad \Pi^c_{\theta i} = -2\epsilon_{kml}\Omega_m Y^c_{kli}, \tag{A.16}$$

where

$$X^c_{klij} = -\frac{1}{4\pi}\int_{Vol} \frac{\partial^2 \langle u_l'' u_i\rangle}{\partial x_k'' \partial x_j''} \frac{dVol}{|\mathbf{x}-\mathbf{x}''|}, \qquad Y^c_{kli} = -\frac{1}{4\pi}\int_{Vol} \frac{\partial^2 \langle u_l'' \theta\rangle}{\partial x_k'' \partial x_i''} \frac{dVol}{|\mathbf{x}-\mathbf{x}''|}. \tag{A.17}$$

The tensor Y^c_{kli} is exactly the same tensor as X^b_{kij} that appears in the parameterization of Π^b_{ij}, see Eqs. (A.9)–(A.14). The tensor X^c_{klij} satisfies the following constraints:

$$\begin{aligned}
&\text{symmetry} && X^c_{klij} = X^c_{kilj}, \quad X^c_{klij} = X^c_{jlik}, && \text{(A.18)}\\
&\text{continuity} && X^c_{klii} = 0, && \text{(A.19)}\\
&\text{normalization} && X^c_{klik} = \langle u_l u_i\rangle . && \text{(A.20)}
\end{aligned}$$

Within the limits of a linear approximation, the most general form of X^c_{klij} that satisfies the symmetry constraints (A.18) is

$$\begin{aligned}
X^c_{klij} &= 2e\left[\alpha_1\delta_{li}\delta_{kj} + \alpha_2\left(\delta_{lk}\delta_{ji} + \delta_{lj}\delta_{ki}\right)\right]\\
&+ \alpha_3\delta_{li}a_{kj} + \alpha_4\delta_{kj}a_{li} + \alpha_5\left(\delta_{ij}a_{kl} + \delta_{lj}a_{ki} + \delta_{ki}a_{lj} + \delta_{lk}a_{ji}\right).
\end{aligned} \tag{A.21}$$

Satisfying the continuity (A.19) and the normalization (A.20) constraints, we obtain $\alpha_1 = 2/15$, $\alpha_2 = -1/30$, $\alpha_3 = -1/3 - 11\alpha_5/3$ and $\alpha_4 = 1/3 - 4\alpha_5/3$. Using Eqs. (A.16), (A.14) and (A.21) along with these estimates, we obtain

$$\Pi^c_{ij} = -\frac{2}{3}\left(2 + 7\alpha_5\right)\left(\epsilon_{imk}\Omega_m a_{kj} + \epsilon_{jmk}\Omega_m a_{ki}\right), \qquad \Pi^c_{\theta i} = -\epsilon_{imk}\Omega_m \langle u_k\theta\rangle , \tag{A.22}$$

with only one free coefficient α_5. An estimate of $\alpha_5 = -1/10$ was adopted in a number of studies (e.g Shih, 1996; Hanjalić, 1999).

Mean-Velocity Shear Contributions to Π_{ij} and $\Pi_{\theta i}$

The contributions to the pressure-scrambling terms due to the mean-velocity shear are parameterized in the same way as the contributions due to the Coriolis effects. The mean-velocity shear contributions are represented as

$$\Pi^s_{ij} = -2\frac{\partial U_k}{\partial x_l}\left(X^s_{klij} + X^s_{klji}\right), \qquad \Pi_{\theta i} = -2\frac{\partial U_k}{\partial x_l} Y^s_{kli}, \tag{A.23}$$

where

$$X^s_{klij} = -\frac{1}{4\pi}\int_{Vol} \frac{\partial^2 \langle u_l'' u_i\rangle}{\partial x_k'' \partial x_j''} \frac{dVol}{|\mathbf{x}-\mathbf{x}''|}, \qquad Y^s_{kli} = -\frac{1}{4\pi}\int_{Vol} \frac{\partial^2 \langle u_l'' \theta\rangle}{\partial x_k'' \partial x_i''} \frac{dVol}{|\mathbf{x}-\mathbf{x}''|}. \tag{A.24}$$

As is easy to see, the tensors X^s_{klij} and Y^s_{kli} are exactly the same tensors as X^c_{klij} and Y^c_{kli}, respectively, that appear in the parameterization of the Coriolis contributions to the

pressure-scrambling terms. Using the results of the previous sub-section, we obtain

$$\begin{aligned}
\Pi^s_{ij} = & - \frac{4}{5} S_{ij} e + 6\alpha_5 \left(S_{ik} a_{kj} + S_{jk} a_{ki} - \frac{2}{3} \delta_{ij} S_{kl} a_{kl} \right) \\
& - \frac{2}{3} \left(2 + 7\alpha_5 \right) \left(W_{ik} a_{kj} + W_{jk} a_{ki} \right), \\
\Pi^s_{\theta i} = & - \left(\frac{3}{5} S_{ik} + W_{ik} \right) \left\langle u'_k \theta' \right\rangle,
\end{aligned} \tag{A.25}$$

where S_{ij} and W_{ij} are the symmetric and the antisymmetric parts, respectively, of the mean-velocity gradient tensor.

Resulting Expressions for Π_{ij} and $\Pi_{\theta i}$

Combining Eqs. (A.8) with $\tau_{ru} = \tau_{r\theta} = \tau_\epsilon$, (A.15), (A.22) and (A.25) and returning to the notation with primes, we obtain the following parameterizations of the pressure-scrambling terms in the Reynolds-stress and the temperature-flux equations that are linear in the second-order moments of fluctuating fields:

$$\begin{aligned}
\Pi_{ij} = & \; C^u_t \frac{a_{ij}}{\tau_\epsilon} \\
& - C^u_{s1} S_{ij} e - C^u_{s2} \left(S_{ik} a_{kj} + S_{jk} a_{ki} - \frac{2}{3} \delta_{ij} S_{kl} a_{kl} \right) - C^u_{s3} \left(W_{ik} a_{kj} + W_{jk} a_{ki} \right) \\
& - C^u_b \left(\beta_i \left\langle u'_j \theta' \right\rangle + \beta_j \left\langle u'_i \theta' \right\rangle - \frac{2}{3} \delta_{ij} \beta_k \left\langle u'_k \theta' \right\rangle \right) \\
& - 2 C^u_c \left(\epsilon_{imk} \Omega_m a_{kj} + \epsilon_{jmk} \Omega_m a_{ki} \right),
\end{aligned} \tag{A.26}$$

$$\Pi_{\theta i} = C^\theta_t \frac{\left\langle u'_i \theta' \right\rangle}{\tau_\epsilon} - \left(C^\theta_{s1} S_{ij} + C^\theta_{s2} W_{ij} \right) \left\langle u'_j \theta' \right\rangle - C^\theta_b \beta_i \left\langle \theta'^2 \right\rangle - 2 C^\theta_c \epsilon_{imj} \Omega_m \left\langle u'_j \theta' \right\rangle, \tag{A.27}$$

where $C^u_t = 1.8$, $C^u_{s1} = 4/5$, $C^u_{s2} = -6\alpha_5$, $C^u_{s3} = \frac{2}{3}(2 + 7\alpha_5)$, $C^u_b = 3/10$, $C^u_c = \frac{1}{3}(2 + 7\alpha_5)$, $C^\theta_t = 5.0$, $C^\theta_{s1} = 3/5$, $C^\theta_{s2} = 1$, $C^\theta_b = 1/3$ and $C^\theta_c = 1/2$ are dimensionless coefficients. The only yet undetermined coefficient α_5 can be estimated by satisfying one or the other additional constraint. One way to determine α_5 is to require that the second-moment equations of the TKESV scheme subject to the surface-layer approximation yield the classical logarithmic velocity profile. Details are given in next sub-section.

Logarithmic Velocity Profile Constraints

Consider a fluid layer just above a flat rigid surface where (i) turbulence is stationary and horizontally homogeneous, and (ii) the effects of buoyancy, reference frame rotation, advection and third-order transport are negligible. It is further assumed that (iii) the surface layer is a small portion of the PBL, so that the directional wind shear is negligible, and turbulent fluxes can be considered approximately height-constant, equal to their surface values (in other words, changes of fluxes over the surface layer are small compared to their changes over the entire PBL). Under the assumptions (i)–(iii), the TKE equation (12) reduces to a balance between the shear production and the dissipation,

$$- \left\langle u'_i u'_k \right\rangle \frac{\partial \left\langle u_i \right\rangle}{\partial x_k} - \epsilon = 0, \tag{A.28}$$

and the Reynolds-stress equation (18) with due regard for the parameterization (21) of the pressure-scrambling term reduces to a balance between the shear production and pressure redistribution,

$$-C_t^u \frac{a_{ij}}{\tau_\epsilon} - \left(\frac{4}{3} - C_{s1}^u\right) e S_{ij} - \left(1 - C_{s2}^u\right)\left(a_{ik}S_{jk} + a_{jk}S_{ik} - \frac{2}{3}\delta_{ij}a_{kl}S_{kl}\right) - \left(1 - C_{s3}^u\right)\left(a_{ik}W_{jk} + a_{jk}W_{ik}\right) = 0, \tag{A.29}$$

where the deviatoric part ϵ_{ij}^d of the Reynolds-stress dissipation tensor is incorporated into the parameterization of the slow part Π_{ij}^t of the pressure redistribution term.

In the near-surface layer subject to the above assumptions (i)–(iii), the mean-velocity profile is logarithmic, and the following well-known relations hold true:

$$l = \kappa x_3, \quad -\left\langle u_1' u_3' \right\rangle = u_*^2, \quad e = C_e u_*^2, \quad \frac{\partial \left\langle u_1 \right\rangle}{\partial x_3} = \frac{u_*}{\kappa x_3}. \tag{A.30}$$

Here, κ is the von Kármán constant whose conventional value is 0.4, C_e is a dimensionless constants, and u_* is the surface friction velocity. The x_1 horizontal axis is taken to be aligned with the surface stress so that $\langle u_2' u_3' \rangle = 0$ and $\langle u_2 \rangle = 0$ (in the horizontally-homogeneous layer over a rigid surface, $\langle u_3 \rangle = 0$ by virtue of continuity).

It is straightforward to verify by substituting (A.30) into (A.28), where ϵ is expressed in terms of e and l through (31) and (35), that the logarithmic-layer TKE budget, Eq. (A.28), is satisfied if

$$C_\epsilon = C_e^{-3/2}. \tag{A.31}$$

Using the estimate of $C_e = 3.33$ (e.g. Umlauf and Burchard, 2003; Umlauf et al., 2003), we obtain $C_\epsilon = 0.165$.

With the x_1-axis aligned with $\langle u_1' u_3' \rangle$, the only non-zero components of S_{ij} and W_{ij} are $S_{13} = S_{31} = W_{13} = -W_{31}$. Then, Eq. (A.29) yields the following expressions for the Reynolds-stress components in the near-surface log-layer:

$$a_{12} = a_{23} = 0, \tag{A.32}$$

$$\left\{1 - \frac{4}{3}\left(\frac{1 - C_{s2}^u}{C_t^u}\right)^2 (\tau_\epsilon S_{13})^2 + 4\left(\frac{1 - C_{s3}^u}{C_t^u}\right)^2 (\tau_\epsilon W_{13})^2\right\} a_{13} + \frac{1}{C_t^u}\left(\frac{4}{3} - C_{s1}^u\right)\tau_\epsilon S_{13} e = 0, \tag{A.33}$$

$$\begin{aligned} a_{11} + \frac{\tau_\epsilon}{C_t^u}\left[\frac{2}{3}\left(1 - C_{s2}^u\right) S_{13} + 2\left(1 - C_{s3}^u\right) W_{13}\right] a_{13} &= 0, \\ a_{22} - \frac{\tau_\epsilon}{C_t^u}\left[\frac{4}{3}\left(1 - C_{s2}^u\right) S_{13}\right] a_{13} &= 0, \\ a_{33} + \frac{\tau_\epsilon}{C_t^u}\left[\frac{2}{3}\left(1 - C_{s2}^u\right) S_{13} - 2\left(1 - C_{s3}^u\right) W_{13}\right] a_{13} &= 0, \end{aligned} \tag{A.34}$$

Substituting Eqs. (17), (35), (A.30) and (A.31) along with the expressions $S_{13} = W_{13} = \frac{1}{2}\frac{\partial \langle u_1 \rangle}{\partial x_3}$, $C_{s2}^u = -6\alpha_5$ and $C_{s3}^u = \frac{2}{3}(2 + 7\alpha_5)$ into Eq. (A.33), we obtain the following quadratic equation for the disposable coefficient α_5:

$$44\alpha_5^2 - 4\alpha_5 - \left[1 + \frac{9C_t^u}{4}\left(\frac{4}{3} - C_{s1}^u\right) - \frac{9}{2}\left(\frac{C_t^u}{C_e}\right)^2\right] = 0. \tag{A.35}$$

The physically meaningful negative root of Eq. (A.35) is given by

$$\alpha_5 = \frac{1}{22}\left[1-(1+11C_\alpha^*)^{1/2}\right], \qquad C_\alpha^* = 1+\frac{9C_t^u}{4}\left(\frac{4}{3}-C_{s1}^u\right)-\frac{9}{2}\left(\frac{C_t^u}{C_e}\right)^2. \tag{A.36}$$

Using $C_{s1}^u = 4/5$, $C_t^u = 1.8$ and $C_e = 3.33$, we obtain $\alpha_5 = -0.164$.

With due regard for Eqs. (17), (35), (A.30), (A.31) and (A.33) and the expressions for $S_{13} = W_{13}$, C_{s2}^u and C_{s3}^u given above, Eqs. (A.34) yield the following estimates of the velocity variances in the near-surface log-layer:

$$\begin{aligned}
\langle u_1'^2\rangle &= \frac{2C_e}{3}\left(1-\frac{4\alpha_5}{C_t^u}\right)u_*^2,\\
\langle u_2'^2\rangle &= \frac{2C_e}{3}\left(1-\frac{1+6\alpha_5}{C_t^u}\right)u_*^2,\\
\langle u_3'^2\rangle &= \frac{2C_e}{3}\left(1+\frac{1+10\alpha_5}{C_t^u}\right)u_*^2.
\end{aligned} \tag{A.37}$$

It should be pointed out that with the above estimates of C_t^u, C_e and α_5 the velocity variances are always non-negative, i.e. the realizability requirements are satisfied.

Appendix B. Disposable Constants and Parameters of TKESV-Bas

Estimates of disposable constants and parameters of the baseline version of the TKESV scheme are summarized in Table 1. The values of $C^u_{s2} = 3/5$ and $C^u_{s3} = 13/15$ correspond to $\alpha_5 = -1/10$ [Eq. (26) with $F_l = 0$], i.e. to the one-component or two-component limit of anisotropic turbulence. These optional estimates are given in parentheses.

Table 1: Disposable Constants and Parameters of TKESV-Bas

Constant/ Parameter	Estimate	Equation for	Equation Nos.	Comments
C^d_e	0.1	e	(60)	
$C^d_{\theta\theta}$	0.1	$\langle \theta_l'^2 \rangle$	(61)	
C^d_{qq}	0.1	$\langle q_t'^2 \rangle$	(62)	
$C^d_{\theta q}$	0.1	$\langle \theta_l' q_t' \rangle$	(63)	
R_τ	0.5	$\langle \theta_l'^2 \rangle$, $\langle q_t'^2 \rangle$, $\langle \theta_l' q_t' \rangle$	(61)–(63)	
C_ϵ	0.165	τ_ϵ	(64)	$= C_e^{-3/2}$
κ	0.4	l	(64)	
C_{lb}	1.0	l	(64)	
l_∞	200 m	l	(64)	
C^u_t	1.8	$\langle u_i' u_j' \rangle$	(65)	
C^u_{s1}	4/5	$\langle u_i' u_j' \rangle$	(65)	
C^u_{s2}	0.986 (3/5)	$\langle u_i' u_j' \rangle$	(65)	$= -6\alpha_5$
C^u_{s3}	0.567 (13/15)	$\langle u_i' u_j' \rangle$	(65)	$= \frac{2}{3}(2 + 7\alpha_5)$
C^u_b	3/10	$\langle u_i' u_j' \rangle$	(65)	
C^θ_t	5.0	$\langle u_i' \theta_l' \rangle$	(66)	
C^θ_{s1}	3/5	$\langle u_i' \theta_l' \rangle$	(66)	
C^θ_{s2}	1	$\langle u_i' \theta_l' \rangle$	(66)	
C^θ_b	1/3	$\langle u_i' \theta_l' \rangle$	(66)	
C^q_t	5.0	$\langle u_i' q_t' \rangle$	(67)	
C^q_{s1}	3/5	$\langle u_i' q_t' \rangle$	(67)	
C^q_{s2}	1	$\langle u_i' q_t' \rangle$	(67)	
C^q_b	1/3	$\langle u_i' q_t' \rangle$	(67)	
C_e	3.33		(A.30)	Required to estimate C_ϵ through (A.31) and α_5 through (A.36)
α_5	-0.164 $(-1/10)$		(A.36), or (26)	Required to estimate C^u_{s2} and C^u_{s3}

Appendix C. Turbulence Potential Energy

The quantity P defined by Eqs. (73) and (74) naturally appears in the equations for the Reynolds stress and scalar fluxes. It is characteristic of the potential energy of turbulent flow and can therefore be referred to as the turbulence potential energy (TPE). By way of illustration, consider the temperature-stratified fluid where potential temperature θ is the only thermodynamic variable that affects buoyancy. Then, $q_l = 0$, $q_t = 0$, $\theta_l = \theta$, $\mathcal{I}_\theta = 1$, $N^2 = -\beta_3 \partial \langle\theta\rangle / \partial x_3$, and Eq. (73) is simplified to give

$$P = \tau_\epsilon^2 \beta_3^2 \left\langle \theta'^2 \right\rangle . \tag{C.1}$$

The definition of TPE is not unique, however. For example, the following definition of TPE has been used in the analyses of atmospheric turbulence (see e.g. Zilitinkevich et al., 2007; Mauritsen et al., 2007):

$$P_N = \frac{1}{2} N^{-2} \beta_3^2 \left\langle \theta'^2 \right\rangle . \tag{C.2}$$

A transport equation for P_N can be readily derived using the transport equation for buoyancy (potential temperature) variance. Assuming that N^2 varies slowly in space and time and using the boundary-layer approximation, we obtain

$$\frac{\partial P_N}{\partial t} = \beta_3 \left\langle u_3' \theta' \right\rangle - \frac{1}{2} \frac{\partial}{\partial x_3} \left(\frac{\beta_3^2}{N^2} \left\langle u_3' \theta'^2 \right\rangle \right) - \frac{\beta_3^2}{N^2} \epsilon_{\theta\theta}, \tag{C.3}$$

In the boundary-layer approximation, the transport equation for the TKE, $e \equiv \frac{1}{2} \left\langle u_i'^2 \right\rangle$, reads

$$\begin{aligned} \frac{\partial e}{\partial t} = & -\beta_3 \left\langle u_3' \theta' \right\rangle - \left(\left\langle u_1' u_3' \right\rangle \frac{\partial \langle u_1 \rangle}{\partial x_3} + \left\langle u_2' u_3' \right\rangle \frac{\partial \langle u_2 \rangle}{\partial x_3} \right) \\ & - \frac{\partial}{\partial x_3} \left(\frac{1}{2} \left\langle u_3' u_i'^2 \right\rangle + \left\langle u_3' p' \right\rangle \right) - \epsilon. \end{aligned} \tag{C.4}$$

The term $-\beta_3 \left\langle u_3' \theta' \right\rangle$ on the r.h.s. of Eq. (C.4) (the buoyancy flux) appears with the opposite sign on the r.h.s. of Eq. (C.3). It describes the conversion of the TPE into the TKE that occurs in unstable density (buoyancy) stratification, and vice versa where the stratification is stable. The use of TPE defined through Eq. (C.2) is advantageous as it makes the TPE transport equation particularly convenient and facilitates the analysis of turbulence energetics. For example, Eqs. (C.3) and (C.4) can be added, leading to the total (TPE+TKE) turbulence energy equation that has been used by some researchers in the analyses of stably-stratified turbulent flows (e.g. Zilitinkevich et al., 2007; Mauritsen et al., 2007; Zilitinkevich et al., 2009, 2013).

Note, however, that the TPE defined through Eq. (C.2) is a well-defined quantity (non-negative and finite) only if the flow is stably stratified ($N^2 > 0$). The quantity P_N bears a close analogy to the available potential energy defined as a part of the total potential energy of the stratified flow that can be converted into kinetic energy (see e.g. Vallis, 2006, for a comprehensive discussion). Where the buoyancy stratification is neutral ($N^2 = 0$) or unstable ($N^2 < 0$), P_N is infinite or negative and is not really convenient to use. For the Earth's atmosphere, where the buoyancy stratification is due to both temperature and humidity and the thermodynamics is strongly complicated by phase changes, a TPE transport equation as simple and elegant as Eq. (C.3) is difficult to derive. It is therefore advantageous to work with the variance and covariance equations for the scalar quantities that can be derived from the first principles in a fairly straightforward way. The quantity P defined by Eqs. (73)

and (74), or by Eq. (C.1) in the case of temperature-stratified flow, is merely a diagnostic quantity that naturally appears in the equations for the Reynolds stress and scalar fluxes. It has the physical meaning or turbulence potential energy but a separate transport equation for P is actually not needed.

Appendix D. Stability Functions in Shear-Free Flow

Consider a simple case of shear-free flow. With $S_{ij} = W_{ij} = 0$ (no mean velocity shear), the Reynolds-stress and scalar-flux equations (65)–(67) are considerably simplified (recall that the reference frame rotation is also neglected, $\Omega_i = 0$). The off-diagonal components of the Reynolds stress tensor are zero, $\langle u_1' u_2' \rangle = \langle u_1' u_3' \rangle = \langle u_2' u_3' \rangle = 0$, and so are the horizontal components of the scalar fluxes, $\langle u_1' \theta_l' \rangle = \langle u_2' \theta_l' \rangle = 0$ and $\langle u_1' q_t' \rangle = \langle u_2' q_t' \rangle = 0$. The diagonal components of the Reynolds stress tensor (i.e. the velocity variances) are given by

$$\left\langle u_1'^2 \right\rangle = \left\langle u_2'^2 \right\rangle = \frac{2}{3} e - \frac{2\left(1 - C_b^u\right)}{3 C_t^u} \tau_\epsilon \left(-\beta_3 \left\langle u_3' \theta_v' \right\rangle \right), \tag{C.1}$$

$$\left\langle u_3'^2 \right\rangle = \frac{2}{3} e + \frac{4\left(1 - C_b^u\right)}{3 C_t^u} \tau_\epsilon \left(-\beta_3 \left\langle u_3' \theta_v' \right\rangle \right), \tag{C.2}$$

and the vertical scalar fluxes are given by

$$\left\langle u_3' \theta_l' \right\rangle = -\mathcal{F}_{\mathrm{H1}} \tau_\epsilon e \frac{\partial \left\langle \theta_l \right\rangle}{\partial x_3} - \mathcal{F}_{\mathrm{H2}} \tau_\epsilon \beta_3 \left\langle \theta_l' \theta_v' \right\rangle, \tag{C.3}$$

$$\left\langle u_3' q_t' \right\rangle = -\mathcal{F}_{\mathrm{H1}} \tau_\epsilon e \frac{\partial \left\langle q_t \right\rangle}{\partial x_3} - \mathcal{F}_{\mathrm{H2}} \tau_\epsilon \beta_3 \left\langle q_t' \theta_v' \right\rangle, \tag{C.4}$$

$$\mathcal{F}_{\mathrm{H1}} = \left[1 + \frac{4\left(1 - C_b^u\right)}{3 C_t^u C_t^\theta} \tau_\epsilon^2 N^2 \right]^{-1} \left[\frac{2}{3 C_t^\theta} + \frac{4\left(1 - C_b^u\right)\left(1 - C_b^\theta\right)}{3 C_t^u \left(C_t^\theta\right)^2} \frac{P}{e} \right], \tag{C.5}$$

$$\mathcal{F}_{\mathrm{H2}} = \frac{1 - C_b^\theta}{C_t^\theta}, \tag{C.6}$$

where N^2 and P are given by Eqs. (72)–(74), and $C_t^q = C_t^\theta$ and $C_b^q = C_b^\theta$ are used to obtain Eq. (C.4). In the shear-free limit, $\mathcal{F}_{\mathrm{H2}}$ is merely a constant and $\mathcal{F}_{\mathrm{H1}}$ is a function of $\tau_\epsilon^2 N^2$ and P/e. There is no problem with the stability function $\mathcal{F}_{\mathrm{H1}}$ in the case of stable buoyancy stratification, where N^2 is positive (with the x_3-axis directed vertically upward, $\beta_3 < 0$). If the stratification is unstable, $N^2 < 0$ and the expression in the denominator (first set of square brackets) on the the r.h.s. of Eq. (C.5) may approach zero or become negative, leading to physically meaningless values of $\mathcal{F}_{\mathrm{H1}}$.

A similar problem with the stability functions is encountered within the framework of a one-equation closure scheme that carries prognostic transport equation for the TKE whereas all other second-moment equations, including the scalar-variance and scalar-covariance equations, are reduced to diagnostic algebraic expressions. By way of illustration, we further simplify the discussion and consider a temperature-stratified flow, where moisture effects are neglected and $\theta_l = \theta$. Within the framework of the one-equation TKE scheme, the following down-gradient formulation for the vertical potential-temperature flux holds:

$$\left\langle u_3' \theta' \right\rangle = -\mathcal{F}_{\mathrm{H}} \tau_\epsilon e \frac{\partial \left\langle \theta \right\rangle}{\partial x_3}, \tag{C.7}$$

$$\mathcal{F}_{\mathrm{H}} = \frac{2}{3 C_t^\theta} \left\{ 1 + \left[\frac{4\left(1 - C_b^u\right)}{3 C_t^u C_t^\theta} + 2 R_\tau \frac{1 - C_b^\theta}{C_t^\theta} \right] \tau_\epsilon^2 N^2 \right\}^{-1}. \tag{C.8}$$

As Eq. (C.8) suggests, $\mathcal{F}_{\mathrm{H}}$ may become infinite or negative in convective conditions, where $N^2 < 0$.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

Abstract

The main aim of PT AEVUS was the implementation and testing of the TERRA_URB scheme into the COSMO model. The PT was led by the Italian Aerospace Research Center (CIRA, Italy) and involved researchers from four institutions: ARPA Piemonte (Italy), Russian Hydrometeorological Center (RHM, Russia), German Meteorological Service (DWD, Germany) and the University of Ghent (Belgium). Several case studies have been selected in Europe, according to the availability of data from the different research teams involved in the task. Selected periods have been simulated, in order to test the capabilities of the COSMO model with TERRA_URB (TU) in reproducing the main features of specific dynamics such as the Urban Heat Islands (UHIs). The key conclusion of the work is that the version of COSMO model including TU, 5.05urb5, in general successfully simulates the key features of the UHIs. The outcomes of the PT have also stimulated the research groups to continue the activities in a new priority task (PT AEVUS 2) started in September 2019. The description of the PT with the Gantt chart and the related FTEs can be found on the COSMO web site: http://www.cosmo-model.org/content/tasks/pastTasks/pt_aevus.priv.pdf

1 Introduction

The modelling of urban environment has increased significantly in the last years; in fact, different parametrizations for the land use type have been developed. In COSMO model, cities are represented by natural land surfaces with an increased surface roughness length and a reduced vegetation cover (modification of soil and vegetation parameters of the TERRA model). However, in this representation, urban areas are still treated as water-permeable soil with aerodynamic, radiative and thermal parameters similar to the surrounding natural land. Therefore, this basic representation could not reliably capture the urban physics and associated urban-climatic effects including urban heat islands. For this reason, further developments of the parametrization of the urban land have been carried out. In the last years, three urban parametrizations have been incorporated in COSMO for the standard land-surface module TERRA-ML: a DCEP - multilayer urban canopy model, TEB - single layer urban canopy model, and TERRA_URB - bulk parametrization scheme with a prescribed anthropogenic heat flux. Anthropogenic heat emissions are included as an additional heat source to the first aboveground model layer. The urban canopy scheme DCEP coupled with COSMO-CLM has been evaluated extensively against data over Basel (Schubert and Grossman-Clarke, 2014), while TEB has been evaluated over Berlin (Trusilova et al. 2013). However, later study for Moscow revealed a problem in coupling between urban module and the atmospheric module in COSMO version with TEB scheme, which does not allow to adequately simulate the heat transfer from the urban surface to the lower atmosphere (Varentsov et al. 2017). TERRA_URB offers an intrinsic representation of the urban physics with modifications of the input data, soil module and land atmospheric interactions (the details can be found in Wouters et al. (2016)). TERRA_URB (in the following TU) includes the effects of buildings on the air flow without resolving the energy budgets of the buildings themselves, but using the externally calculated anthropogenic heat flux. This approach allows representing effects of multiple cities on the atmosphere without requiring additional data on the building structure. TU is computationally fast and is recommended for studies with spatial and temporal scales where the interactions between the urban canyon air and the atmosphere do not need to be resolved in detail. The latest version of TU implements the Semi-empirical Urban canopy parametrization (SURY). It translates urban-canopy parameters (containing 3D information) into bulk parameters. TU takes additional surface parameter input fields:

ISA (Impervious Surface Area, see Flanner, 2009) and AHF (Annual-mean anthropogenic Heat Flux, see Maucha et al.,2010), generated with EXTPAR via the WebPEP interface. By default, TU takes fixed values for the urban canopy parameters: variation of urban-canopy parameters is optional and could be don inside the model code. The aim of this PT is an evaluation and a deep verification of the performances of the code using a series of selected case studies, in particular in order to verify the capabilities in reproducing the urban dynamics and specific phenomena, e.g. Urban Heat Islands (UHIs) (Milelli, 2016), in order to decide if (and how) to improve the calibration of the namelist parameters, or the parametrization itself. Since the goal of the urban scheme is to catch small-scale features, only very-high resolution runs have been considered. This document is organized as follows: Section 2 contains a list and description of the subtasks in which the PT is organized. Sections 3 to 7 contain a description of the activities performed by the several research teams involved in the PT (UniGhent, DWD, CIRA, RHM, ArpaP) and the main conclusions are described in Section 8. A technical description of the TU implementation in COSMO model is included as Appendix to this report.

2 Tasks and achievements

A concise summary of the tasks and achievements during the project is presented in this section.

Task 0: installation and debugging of the beta COSMO version including TERRA_URB

The primary task of PT was installation and debugging of the different version of COSMO on the supercomputing facilities of the research centres involved in this PT. In total, 6 versions of the model were installed and tested, namely COSMO5.04g_urb1, COSMO5.05_urb1, COSMO5.05_urb2, COSMO5.05_urb3, COSMO5.05_urb4, COSMO5.05_urb5. These versions were consequently developed and updated during the PT. Initial releases contained a number of bugs (COSMO5.04g_urb1, COSMO5.05_urb1), which were found and fixed by PT participants during the debugging activities (details could be found in Appendix A). The revealed bugs were related with the implementation of TU itself, implementation of the skin-layer temperature scheme, input and output issues. All the problems and bugs, which were revealed during the PT AEVUS, were completely fixed in the recent release, COSMO5.05_urb5, which could be considered as a stable model version for further development.

Task 1: selection of case studies

The selection of certain periods for the each of study areas was based on the experience of each participating institution. In general, considered cases include the days with pronounced urban heat islands and extreme temperature events (warm weather in summer or cold weather in winter). More specifically, two regions have been considered in Italy: the urban areas of Turin and Naples, for which observations in urban and rural context are available. Simulations have been performed over periods selected in recent summer and winter seasons. Moscow (about 35 km diameter of urban landscapes, the biggest European city) with 50-80 km surrounding rural region has been chosen as test domain for Russia. Urban areas of Belgium, selecting summer and winter periods (from 2012 onwards) have been considered, performing an extensive evaluation using "standard" scores, with urban climate observations (in terms of air temperature at 2 m and UHI for Antwerp and Ghent, and boundary-layer temperatures and UHI observed from 100m high mast towers), boundary-layer profiles and satellite imagery.

Task 2: simulation setup and runs

Appropriate simulation setups have been selected for all the considered test cases. In particular, the reference configuration (ctrl) has been built in order to perform a comparison, ctrl (with TU scheme off) and ctrl-TU (with TU scheme on).

Task 3: calibration of TERRA_URB scheme

The TU scheme has two mandatory input fields, namely the Impervious Surface Area (ISA) and the annual-mean Anthropogenic Heat Flux (AHF), varying throughout the domain. The TU scheme also uses the Semi-Empirical Urban Canopy parametrization (SURY) (Wouters et al, 2016) in order to calculate the additional bulk parameters needed. These additional parameters are currently set to default values and hard-coded. Default values could not be suitable for the area under study, depending on the urban canopy properties. For this reason, it would be necessary to investigate the model sensitivity to these parameters, but for time constrains this task has been postponed to the follow-up of the PT.

Task 4: evaluation and verification of the case studies

The verification is the key point of the work. It has been used a dense network of weather stations, to determine the performance of the model in its various flavours, both at the surface and in the atmosphere.

Task 5: writing of the final report

A significant amount of documentation has been produced, and, in particular, the goal to make public the work performed within the COSMO PT, not only to the COSMO members but also to the wider scientific community, has been achieved.

3 Activity performed at University of Ghent: perturbation experiments for Brussels during the 2003 heat wave (H. Wouters)

A range of experiments has been performed to test the sensitivity of climate modelling to urban parametrization for Brussels during the heat wave of 2003 (1st August 2003 until 15th August 2003). The simulations have been performed on a 80x80 grid cell domain (0.025 degree resolution) centred over Brussels, and they are nested in Era-Interim (0.75 degree resolution) driven simulations over the EURO-CORDEX domain (0.11 degree resolution). Six perturbation experiments have been performed with different variants and parameters: the first one is a simulation with the default COSMO model 5.05 without urban parametrization (COSMO5.05 (no urb)). The second one is the initial implementation of TU2.3 (COSMO 5.05_urb_ini), which represents the buildings in the domain, but excluding the anthropogenic heat flux due to human activity.

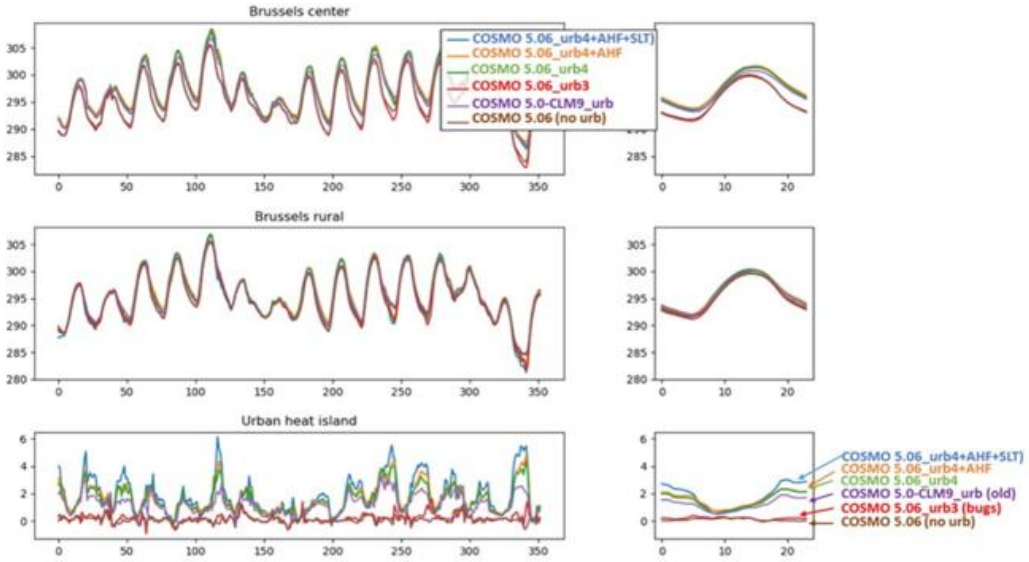

Figure 1: Model time series of T_2m for Brussels center, a rural location and the associated urban heat islands (urban-rural difference) during the heat wave of 2003 for the different perturbation experiments.

The third one refers to a simulation with the same version TU2.3, but implemented in a previous COSMO model (COSMO5.0_clm9_urb), which has been developed and used for climate applications. For description, evaluation and applications, see Wouters et al., 2015; Wouters et al., 2016; Wouters et al., 2017; Demuzere et al., 2017. A fourth simulation refers to a bug fix release of the implementation of TU2.3 into COSMO 5.05 (COSMO 5.05_urb4). The fifth simulation is analogous to the previous simulation, but including the anthropogenic heat flux. The last simulation is the same as the fifth simulation but activating the skin-layer resistance formulation that has been recently integrated into COSMO.

Time series and horizontal profiles of T_2m are shown in Figs. 1 and 2. They indicate that both the COSMO model version and the (urban) land-surface parametrization scheme substantially affect the urban heat wave model results, especially regarding the simulation of the UHI intensities. While the default COSMO model version did not show any UHI, the implementation of TU and additional bug fixes lead to a higher urban air temperature and hence a realistic simulation of the UHI intensity that is most pronounced during the evening and night time. While the formulation of the TU in the new COSMO model version (COSMO5.05_urb4) is similar to the implementation in the previous version (COSMO5.0_clm9_urb), urban heat island intensities now appear to be more pronounced. This suggests that not only the urban land-surface parametrization itself but also changes in the atmospheric model physics and the associated changes in the land-atmosphere feedbacks are determinant for urban climate modelling results. Moreover, the implementation of the skin-layer resistance formulation leading the higher decoupling of surface and air temperature and hence to lower temperature in the rural areas, also results in a more pronounced urban heat island intensity. Since the previous version was showing an overall underestimated UHI according to in situ measurements for Antwerp Belgium (Wouters et al., 2017), the higher UHI values suggest that the new implementation in COSMO5.05_urb4 may have a better model performance in representing urban climate than the previous one in COSMO5.0_clm9.

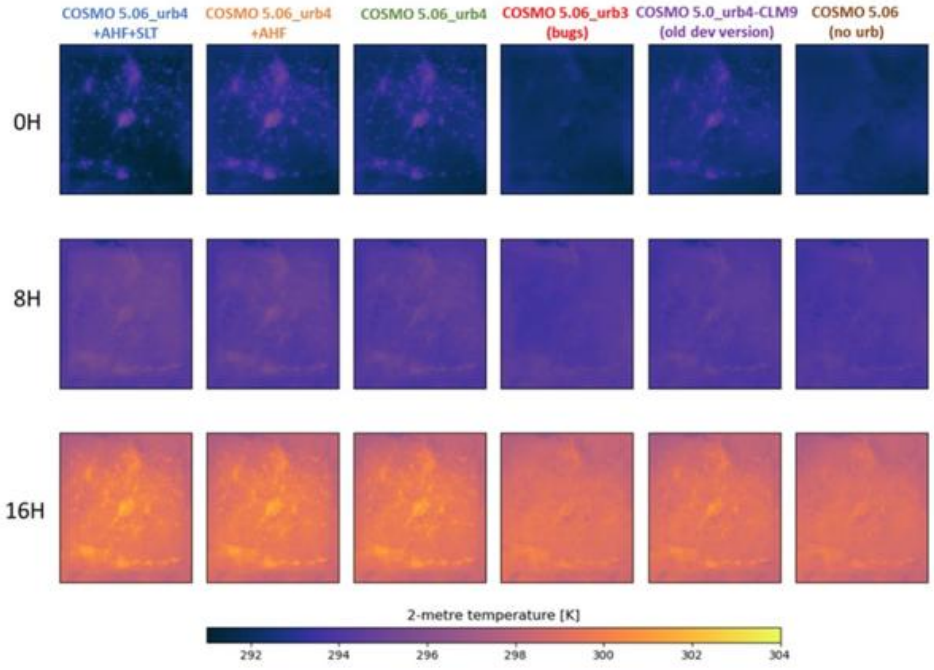

Figure 2: Horizontal profiles of modelled absolute 2-metre air temperature for Brussels at 0H 8H and 16H UTC averaged for the 2003 heat wave (1st August 2003 to 15th August 2003) for different perturbation experiments.

4 Activity performed at DWD: Improved processes in the land surface model TERRA: Bare soil evaporation and skin temperature (J.-P. Schulz, G. Vogel)

Land surface processes have a significant impact on near-surface atmospheric phenomena. They determine near surface sensible, latent heat fluxes, and the radiation budget, and thus influence atmosphere and land characteristics, such as temperature and humidity, the structure of the planetary boundary layer, and even cloud formation processes. All these processes are also very relevant for urban-atmospheric interactions. For example, the UHI is defined as a difference between urban and rural temperatures, so an adequate simulation of the UHI intensity, its dynamics and impacts on atmospheric processes in the model requires a realistic simulation of urban temperature and the rural temperate as well. The typical problem of COSMO model is an overestimation of nocturnal temperatures, which is also a problem for reproducing the observed UHI intensity (see Sec. 6 and Varentsov et al., 2017). It is therefore essential to simulate the land surface processes for rural areas in atmospheric models as realistically as possible.

Verifications have shown that the bare soil evaporation simulated by the land surface scheme TERRA of the COSMO model is systematically overestimated under wet conditions. Furthermore, it turned out that the amplitude of the diurnal cycle of the surface temperature is systematically underestimated. In contrast, the diurnal cycles of the temperatures in the soil are overestimated, instead. This means that the other components of the surface energy and water balances are biased as well, for instance, the surface turbulent heat fluxes as well as

the soil water content. Data from the Meteorological Observatory Lindenberg of the German Meteorological Service (DWD) were used to analyse this model behaviour. The erroneous formulation of bare soil evaporation was replaced by a scheme based on a resistance formulation, which efficiently reduces the simulated vapour flux (Schulz and Vogel 2016). In the standard model configuration of TERRA, there is no representation of the vegetation in the surface energy balance. This means, there is no energy budget including a temperature for the vegetation layer. Furthermore, the insulating effects by the vegetation at the sub-canopy level are missing as well. A scheme providing both of these missing model characteristics was implemented in TERRA, the so-called skin temperature formulation (Viterbo and Beljaars 1995, Schulz and Vogel 2017). As a result, the simulated diurnal amplitude of the surface temperature is increased and the one of the soil temperature is reduced.

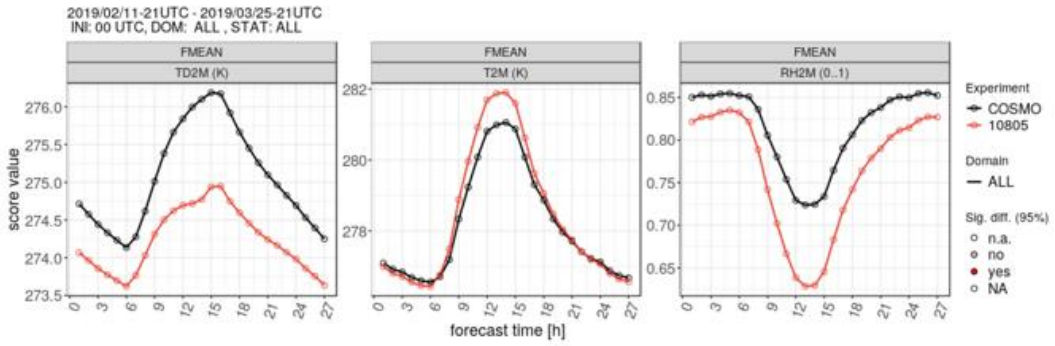

Figure 3: Diurnal cycles of the dew point temperature (TD2M), atmospheric temperature (T2M) and relative humidity (RH2M), all at 2-m above ground, averaged over the whole experimental period of 11 February to 25 March 2019. The COSMO operational reference version is depicted in black, the experiment in red.

A numerical experiment with the COSMO model was carried out that uses, beside the new formulations of bare soil evaporation and the skin temperature, a more realistic exponential root profile, a new interception reservoir for collecting dew on the leaves, and an improved formulation of the dependence of the soil thermal conductivity on soil moisture (Schulz et al. 2016). A comparison of this experiment with the operational COSMO model at DWD as reference is shown in Fig. 3. The experimental period is 11 February to 25 March 2019, i.e. six weeks. The figure shows the diurnal cycles of the dew point temperature, atmospheric temperature and relative humidity, all at 2-m above ground, averaged over the whole period. The experiment is substantially drier, as seen in the dew point temperature and relative humidity. This is mainly due to the new formulation of bare soil evaporation, which corrects for the systematically overestimated moisture fluxes of the reference model version. Furthermore, the simulated diurnal amplitude of the 2-m temperature is increased in the experiment. This is partly due to the decrease of the latent heat flux and its cooling effect, and partly due to the skin temperature formulation. The reference model version shows a substantial moist bias which is almost completely removed in the experiment (see Fig. 4). A pronounced cold bias during daytime in the reference model is considerably reduced in the experiment. The root mean square errors of the humidity and temperature fields are significantly reduced during the whole day.

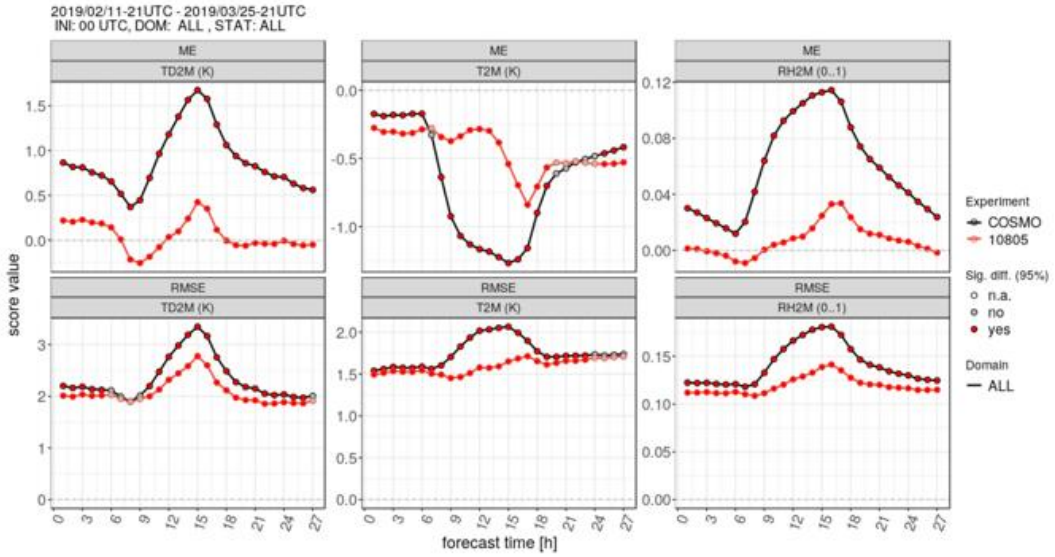

Figure 4: Same as Fig. 3, but for the mean error (ME) and the root mean square error (RMSE) of TD2M, T2M and RH2M.

5 Activity performed ad CIRA: High resolution simulations for the representation of Urban Heat Islands over South Italy (E. Bucchignani, P. Mercogliano)

Numerical simulations have been performed in order to test the capabilities of the COSMO-LM model with TU in reproducing the main climate features of urban areas, and in particular, of the UHIs in a selected area of southern Italy. Tests have been performed over a domain centred over Campania and Lazio region (Fig. 5), employing a spatial resolution of 0.009°(about 1 km), for two selected test cases: the first one (A) is 8-10 August 2017, since in these days the city of Naples experienced extreme temperature and uncomfortable conditions for the population. The second one (B) is 6-8 June 2019, since in these days a sudden increase of the daily maximum temperature was recorded, from about 27 °C to about 33 °C. Therefore, these periods represent a suitable benchmark to test the urban parametrization of COSMO-LM.

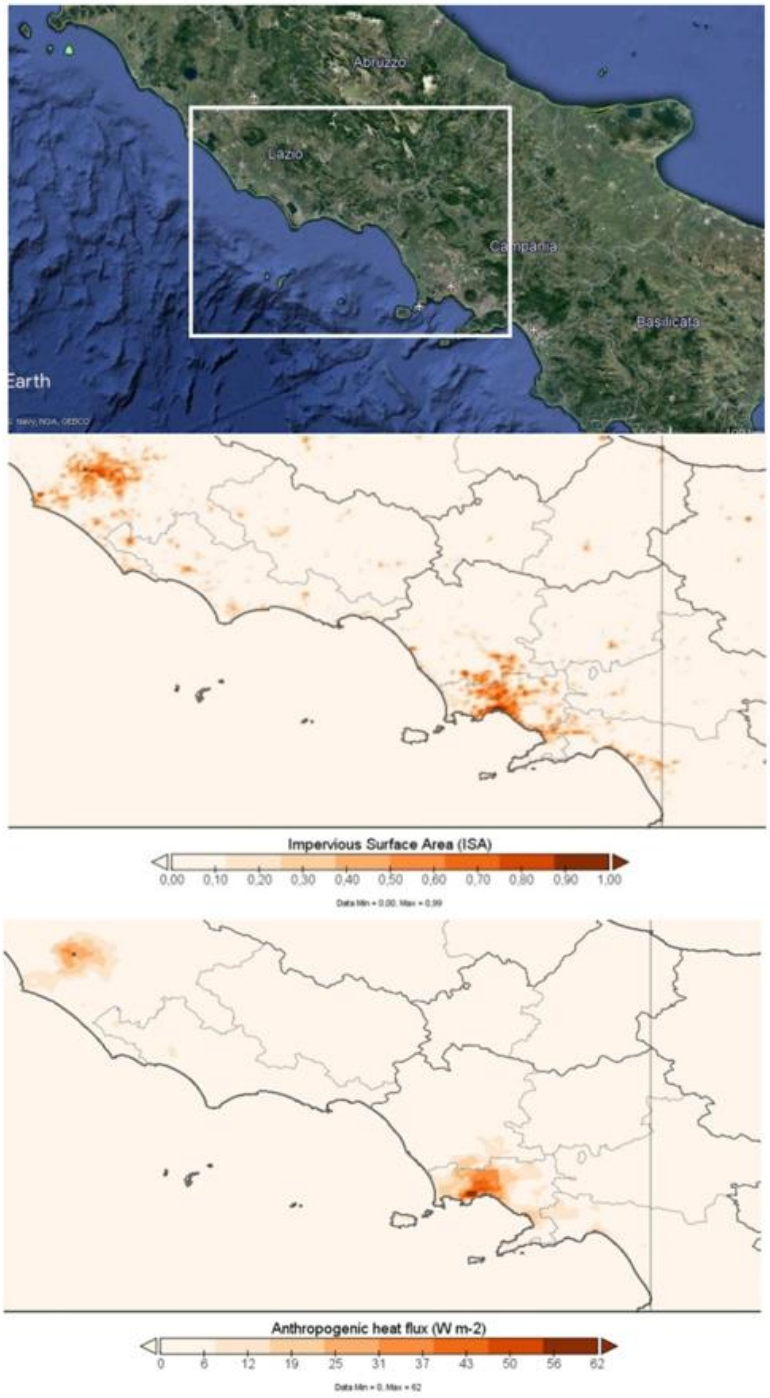

Figure 5: top: the computational domain; middle: impervious surface area; bottom: anthropogenic heat flux distributions.

Two different schemes of canopy parametrizations with respect to the surface energy balance have been considered: the "surface energy balance equation" solved at the ground surface (canopy energetically not represented, itype_canopy = 1) and the skin temperature formulation (itype_canopy = 2). In the second case, the value of implicitness of the vegetation-skin temperature parametrization (cimpl) must be specified. Previous sensitivity tests showed that this second option leads to a better representation of the urban/rural contrasts in surface-atmosphere exchanges, which was found to reduce the negative bias in the UHI in-

tensity. This option also allows investigating the effects of vegetation insulation on urban climate. For each day considered, the following simulations have been performed:

- **NOURB**: Setting OFF the TU scheme
- **URB**: Setting ON the TU scheme and itype_canopy =1
- **URB_itc2**: Setting ON the TU scheme and itype_canopy =2, cimpl =120
- **URB_itc22**: Setting ON the TU scheme and itype_canopy =2, cimpl = 600

Model evaluation has been performed in terms of 2m temperature (T_2m) and 2m relative humidity (Rel_hum) against the following observational data:

- hourly time series of T_2m and Rel_hum provided by the University of Naples, meteorological station located in Fuorigrotta quarter (urban area 14.19°E, 40.82°N).
- daily time series of T_2m and Rel_hum provided by SCIA ISPRA for the rural station of Grazzanise.

In the figures of the next section, observational values are identified as OBS.

5.1 Test case A: 8 - 10 August 2017

Fig. 6 shows the time series of T_2m over the period 8-10 Aug 2017 at the urban area of Naples (top) and the rural area of Grazzanise (bottom). For Grazzanise, only max and min daily observational values are available. The middle panel shows the spatial T_2m distribution for Aug 10th 2017 at 13.00 in a series of points close to Naples location (Naples is located in point 8). AHF is the Anthropogenic Heat Flux Distribution. In Naples, for this test case, it is evident (see also values shown in Tabs. 1-2-3) that URB simulation improves the representation of the mean daily T_2m values with respect to NOURB (improvements larger than 1 °C). Moreover, URB significantly increases the daily minimum values and this has a positive effect in the reduction of the bias. Benefits are achieved also for the daily maximum temperature, anyway a general underestimation with respect to observational data is still evident. The usage of "skin temperature scheme" does not provide any change, as it should not make a significant effect on the temperature in urban areas, because when TU is switched on, it uses a very high skin-layer conductivity for urban areas. Tab. 4 shows the spatial correlation values between simulated (all the simulations) and observed time series of T_2m, revealing that URB values are better correlated to observation than NOURB values. In Grazzanise as expected, URB simulation does not provide changes on the maximum temperature (Tab. 5), but an increase on the minimum one (Tab. 6). This has positive effects on reducing the bias in some days, but in other cases has a negative effect. The usage of itype_canopy=2, as expected in points where AHF is zero or very low, decreases the nocturnal temperatures in rural areas and increase the UHI intensity (urban-rural temperature difference). Setting cimpl = 600 does not provide relevant improvements. Fig. 7 shows the time series of relative humidity (Rel_hum) over the period 8-10 Aug 2017 at (a) the urban area of Naples and (c) the rural area of Grazzanise. For Grazzanise, only daily average observational values are available. Panel (b) shows the spatial Rel_hum distribution for Aug 10th 2017 at 13.00 in a series of points close to Naples location.

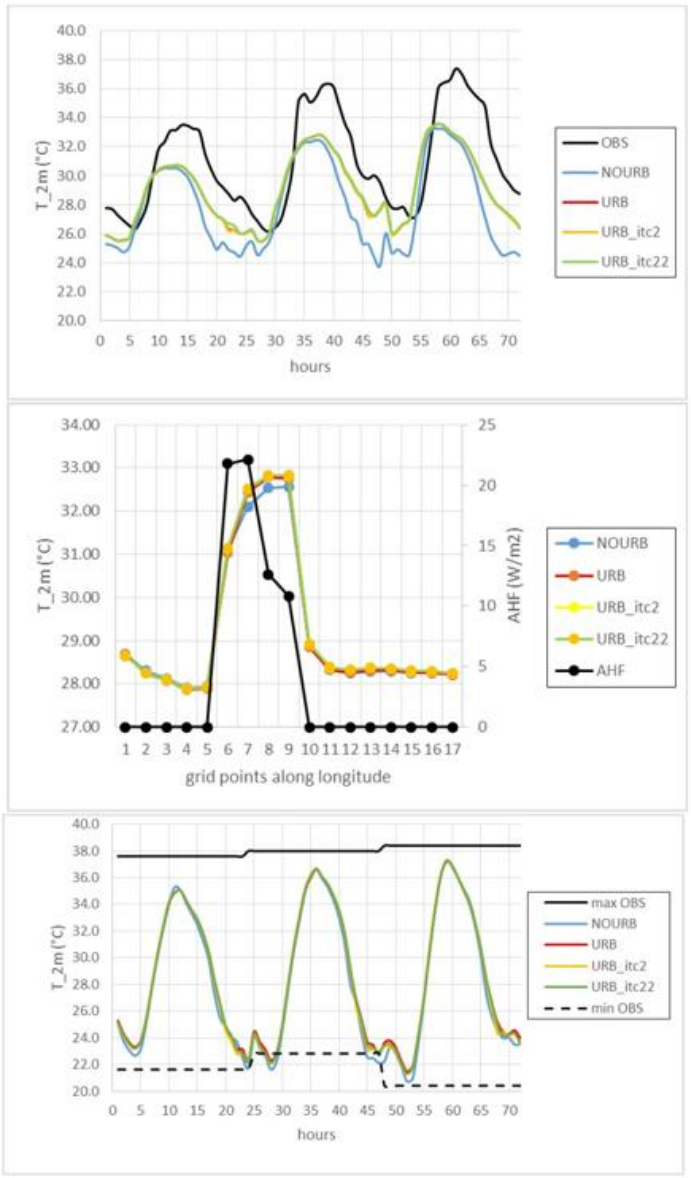

Figure 6: Time series of T_2m over the period 8-10 Aug 2017 at the urban area of Naples (top) and the rural area of Grazzanise (bottom); middle panel: spatial T_2m distribution for Aug 10th 2017 at 13.00 in a series of points close to Naples location (Naples is located in point 8). AHF is the Anthropogenic Heat Flux Distribution.

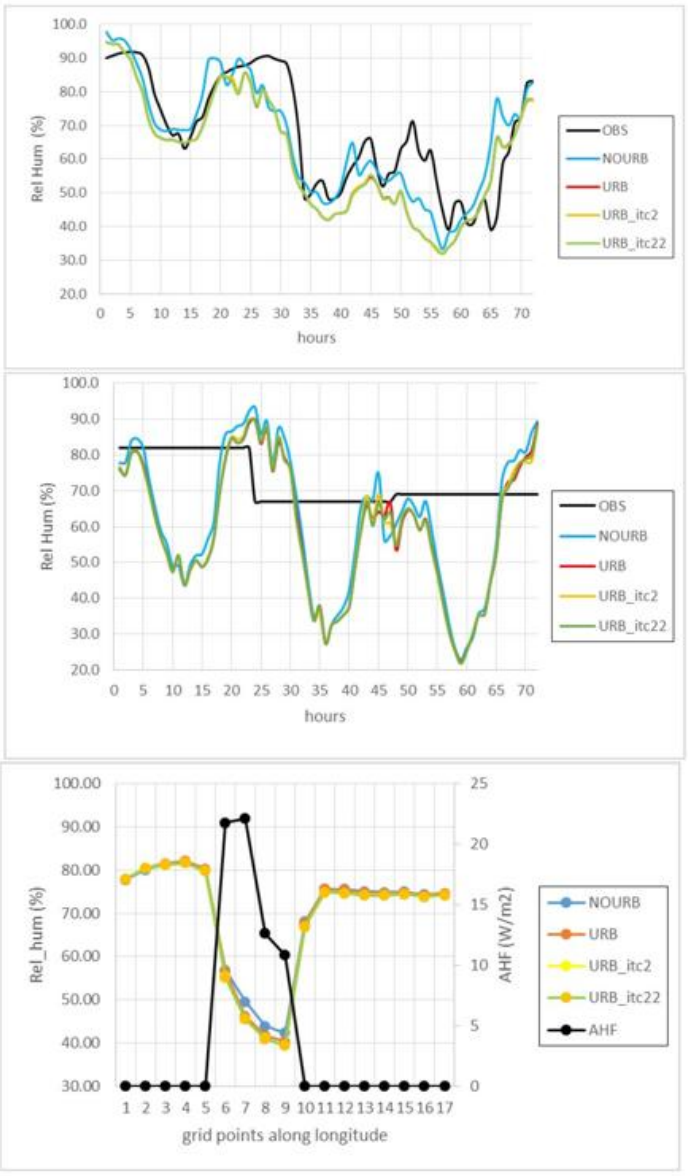

Figure 7: Time series of Rel_hum over the period 8-10 Aug 2017 at the urban area of Naples (top) and the rural area of Grazzanise (bottom). For Grazzanise, only daily average observational values are available; middle panel: spatial Rel_hum distribution for Aug 10th 2017 at 13.00 in a series of points close to Naples location

In Naples, URB simulation provides lower values of relative humidity with respect to NOURB (Tab. 7), leading to a general worsening of performances, with few exceptions. A slight improvement is recorded assuming itype_canopy =2: in fact Tab. 8 shows that in this case simulated values are better correlated to observations. A similar behaviour is recorded also in Grazzanise (Tab. 9), since in this rural area the usage of itype_canopy=2 provides slight better values with respect to itype_canopy = 1. In general, the configuration with itype_canopy=2 does not show consistent improvements with respect to other test cases where it has been tested. This is probably due to the short distance from the sea of the city of Naples. Further investigations need to be done to confirm this hypothesis.

5.2 Test case B: 6 - 8 June 2019

For this test case, only urban simulations assuming itype_canopy = 1 have been performed. Fig. 8 shows the time series of T_2m over the period 8-10 Aug 2017 at the urban area of Naples (top) and the rural area of Grazzanise (bottom). For Grazzanise, only max and min daily observational values are available. In the urban area of Naples, the maximum daily values increase of 0.6 °C (on 6th), 0.8 °C (on 7th) and 0.6 °C (on 8th), but anyway a general underestimation with respect to observational data is still evident. Improvements is confirmed by the higher values of correlation for URB simulation with observations (Tab. 10). In Grazzanise, URB simulation generally does not provide changes on the temperature values, apart from a few nocturnal values that are increased. The diurnal cycle amplitude is always underestimated with respect to observations. Fig. 9 shows the time series of Rel_hum over the period 8-10 Aug 2017 at (a) the urban area of Naples and (c) the rural area of Grazzanise. For Grazzanise, only daily average observational values are available. In Naples, URB simulation provides lower values of humidity, which are better correlated to observation than NOURB (Tab. 11). Also in the rural area of Grazzanise, URB provides a general increase of performances.

6 Activities performed at RHM: high resolution simulations of the urban heat island of Moscow megacity (M. Varentsov, I. Rozinkina, G. Rivin, D. Blinov, A. Kirsanov)

The simulations for the selected cases were performed using the same modelling framework that was used in the previous modelling studies for Moscow (Varentsov et al., 2018; 2019). A chain of nested domains (D3-D1) was used, for a dynamic downscaling of the ERA-Interim reanalysis data for Moscow region for the periods of selected case-studies (about 15 days). The horizontal grid spacing for the domains D3, D2 and D1 was 12, 3 and 1 km respectively (Fig. 10). The TERRA_URB scheme was used only for the final D3 domain with 1-km grid step (180x180 grid cells). In contrast to tests for other cities, where default external parameters AHF and ISA from EXTPAR were used, for Moscow region these external fields were clarified based on OpenStreetMap data (Samsonov et al., 2015; Varentsov et al., 2017; Varentsov et al., 2017).

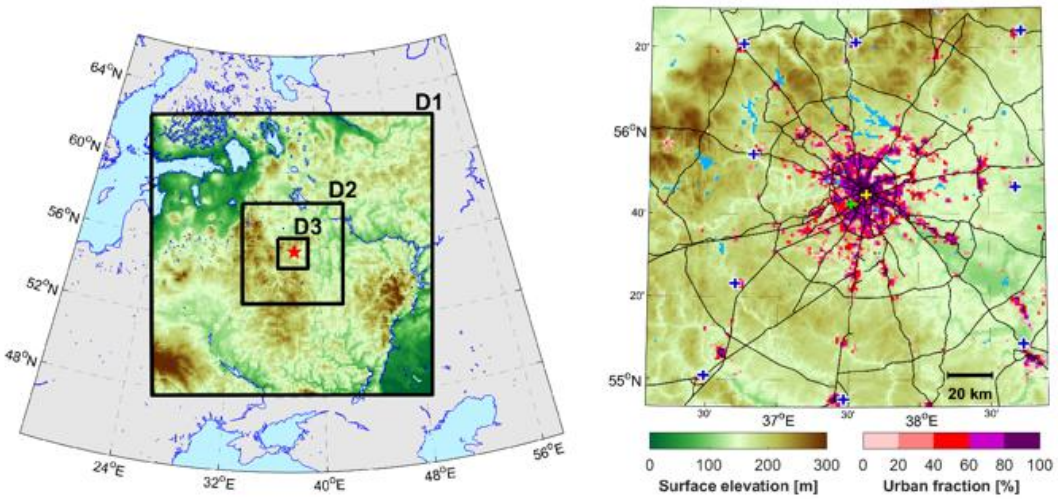

Figure 10: The configuration of the nested domains, used for simulations with the COSMO model, with surface elevation shown by the color scale, and water surfaces shown by the light-blue color (left). A detailed map of the finest D3 domain, used for the urban climate simulations with the COSMO-CLM model coupled to TERRA_URB, with urban fraction shown by an additional color scale (right). The location of the weather stations used for the estimation of the urban heat island (UHI) intensity is also shown (right). The yellow cross indicates Balchug station (considered as the city center), the green cross indicates MSU (Moscow State University) station, and blue crosses indicate the nine rural reference stations around Moscow. The black lines represent the primary road network (right).

For each considered case, three different simulations were performed. The older model version COSMO5.0_clm9_urb was used in the simulations called v5_REF and v5_MOD. In v5_REF simulations, the default values were used for the most of namelist settings; in the v5_MOD simulations, it was used the namelist settings that were carefully tuned in the previous modelling studies for Moscow in order to minimize the systematic model errors, including the well-known nocturnal warm bias. The most important differences between the tuned and default setup include the changes of the minimum coefficients of turbulent diffusion (tkhmin and tkmmin) and the scale of the subgrid thermal inhomogeneity (pat_len) according to (Cerenzia et al., 2014), the use of a new parametrization of bare soil evaporation (Schulz & Vogel, 2016) and a new skin-layer temperature scheme (Schulz & Vogel, 2017). The last set of simulations, v505_REF, was performed with a use of the new model version 5.05urb4. In general, the default namelist settings were used for v505_REF simulations, however, these settings are different from the default settings of the model version 5.0. It is important to highlight that all of new turbulence developments were switched on in simulations with 5.05 model version (loldtur = FALSE). The skin-layer temperature scheme was not used in the simulations with new model version. The key differences among namelist settings for v5_REF, v5_MOD and v505_REF simulations are given in Table 12.

The model verification was performed using the observational data from a dense network of the weather stations and air pollution control stations (more than 70 points in total within the D3 domain), as well as the data from the network of microwave temperature profilers MTP-5. MTP-5 profilers are remote sensing devises which provide temperature profile in the lowest 600 or 1000 m (depends on modification) with 50 m vertical resolution every 5 minutes. The MTP-5 data were provided by Lomonosov Moscow State University, A.M. Obukhov Institute of Atmospheric Physics of Russian Academy of Science (IAP RAS),

Central Aerological Observatory (CAO) and Mosecomonitoring agency. The location of the observational sites in Moscow city and its closest surroundings is shown in Fig. 11.

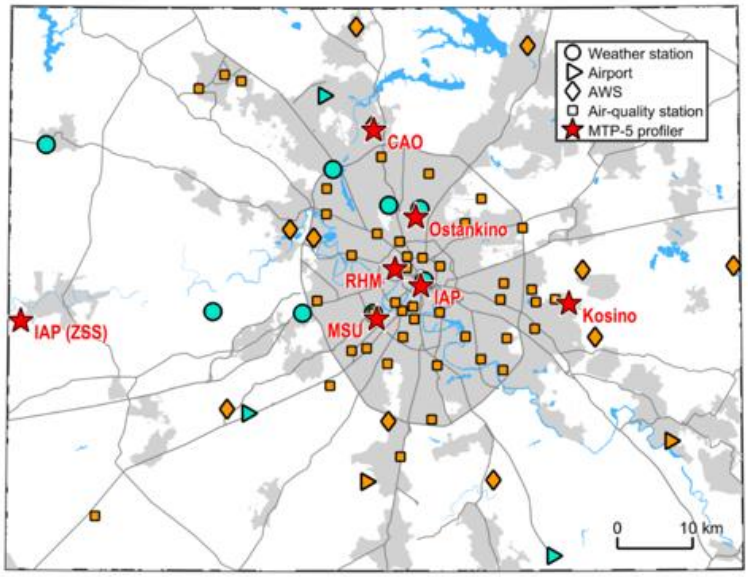

Figure 11: The location of the observational sites, used for the model verification for Moscow region. The orange colour indicates the relatively new observational sites; the cyan colour indicates the sites with long-term observational series.

The verification was focused mainly on the rural temperature and the UHI intensity (a difference between air temperature at the given urban site and mean rural temperature, averaged over 9 stations around Moscow, see Fig. 11). The UHI intensity was defined as a temperature anomaly with respect to the mean rural temperature, which was averaged over the 9 rural stations around Moscow. The greatest attention was paid to the UHI intensity in the city centre, where the Balchug weather station is located. Two case studies were considered for Moscow. The first case is from 17.05.2014 to 29.05.2014. It was a period in late spring (May) with warm, calm and clear weather which included several

days with intensive UHI. The second case study is from 01.01.2017 to 15.01.2017. It was a winter period which included a sub-period of the extremely cold weather from 6 to 10 of January, when temperature dropped below -35°Cin the countryside, and the intensive UHI was observed during more than one day under the conditions of strongly stable stratification of the atmosphere (Yushkov et al., 2019). The unique feature of winter period is that MTP-5 data were also available for city centre, for the IAP RAS site.

6.1 Test case A: 17 - 29 May 2014

For the first considered case in May 2014, the comparison between the modelling results and observations has clearly shown the significant difference between REF and MOD simulations with an older model version COSMO5.0_clm9_urb. The REF simulations strongly overestimate the nocturnal temperature at rural areas and underestimate the UHI intensity, while in the MOD simulations the nocturnal temperature and UHI intensity are much closer to the observations (Fig. 12).

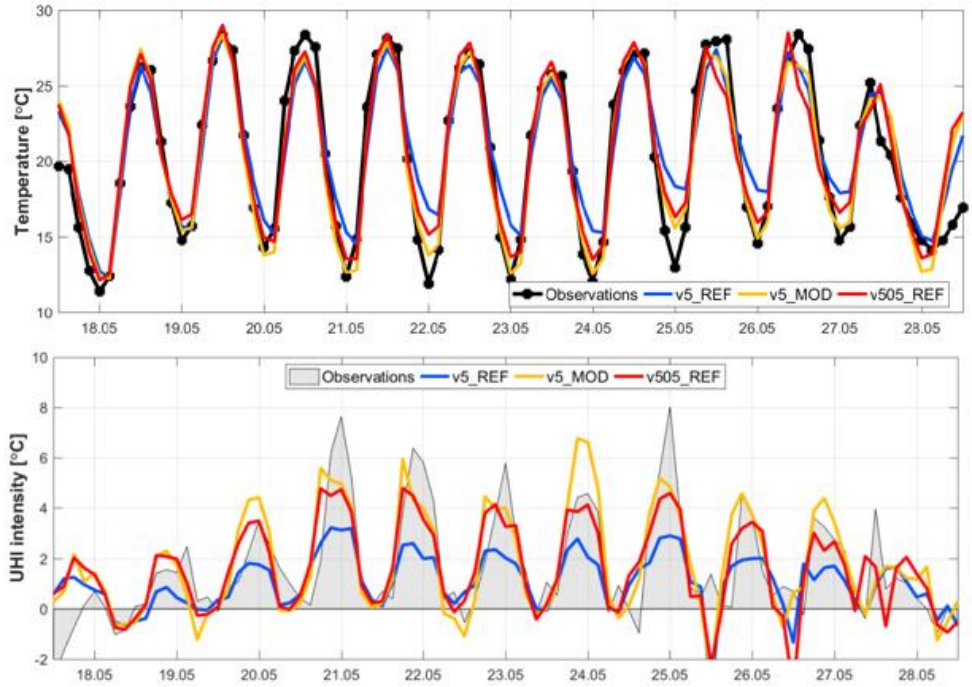

Figure 12: The variations of the mean rural air temperate and the UHI intensity for the city centre (temperature difference between the value for Balchug weather stations and the mean rural value) according to observations and modelling results for case (18-28 May 2014).

The new model version (v505_REF) simulates the rural temperate and UHI intensity almost as well as the old version with tuned settings (v5_MOD). A comparison between the simulated vertical temperature profiles and observations of MTP-5 profiler at a rural site (Zvenigorod, 50 km to the west from Moscow) and a suburb site (CAO, northern suburb of Moscow) has clearly shown that the differences between the different simulations in field of the near-surface temperature are densely linked with the differences in vertical temperature profiles. The v5_REF simulations strongly underestimate the strength of the nocturnal temperature ingestion, while v5_MOD and v505_DEF simulations reproduce it much closer to observations (Fig. 13). In general, v505_DEF simulations still slightly overestimate the

minimal nocturnal temperatures and slightly underestimate the maximum UHI intensity as well as the strength of nocturnal temperature invasion. However, the Skin Layer Temperature Scheme was not used in v505_DEF simulations, so we could expect that the use of Skin Layer Temperature Scheme in new model version will eliminate these biases. Figs. 14 and 15 show that v505_DEF simulation generally nicely captures the spatial structure of the nocturnal UHI of Moscow, as well as v5_MOD simulation.

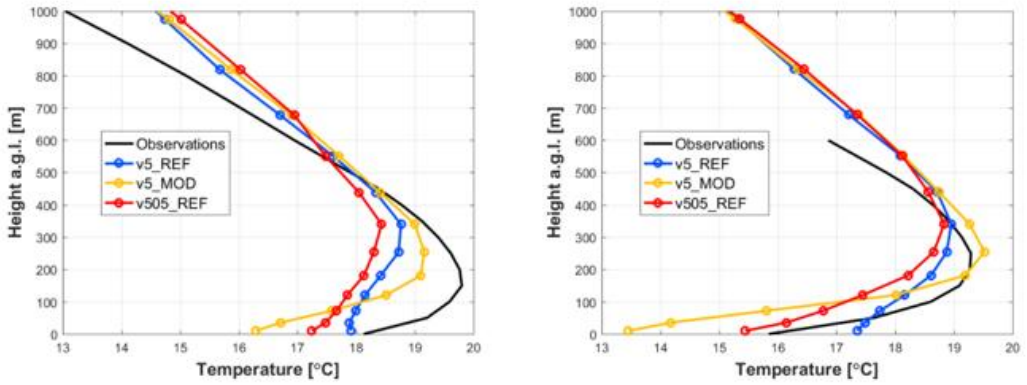

Figure 13: The observed and simulated nocturnal (00UTC) vertical temperature profiles, averaged over the period of 20-27 May 2014 for CAO suburb site (left) and Zvenigorod rural site(right).

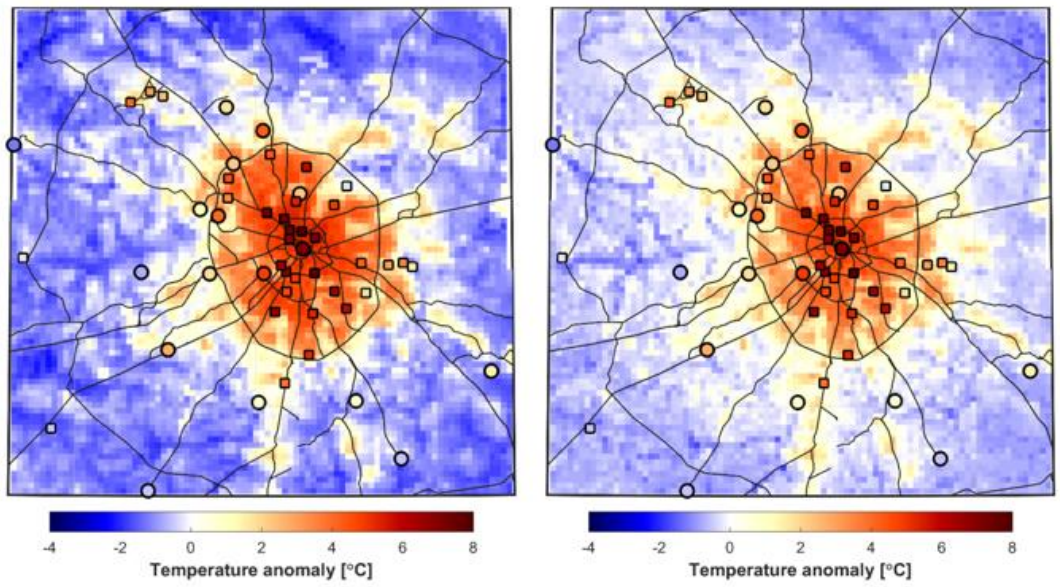

Figure 14: The spatial structure of the average nocturnal (00UTC) urban temperature anomaly in Moscow region according to observations (coloured squares and circles) and simulations v5_MOD (left) and v505_REF (right), shown as coloured background. The averaging is performed over 20-27 May 2014. The temperature anomaly is defined as a deviation from the mean rural value, averaged over 9 rural reference weather stations.

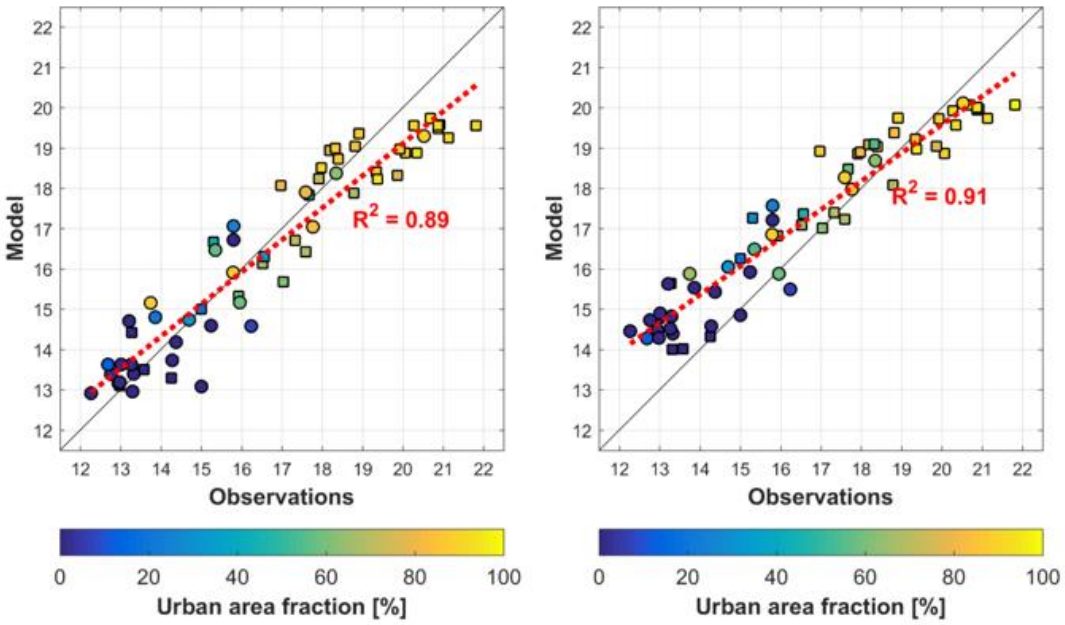

Figure 15: The dependence between the observed and modelled values of the mean nocturnal (00UTC) temperature for v5_MOD (left) and v505_REF (right) simulations. The averaging is performed over 20-27 May 2014. Each point corresponds to a different weather station (circles) or air-quality control stations (squares), the colour of the point represents the urban area fraction for corresponding model grid cell.

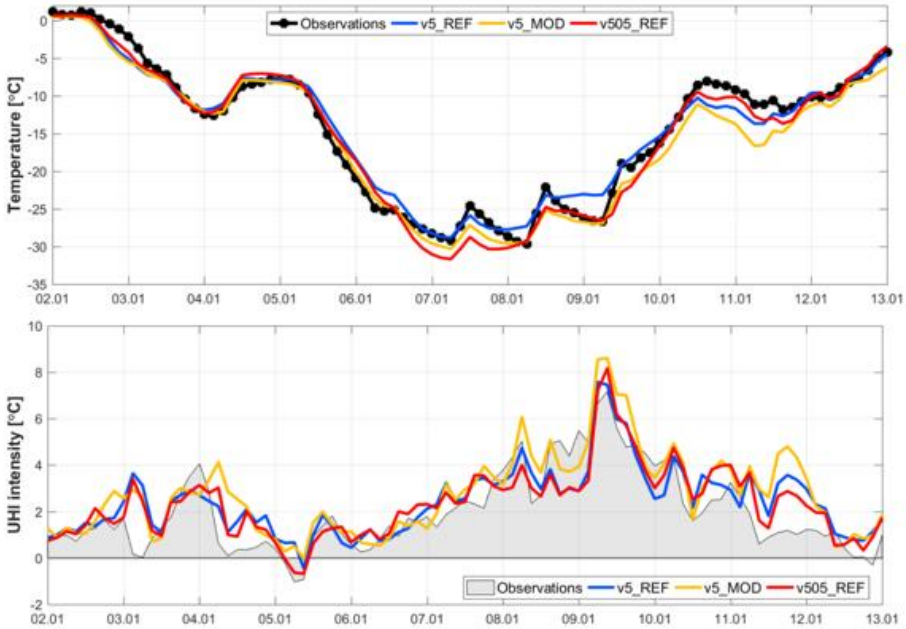

Figure 16: The variations of the mean rural air temperate and the UHI intensity for the city centre (temperature difference between the value for Balchug weather stations and the mean rural value) according to observations and modelling results for case (2-13 January 2017).

6.2 Test case B: 1 - 15 January 2017

For the winter case, all of the considered model runs generally nicely simulate the temporal dynamics of the mean rural air temperature and the UHI intensity for the city centre during this case (Fig. 16). The simulation with the newest model version, 5.05urb, has a cold bias for the peak of cooling at 7th of January, but shows the best correlation with observations, especially after the peak of cooling. Despite a very simple approach used for the AHF definition in TU, the simulations capture the dynamics of the UHI intensity quite nicely. The considered case allows verifying the model ability to simulate the spatial structure of the UHI in different conditions. At 8th of January the UHI was shifted to the southwest by prevailing north-eastern wind, and at the 9th January the UHI was collocated with the urban areas under calm weather conditions. The model generally successfully captures these features; however, the v505_REF simulation shows a lower agreement with observations than v5_MOD simulation (Fig. 17). The data from the network of MTP-5 profiles give a unique possibility to evaluate the vertical temperature profiles in the rural and urban sites during the period of frosty weather. All of the model runs successfully simulate the intensive temperature inversion in the lower atmosphere, which was observed during the last day of the frosty period and promoted the development of the UHI (Fig. 18). The model run with old model version without tuning, v5_REF underestimates the strength of inversion and overestimates the near-surface temperatures. The tuned model run with the old version (v5_MOD) captures the observed vertical temperature profile the best. The model run with the new version (v505_REF) also captures the near-surface temperatures and the inversion strength, but overestimates the height of inversion. All of the model runs successfully simulate the difference between rural and urban temperature profiles, including the UHI in the lowest 100 m above the ground, and a negative temperature anomaly over the city. Such anomaly corresponds to a so-called crossover-effect, which is known from the literature but is still poorly investigated (Khaikine et al., 2006; Lokoshchenko et al., 2016).

The key conclusion from the presented verification results is that the new version of COSMO model including TU, 5.05urb4, in general successfully simulates the key features of the UHI of Moscow megacity for the considered cases, including the spatio-temporal variations of the UHI intensity. The results obtained with the new version (v505_REF runs) are generally consistent with the results obtained with the old version COSMO5.0_clm9_urb (v5_REF and v5_MOD runs). Moreover, even without any special tuning, the simulations with the new model version (v505_REF runs) show almost as good verification results as the carefully tuned simulations with the old model version (v5_MOD runs). Such result indicates the improvements that come from a use of the new ICON-based model physics in the new model version. However, in some cases the new model version is still not perfect, which is shown based on the example of the extreme winter frosts in Moscow. Further improvements are expected from the tuning and calibration of the new model version, including the tuning for the namelist settings, the use of the skin-layer temperature scheme and the improvements of the external parameters for the TERRA_URB scheme.

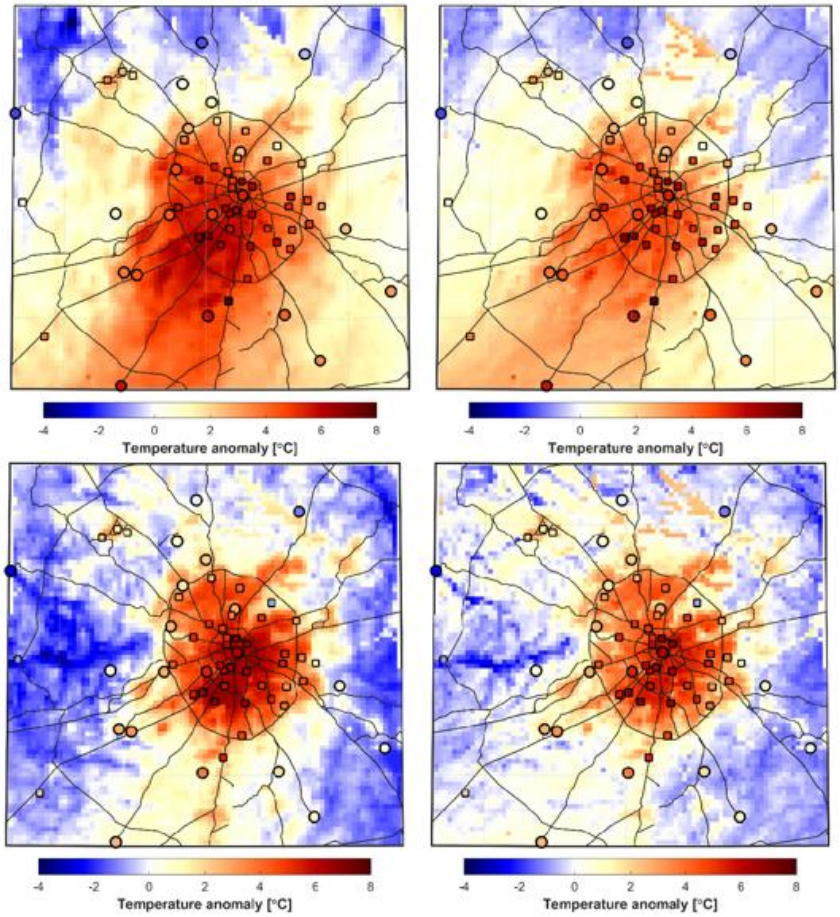

Figure 17: The spatial structure of the urban temperature anomaly in Moscow region according to observations (coloured squares and circles) and simulations v5_MOD (top left,bottom left) and v505_REF (top right, bottom right), shown as coloured background. The averaging is performed over the whole day of 8th of January 2017 (top panels) and 9th of January 2017 (bottom panels). The temperature anomaly is defined as a deviation from the mean rural value, averaged over 9 rural reference weather stations.

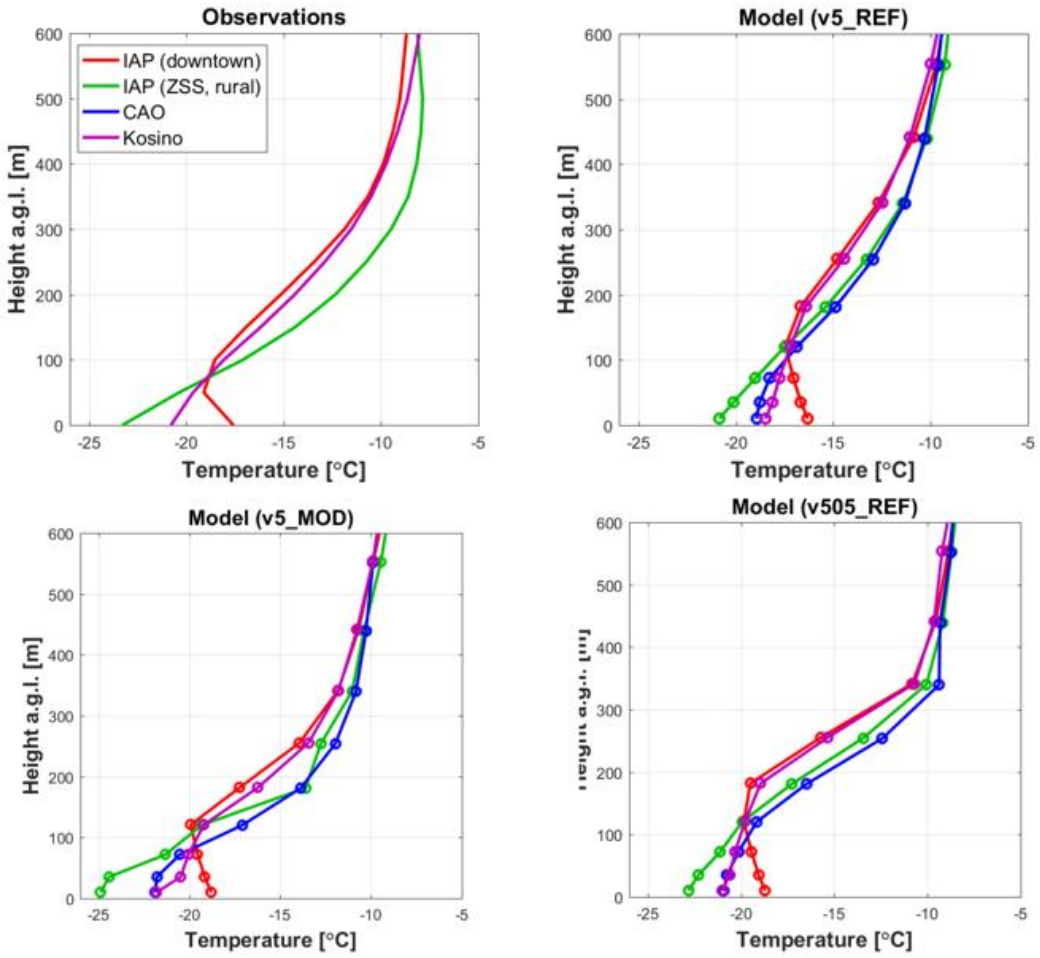

Figure 18: The vertical temperature profiles, averaged of 9th of January 2017, for four sites of Moscow region according to observations (top left) and different model runs (top right and bottom panels). The sites are: city centre (IAP site), rural area near Zvenigorod in 50 km to the west from Moscow (IAP ZSS site), Kosino site in the eastern suburb and CAO site in the northern suburb. The observations for CAO site are not available for the considered period.

7 Activities performed at Arpa Piemonte (V. Garbero, M. Milelli)

This study uses COSMO runs over a domain that includes the Piemonte region (Fig. 19) with a 1 km grid step (480x320 grid cells), driven by initial and boundary conditions provided by the ECMWF Operational Analysis at 9 km horizontal resolution every 6 hours. Simulations were conducted by activating or not the urban scheme TERRA_URB and by using different schemes to calculate the surface temperature, the canopy scheme or the skin conductivity scheme respectively. The urban scheme needs new external parameters (Fig. 21), ISA (impervious surface area) and AHF (anthropogenic heat flux), while the conductivity scheme requires the skin conductivity field (SKC, Fig. 22): all these parameters have been provided by EXTPAR.

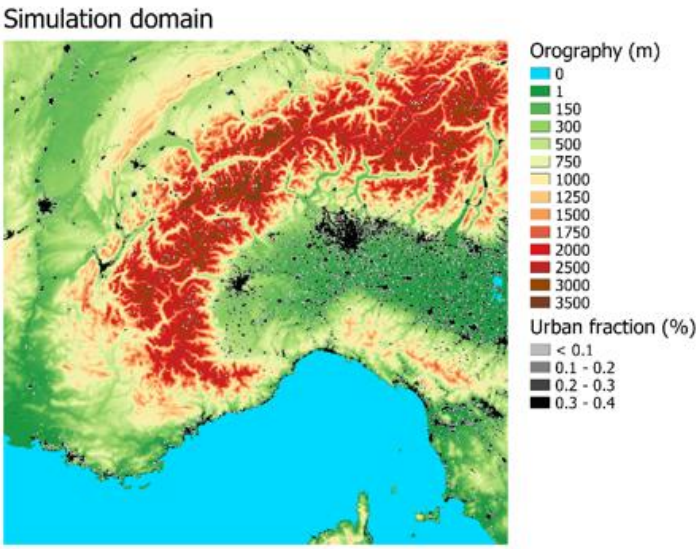

Figure 19: Domain of the simulations.

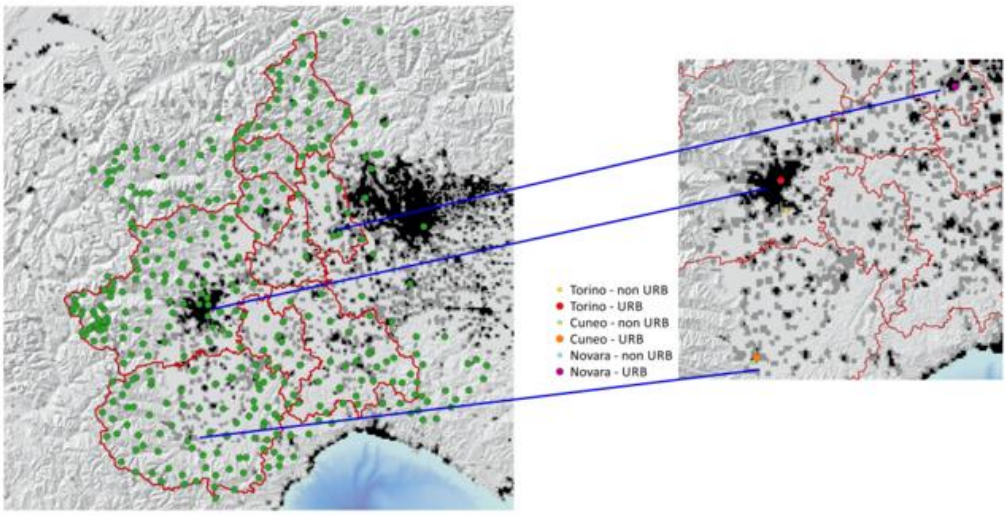

Figure 20: Ground network (left) with the rural/urban stations of the main cities, Torino, Cuneo and Novara (detail on the right).

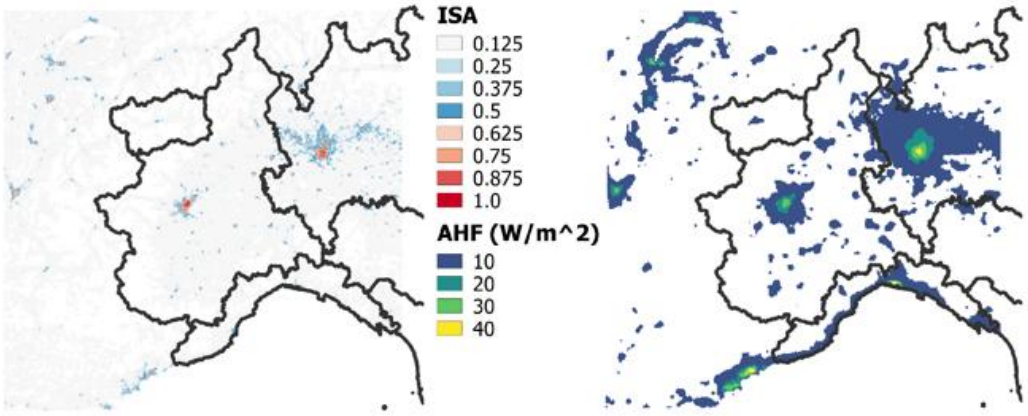

Figure 21: ISA (left) and AHF (right) fields.

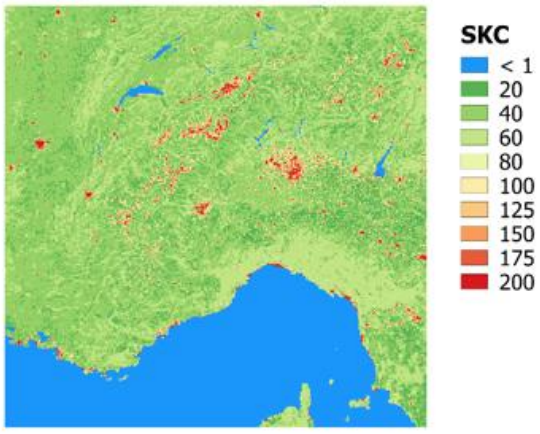

Figure 22: SKC field.

First of all a careful analysis of the UHI in the main cities has been conducted (see Fig. 20), starting from the study of Milelli (2016) and Milelli et al. (2017). In Figs. 24, 25 and 26 the UHI (difference between T2m_urban and T2m_rural) of Cuneo, Novara and Torino (respectively) has been compared. As expected, In Cuneo and Novara the effect is much less evident then in Torino, being smaller cities, nevertheless in Cuneo there is an indication of UHI influence. Therefore, for the selection of the case studies, we focused on the Torino area (Fig. 23), selecting stations 1 and 9 as reference for urban and rural area respectively. After looking at the UHI index defined as $T2m_urban - T2m_rural$ (see Fig. 27), two case studies

have been selected, one in July 2015 (case A) and the other one in October 2017 (case B). The general scheme of the runs is described in Tab. 13.

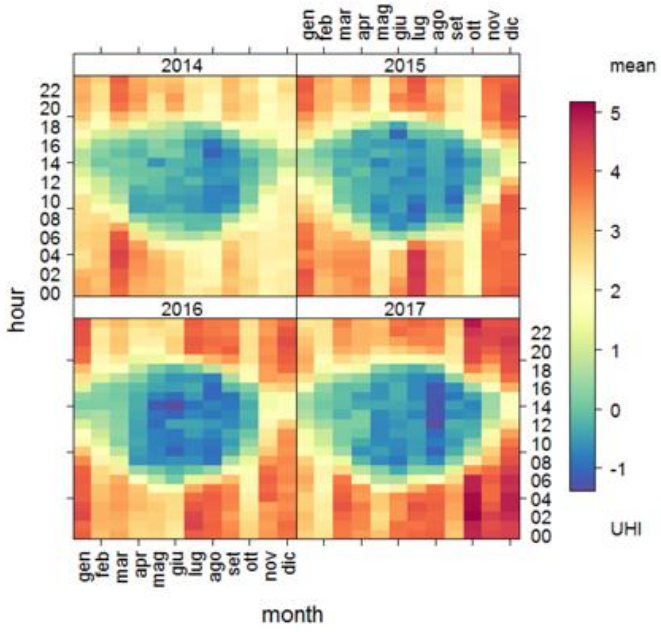

Figure 26: Mean daily cycle of UHI in Torino during 2014-2017 month by month.

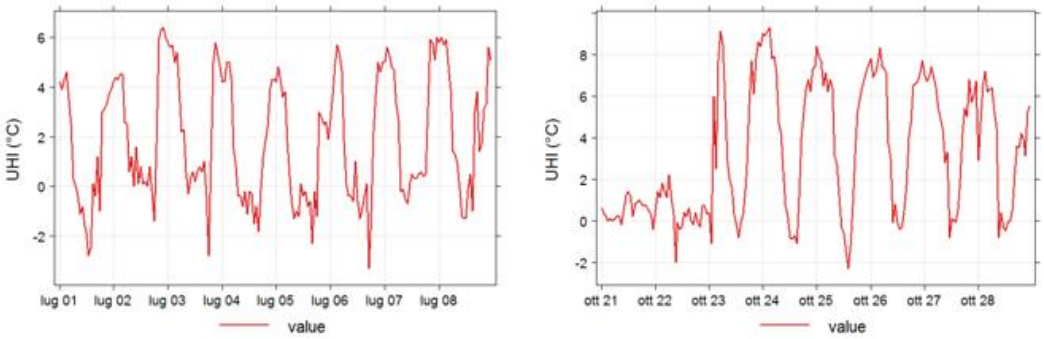

Figure 27: Detail of UHI in Torino in July 2015 (left) and October 2017 (right).

7.1 Test case A: July 2015

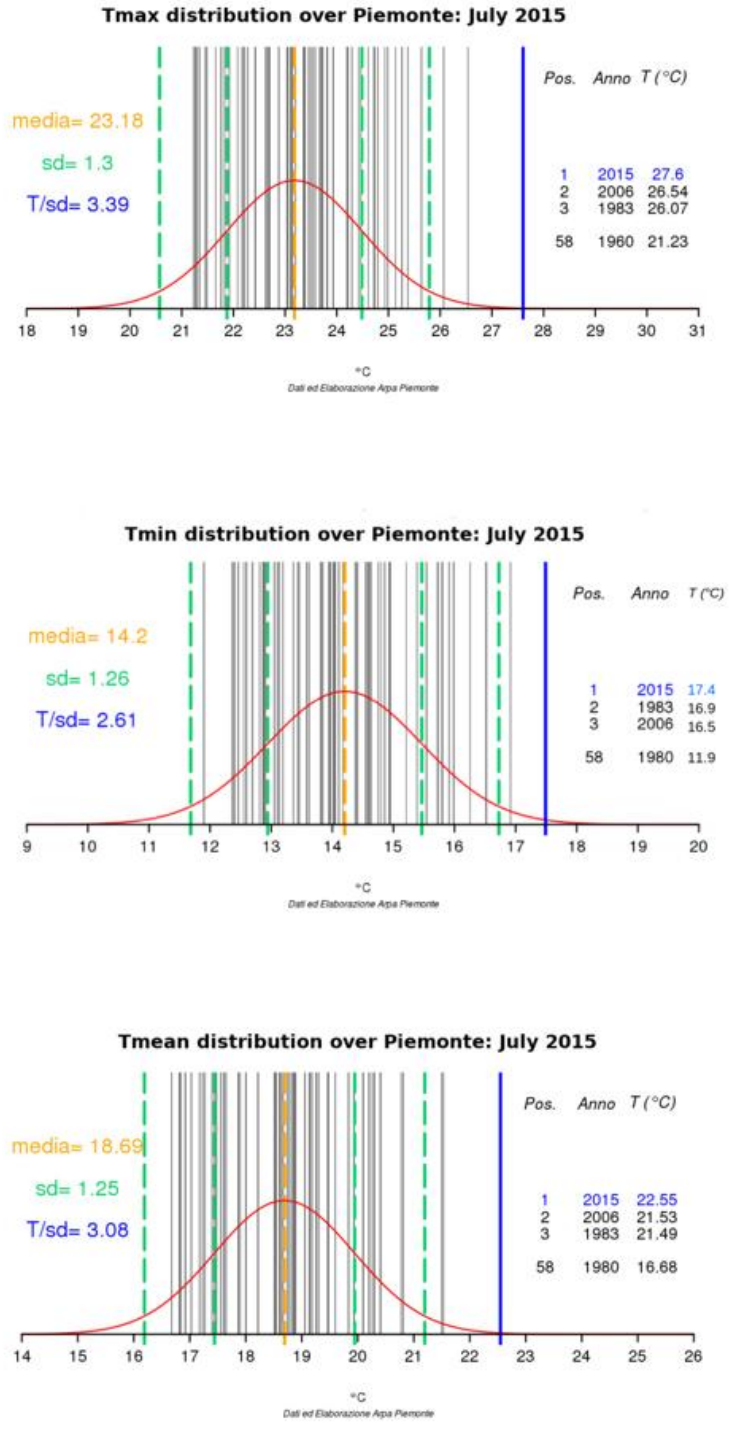

Figure 28: Distribution of T2m max (top), min (middle) and mean (bottom) in July 2015 over Piemonte.

During the first half of July 2015, an intense heat wave stroke Northern Italy with extreme temperature values and uncomfortable conditions for the population. In particular July 2015 has been the hottest July since 1958 (Fig. 28). It comes out that July 2015 is ranked first

in all the measurements. In Torino, the maximum temperature reached 38.5°C during that period and ground stations data pointed out the presence of a clear UHI effect. This is the reason why this area and this period represent a suitable benchmark to test the capabilities of COSMO, and in particular of the urban parametrisation. The simulation in hindcast mode focused on the first week (20150701 00UTC - 20150707 00UTC). In Fig. 29 is plotted the mean bias of UHI index averaged over the entire period of simulation, for the 4 runs. In general the introduction of TERRA_URB (UC1 and UC2) changes the sign and reduces the bias with respect to the respective runs without (CC1 and CC2), although in Cuneo and Novara there is a slight worsening. The effect is more pronounced using Torino Consolata which is in fact the referent urban station in Torino. The SKC scheme improves the UHI slightly (runs CC2 and UC2) with respect to CC1 and UC1.

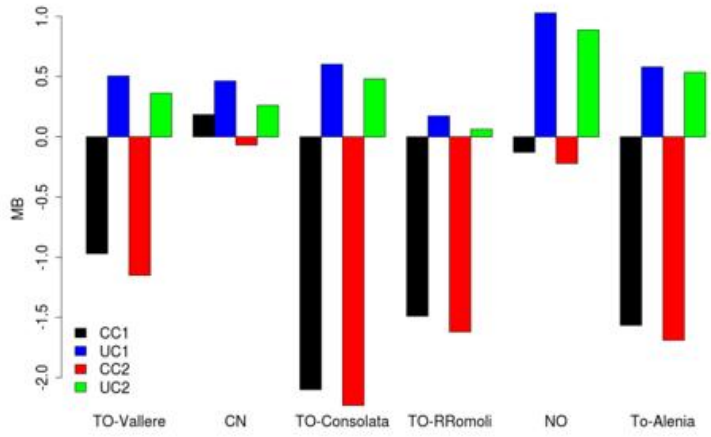

Figure 29: Mean Bias of UHI index over the entire period in a selection of stations. For Torino, different urban stations are used here.

Looking at the mean diurnal cycle, in Fig. 30 we plotted the MB and the RMSE using different samples of stations. In the top row the verification is performed with the whole network available (Fig. 20). The differences among the four runs are negligible, but this is a positive result because the impact of TERRA_URB should be limited to urban areas which are much less extended than rural ones. In the bottom row, the same plots have been made with urban stations only. There it is possible to appreciate the improvement of the new parametrisation, although there is a general heating as it can be better seen in the bias plot. Concerning the impact of SKC, a small difference (in positive direction) can be seen only during night time. Finally, having a look at Fig. 31, the time series of UHI index in Torino are plotted for the entire period. In each graph we compare only two pairs of runs, to better highlight the differences. In the first row it is evident the impact of TERRA_URB with a strong improvement during the night, catching the positive peaks of UHI. On the other hand, during day time the negative peaks of UHI are not seen by the model, with or without urban parametrisation. In the bottom row, SKC seems to have a neutral impact.

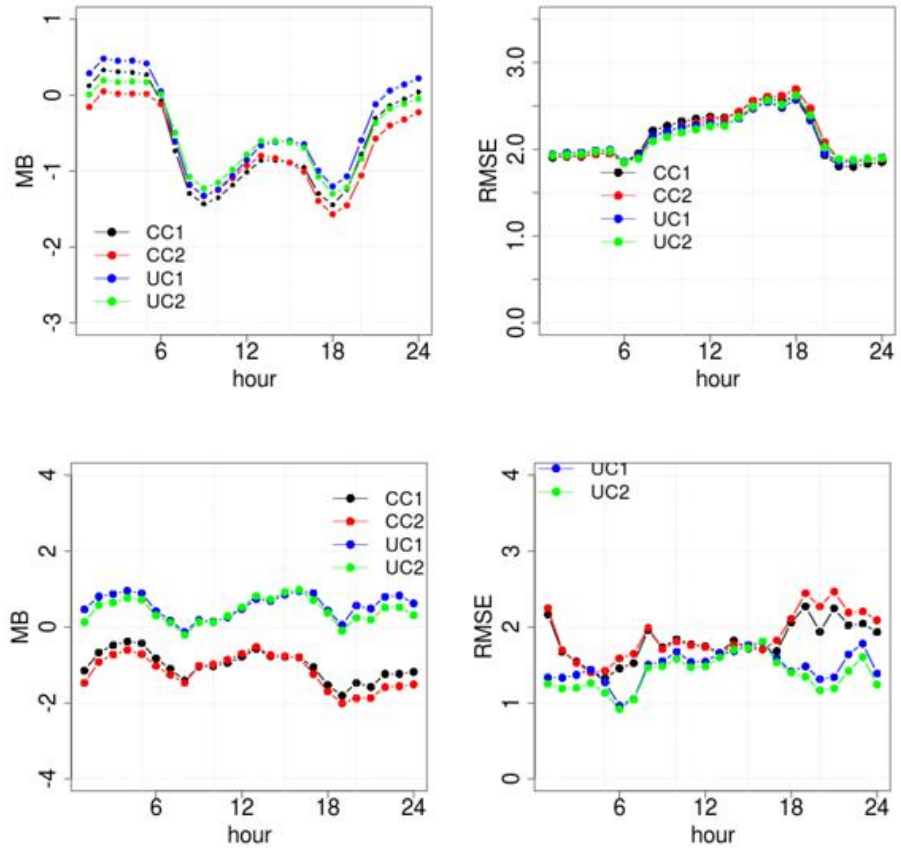

Figure 30: Mean Bias (left) and RMSE (right) using the four configurations in Table 13. All stations of Fig. 19 included (top row); only urban stations included (bottom row).

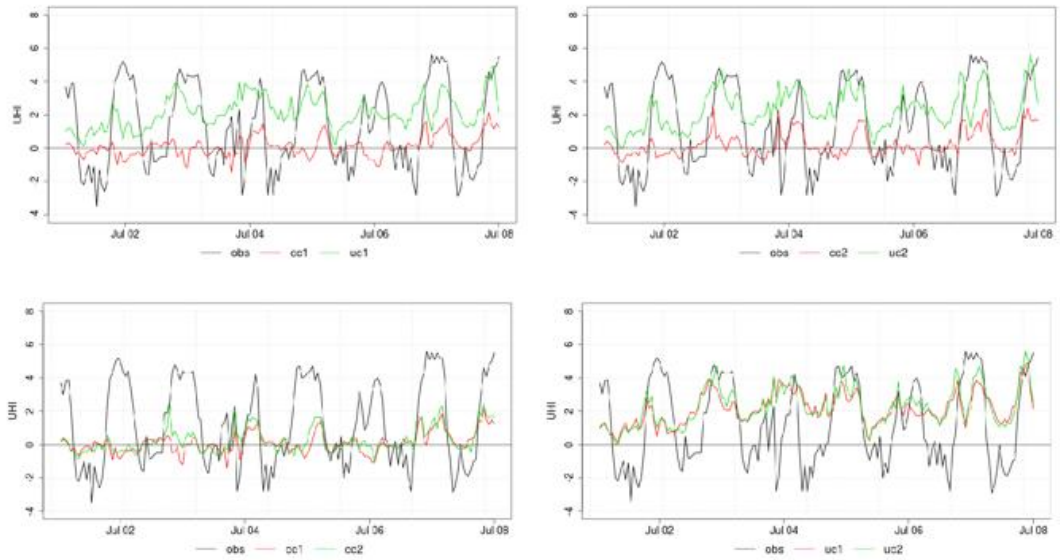

Figure 31: UHI index in Torino for the whole period of simulation. CC1 vs UC1 (top left), CC2 vs UC2 (top right), CC1 vs CC2 (bottom left), UC1 vs UC2 (bottom right).

7.2 Test case B: October 2017

A second test case has been selected, during a much more "normal" meteorological configuration (no heat wave), but standard autumn high pressure. It has to be pointed out that the UHI is more pronounced in this case, probably because the heating was already on. The simulation started on October 23 at 00UTC for 6 days, ending on October 29 at 00UTC, again in hindcast mode. In Fig. 32 the average bias shows a larger improvement with respect to the previous case, although in To-Vallere the T2m gets overestimated. Unfortunately there were problems with the Cuneo station which is not included. The improvement in urban areas is confirmed also from Fig. 33 (bottom row), but still with a general heating (the bias is shifted by 2 °C). In this test case, bias and rmse have higher values with respect to the previous test case. In Fig. 34 it is confirmed the positive impact during the night, but UC2 (bottom right panel) shows slightly better results than UC1 in the peaks. In other words, the amplitude of the cycle is larger with higher maxima and lower minima.

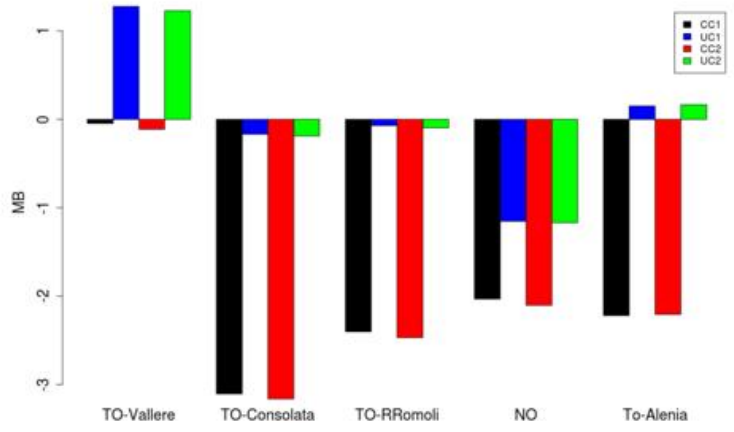

Figure 32: Mean Bias of UHI index over the entire period in a selection of stations. For Torino, different urban stations are used here.

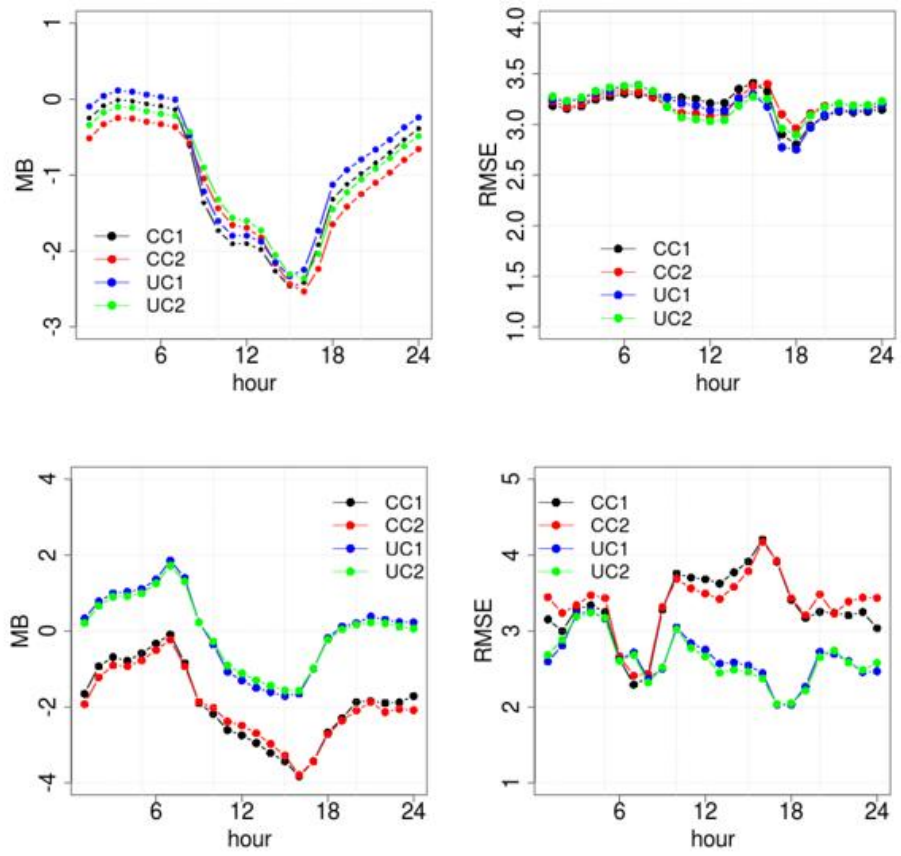

Figure 33: Mean Bias (left) and RMSE (right) using the four configurations in Table 13. All stations of Fig. 19 included (top row); only urban stations included (bottom row).

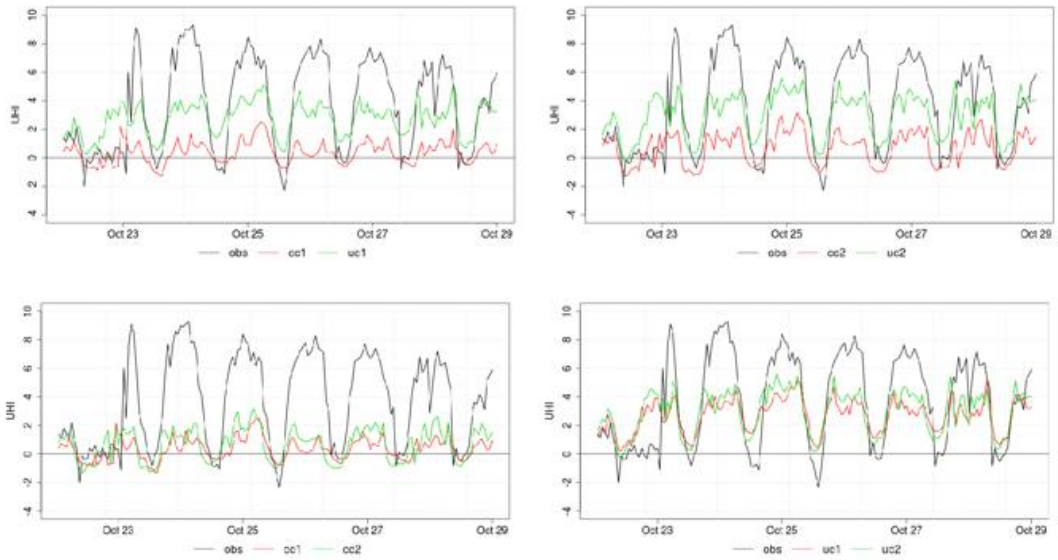

Figure 34: UHI index in Torino for the whole period of simulation. CC1 vs UC1 (top left), CC2 vs UC2 (top right), CC1 vs CC2 (bottom left), UC1 vs UC2 (bottom right).

8 Conclusions

In this report, the activities performed in the framework of PT AEVUS are presented. The main aim of this PT was an evaluation of the performance of a COSMO model version including the urban parametrization TERRA_URB (TU). It is a bulk parametrization scheme including prescribed Anthropogenic Heat Flux and Impervious Surface Area datasets which provides an intrinsic representation of the urban physics. For this purpose, modifications are applied to the model input data, the land surface scheme, and to the land-atmosphere interactions.

The activities were carried out by the modelling groups participating in the task, covering wide ranges of computational domains and periods. A support activity was carried out at DWD, in order to provide the so called skin temperature formulation as part of the land surface scheme TERRA. The skin temperature scheme provides an explicit representation of the vegetation canopy as a component of the surface energy balance. Therefore, it lead to a more efficient decoupling between the surface and the air temperature. In particular, the scheme allows for a more efficient night-time cooling, particularly in the rural areas, and therefore corrects for an important systematic model error of TERRA. As a result, the Urban Heat Island (UHI) intensity, i.e. the temperature difference between urban and rural areas, can be simulated more accurately. Experiments performed over the area of Brussels during the heat wave of 2003 revealed that TU allows an accurate representation of the UHI intensity, most pronounced during the evening and night-time. The numerical simulations over southern Italy on selected test cases have shown that the usage of TU produces a remarkable increase of temperature in urban areas, reducing the model bias. In rural areas, TU provides slight increases on both maximum and minimum temperature daily values, so that the diurnal cycle is always underestimated. Preliminary tests conducted using the skin temperature formulation have shown a reduction of the nocturnal temperatures in rural areas and an increase of the UHI intensity. A careful analysis and comparison with detailed near-surface and boundary layer observations has been conducted over the Moscow megacity area. Results reveal that the model with TU reasonably captures the spatial structure of the UHI by reducing the nocturnal temperature, including the spatio-temporal variations of the UHI intensity. The vertical structure of the UHI (only the lowest 100 m in the considered winter case) is well captured in comparison with the observed temperature profiles. Numerical simulations were conducted over the Piemonte region in order to test the capabilities of TU in simulating UHI in periods characterized by intense heat waves. It was found that the introduction of TU generally reduces the bias. Moreover, the usage of the skin temperature formulation improves the UHI representation slightly. Benefits provided by TU are particularly evident during the night, catching the positive peaks of UHI.

Overall, satisfactory results have been achieved in the framework of PT AEVUS. Further improvements are expected from a more accurate calibration and tuning of the last model version. In particular, an optimized namelist setting for an improved COSMO model performance will be specified, this includes the usage of the skin temperature scheme, and the external physiographic parameters will be improved. These activities will be carried out in the frame of the ongoing PT AEVUS2 (September 2019 - September 2020).

Summarizing, looking at the whole set of results, the authors believe that the TU scheme is suitable to be inserted into the main trunk of the COSMO model and to be distributed in the next official release.

9 Acknowledgements

The authors would like to thank all the scientists involved in the work. In particular Matthias Demuzere for the useful hints about the external datasets, Andreas Will for his suggestions, Pavel Khain for pointing out a few bugs and Jean-Marie Bettems for the support as Working Group Coordinator.

The authors are also thankful to Lomonosov Moscow State University, A.M. Obukhov Institute of Atmospheric Physics of Russian Academy of Science, Central Aerological Observatory and Mosecomonitoring agency and, personally, to Dr. Vladislav Yushkov, Dr. Irina Repina, Arseniy Artamonov and Evgeny Miller for providing the observation data used in the modelling study for Moscow. The simulations and data analysis for Moscow were partially supported by the Grant for the implementation of activities on the development of the system for monitoring and forecasting of, as well as warning against severe and adverse weather events in Moscow city (Resolution of the Government of Moscow No. 257-PP, April 3, 2018). RHM team is thankful to Prof. Dr. Alexander Kislov for scientific advising on the performed modelling studies for Moscow.

A Appendix

Implementing TERRA_URB in COSMO-Model Version 5.05

Ulrich Schättler

Deutscher Wetterdienst

Version 3.0, November 2019

The urban-canopy land-surface scheme TERRA_URB has been implemented in COSMO-Model Version 5.05. The TERRA_URB version used is 2.3, which is taken from the CCLM version COSMO-5.0-clm9. in the following we want to document this implementation into COSMO and try to highlight the technical differences to the implementation in COSMO-5.0-clm9.

Latest Actions in November 2019

This branch of the COSMO-Model is called COSMO-Model 5.05_urb5.
(`cosmo_191119_5.05_urb5.tar.bz2`).

NOTE:
The version `cosmo_191107_5.05_urb5.tar.bz2`, distributed early November 2019 was NOT CORRECT, due to a problem in the source code management.

Implemented a bug fix from Mikhail Varentsov in module `sfc_utilities.f90`, routine `diag_snowfrac_tg`, where usage of skin temperature `t_skin` has been forgotten in case of `itype_canopy = 2`.

Latest Actions in March 2019

This branch of the COSMO-Model is called COSMO-Model 5.05_urb4.
(`cosmo_190329_5.05_urb4.tar.bz2`).

Version 5.05_urb3 gives different results when running the model with `lterra_urb = .FALSE.` or running with `lterra_urb = .TRUE.`, and `ntiles = 0` and setting `FR_PAVED` and `AHF` to zero. In principle, these two runs should have the same results. This has been fixed by the following modifications:

- Treatment of `fr_snow` (fraction of snow): in the former TERRA_URB V5.0_clm19_urb2.3 the fraction of snow was computed at the beginning of TERRA. Now it is calculated in an extra routine, which is called after TERRA. This makes it necessary to introduce `fr_snow` as a tile variable to save the values of each tile for the next step. This was not done up to now, therefore using a value of the wrong tile in the next step.
- Treatment of `tl_freshsnow`: the values of the two tiles were not averaged up now, which gave wrong values for computing the surface albedo during a radiation step.
- The tile variables `tl_snow_melt`, `tl_runoff_s`, `tl_runoff_g` were not averaged to the 0-tile. This does not modify the results, as these are only diagnostic values. But now also the meteograph files `M_xxx` are identical.

Besides these real bugs, there were a few other modifications necessary ro really get bit reproducible results:

1. Setting of the natural tile `plcov`: all plants are considered to be in the natural tile, so `plcov` (urban tile) is 0.0 and the `plcov` (natural tile) has to be modified accordingly. But how it was done gave a different value even in grid points where `FR_PAVED=0.0` (no urban tile). Just for these cases I set `plcov` (natural tile) to the value read for `plcov` for the whole grid box (in module `sfc_tile_approach`, subroutine `tile_define_vegetation_canopy`, settings for `itl=1` (natural tile).
2. Averaging of the two tiles to the 0-tile in subroutine `tile_average_ground` (in module `sfc_tile_approach.f90`) is done with `temp**4` and then taking the 4th root of the result: `EXP (0.25_wp * LOG(temp))`. But this changes the result numerically. For now I do the averaging just as with the other variables.
3. `turb_transfer.f90`: calculation of variables `kbmo` and `dz_s0_h` for `lterra_urb=.TRUE.`: also these computations I modified in a way that they are bit reproducible in case there is only the natural tile.
4. `turb_interface.f90`: The transfer-scheme `turbtran` also uses the `ke`-values of the variables `tkvm`, `tkvh` and `tke`, but only the values for `ke1` are set in `turbtran`. The `ke`-values are only set in `turbdiff` (the atmospheric scheme). But `turbdiff` is not computed for all tiles, only for the averaged 0-tile. Therefore I do a copying of the 0-tile to the natural and the urban tile just for the `ke`-values.

Issues that have to be investigated / clarified:

- Re-think the formula of how `plcov` is modified to get the part of the urban tile (issue 1: above). What I did is only for urban tile=0, but what to do, if urban tile > 0 and natural tile > 0?
- Averaging of the temperatures with `**4`: this gives really big values (about 10E+9); is this really necessary? What is the advantage compared to the usual way? (issue 2: above)
- What to do with the `ke`-values of `tkvm`, `tkvh` and `tke` for the different tiles (issue 4: above)?

Additional technical changes and bug fixes:

- The rank of the external parameter `SKC` was erroneously set to 3, but has to be 2 (in `src_setup_vartab.f90`). Therefore the SKC could not be read and an error was reported by the model. This has been fixed now.
- Implemented additional debug output for a user-defined grid point in TERRA and the turbulence routines.

Latest Actions in October 2018

This branch of the COSMO-Model is called COSMO-Model 5.05_urb3.

- The skin temperature approach has been introduced by Jan-Peter Schulz

- The option `itype_canopy == 2` is fully working now

Latest Actions in September 2018

This branch of the COSMO-Model is called COSMO-Model 5.05_urb2.

- The files `ObjFiles` and `ObjDependencies` have been corrected. The definition of the new modules were missing (thanks to Mikhail).
- A bug fix in `turb_transfer.f90` has been implemented (similar to COSMO 5.05_1 from 31. July 2018).
- In the documentation some default values have been corrected (thanks to Pavel).

Latest Actions in April 2018

This branch of the COSMO-Model is called COSMO-Model 5.05_urb1.

- The former implementation of TERRA_URB in COSMO-Model 5.04g has been updated to the latest COSMO version 5.05.
- Output of tile variables has been implemented in GRIB1 and in restart files. A proper restart is now possible with this version.
- Modifications to the subroutine `tile_average_ground` to perform stable runs with different test cases (from module `sfc_tile_approach.f90`).
- Bug fix in `organize_physics.f90`: the variable `zqv_s` has to be set in all time steps, because this variable is used in the tracer module. This bug was the reason that there were no bit-identical results between version 5.04g and 5.04g_urb1 with setting `lterra_urb=.FALSE.`
- A few other technical modifications (described in DOCS/misc.global).

Latest "CAUTIONS" detected

- TERRA_URB cannot run with a coarse radiation grid. Something is going wrong in the radiation then. This has not been investigated further, because we want to remove this coarse radiation grid anyhow. For TERRA_URB you have to run with `nradcoarse=1`.

1. Using a Tile Approach in the COSMO-Model

1.1. Implementation of Tile Variables

The poor man's tile approach from TERRA_URB has been adopted in the COSMO-Model in a slightly different form. For every variable `var` an additional variable `tl_var` is declared in COSMO-5.0-clm9 with an extra dimension for the tiles. For example

surface roughness * g	`gz0 (ie,je)`	`tl_gz0 (ie,je,0:ntiles)`
fraction of plant cover	`plcov(ie,je)`	`tl_plcov(ie,je,0:ntiles)`

where `ntiles` is the number of tiles used. Before calling a routine which should use the tiles, the corresponding index from the tile-variable is copied to the usual variable and this is used in the routine. Afterwards, the result in the usual variable is copied to the corresponding tile index. Index 0 is used for aggregating the different values for the tiles.

In COSMO-Model 5.04g the new COSMO-ICON physics is written using argument lists for all subroutines. With this the copying of variables can be avoided easily by just writing a loop over all tiles around the call to subroutines. Therefore, in the implementation in COSMO-Model 5.04g we only use the tile-variable `tl_var(ie,je,0:ntiles)`. If no tiles are used, `ntiles` is 0 and the usual values are in `tl_var(:,:,0)`.

Implications to the rest of the COSMO-implementation:

- Throughout the COSMO-Model the use of tile-variables has to be adapted from `var(...)` to `tl_var(...,0)`, but not in the I/O.
- In the I/O we do not want to change the pointers in `src_setup_vartab.f90`. Some special implementation is needed for that. For more details see Section 3.

For the COSMO-ICON physics all variables are needed in a different data structure, which we call the blocked structure. One block consists of a part of the grid points of the two-dimensional domain and can be considered as a vector of grid columns. The name of the blocked variables is just the name of the variable with a suffix `_b`. For variables with a time dimension `tl_var(:,:,ntim=2)`, two variables in blocked format are allocated: `tl_var_b(:,:)` and `tl_var_new_b(:,:)`. Automatic copying of the `ijk`-structure to the block structure and back has been implemented for the tiles.

1.2. List of Variables with a Tile Dimension

The following table shows all variables from the COSMO-Model which are now implemented as tile variables (usual variable with dimensions, tile-variables now used in the COSMO-Model with dimensions, corresponding block variables with dimensions). The first line gives the dimensions of the variables in the program.

Two-dimensional variables:

(ie,je)	(ie,je,0:ntiles)	(nproma,0:ntiles)
gz0	tl_gz0	tl_gz0_b
plcov	tl_plcov	tl_plcov_b
lai	tl_lai	tl_lai_b
tai	tl_tai	tl_tai_b
sai	tl_sai	tl_sai_b
eai	tl_eai	tl_eai_b
tcm	tl_tcm	tl_tcm_b
tch	tl_tch	tl_tch_b
tfm	tl_tfm	tl_tfm_b
tfh	tl_tfh	tl_tfh_b
tfv	tl_tfv	tl_tfv_b
t_2m	tl_t_2m	tl_t_2m_b
qv_2m	tl_qv_2m	tl_qv_2m_b
td_2m	tl_td_2m	tl_td_2m_b
rh_2m	tl_rh_2m	tl_rh_2m_b
u_10m	tl_u_10m	tl_u_10m_b
v_10m	tl_v_10m	tl_v_10m_b
shfl_s	tl_shfl_s	tl_shfl_s_b
qvfl_s	tl_qvfl_s	tl_qvfl_s_b
lhfl_s	tl_lhfl_s	tl_lhfl_s_b
runoff_s	tl_runoff_s	tl_runoff_s_b
runoff_g	tl_runoff_g	tl_runoff_g_b
fr_snow	tl_fr_snow	tl_fr_snow_b
freshsnow	tl_freshsnow	tl_freshsnow_b
snow_melt	tl_snow_melt	tl_snow_melt_b

New two-dimensional variables for TERRA_URB:

(ie,je)	(ie,je,0:ntiles)	(nproma,0:ntiles)
frc	tl_frc	tl_frc_b
isa	tl_isa	tl_isa_b
isa_uc	tl_isa_uc	
sa_uc	tl_sa_uc	tl_sa_uc_b
w_imp	tl_w_imp	tl_w_imp_b
w_isa	tl_w_isa	tl_w_isa_b
kbmo	tl_kbmo	tl_kbmo_b

Two-dimensional variables with a time-dimension. Note that the time-dimension is always the last one!

(ie,je,ntim)	(ie,je,0:ntiles,ntim)	(nproma,0:ntiles,ntim)
t_snow	tl_t_snow	tl_t_snow_b
		tl_t_snow_new_b
t_s	tl_t_s	tl_t_s_b
		tl_t_s_new_b
t_sk	tl_t_sk	tl_t_sk_b
		tl_t_sk_new_b
t_g	tl_t_g	tl_t_g_b
		tl_t_g_new_b
qv_s	tl_qv_s	tl_qv_s_b
		tl_qv_s_new_b
w_i	tl_w_i	tl_w_i_b
		tl_w_i_new_b
w_p	tl_w_p	tl_w_p_b
		tl_w_p_new_b
w_s	tl_w_s	tl_w_s_b
		tl_w_s_new_b
w_snow	tl_w_snow	tl_w_snow_b
		tl_w_snow_new_b
h_snow	tl_h_snow	tl_h_snow_b
		tl_h_snow_new_b
rho_snow	tl_rho_snow	tl_rho_snow_b
		tl_rho_snow_new_b

And for the multi-layer snow model:

(ie,je,ntim)	(ie,je,0:ntiles,ntim)	(nproma,0:ntiles,ntim)
t_snow_mult	tl_t_snow_mult	tl_t_snow_mult_b
dzh_snow_mult	tl_dzh_snow_mult	tl_dzh_snow_mult_b
wliq_snow	tl_wliq_snow	tl_wliq_snow_b
w_snow_mult	tl_w_snow_mult	tl_w_snow_mult_b
rho_snow_mult	tl_rho_snow_mult	tl_rho_snow_mult_b

Three-dimensional variables:

(ie,je,ke1)	(ie,je,ke1,0:ntiles)	(nproma,ke1,0:ntiles)
tkvm	tl_tkvm	tl_tkvm_b
tkvh	tl_tkvh	tl_tkvh_b
edr	tl_edr	tl_edr_b

Three-dimensional variables with a time-dimension. Note that `kex` stands for a variable third dimension, because all these variables do have a different extent in the vertical. Again note that the time-dimension is the last one!

(ie,je,kex,ndim)	(ie,je,kex,0:ntiles,ndim)	(nproma,kex,0:ntiles,ndim)
tke	tl_tke	tl_tke_b
t_so	tl_t_so	tl_t_so_b
		tl_t_so_new_b
w_so	tl_w_so	tl_w_so_b
		tl_w_so_new_b
w_so_ice	tl_w_so_ice	tl_w_so_ice_b
		tl_w_so_ice_new_b

NOTE:

This is just a slightly different way of implementing the poor man's tile approach. It is not (and even not similar) to the tile approach used in ICON!

2. Additional Namelist Variables for TERRA_URB

Several new namelist variables have been implemented in COSMO-5.0-clm9, TERRA_URB 2.3 in the group `/PHYCTL/`. All but one have also been implemented in COSMO-Model 5.04g_urb1. The one not implemented is the logical variable `itype_tile`, which is redundant. The actions of `itype_tile` (0: no tiles, 1: tiles) can also be taken from the number of tiles being $= 0$ or > 0.

The implmented namelist variables are described shortly:

Name	Type	Definition / Purpose / Comments	Default
`ntiles`	`INT`	Number of total tiles. • If the COSMO-Model should run without tiles, the default `ntiles` $= 0$ has to be used. • If the COSMO-Model should run with tiles, `ntiles` has to be set explicitly (in contrast to COSMO-5.0-clm9, where the default of this variable was 2).	`0`
`lterra_urb`	`LOG`	To switch on/off the urban parametrization.	`.FALSE.`
`lurb_fab`	`LOG`	To switch on/off the urban fabric (in a bulk approach). It is only active, if also `lterra_urb` is set.	`.TRUE.`
`itype_ahf`	`INT`	Switch for anthropogenic heat flux. Options are: 0: no anthropogenic heat flux; 1: (default) anthropogenic heat according to *Flanner* (2009); latitudinal, annual, and diurnal-dependent anthropogenic heat flux based on an annual-mean input dataset.	`1`
`itype_kbmo_uf`	`INT`	$kB^{-1} = \ln(z_0/z_{0h})$ parametrization in the surface-layer transfer scheme for the urban fabric. Options are: 0: standard from the surface-layer transfer scheme 1: (default) external parametrization according to Brutsaert/Kanda 2: external from Zilitinkevich	`1`

Name	Type	Definition / Purpose / Comments	Default
itype_eisa	INT	Type of evaporation from impervious surfaces. Options are: 0: evaporation just like bare soil (of course, not recommended) 1: no evaporation (dry surface) 2: (default): density function of puddle depths (Wouters et al., 2015)	2
itype_canopy	INT	Type of canopy parametrization with respect to the surface energy balance. Options are: 1: Surface energy balance equation solved at the ground surface, canopy energetically not represented. 2: Skin temperature formulation by Schulz and Vogel (2017), based on Viterbo and Beljaars (1995). This is provided by the new COSMO/ICON code by Jan-Peter Schulz, which is recently adopted by TERRA URB. Model sensitivity tests show that this option leads to a better representation of the urban/rural contrasts in surface-atmosphere exchanges, hence largely improves urban climate modelling. This option also allows to investigate the vegetation insulation in urban areas on urban climate. Please note that this feature is still in experimental stage.	1
cimpl	REAL	value of implicitness of the vegetation-skin temperature parametrization.	120
calamrural	REAL	value of skin-layer conductivity for rural areas (in $Wm^{-2}K^{-1}$).	10
calamurb	REAL	value of skin-layer conductivity for rural areas (in $Wm^{-2}K^{-1}$).	1000

When activating `lterra_urb` the default of the above variables are used. Only the variable `ntiles` has to be set explicitly to 2!

3. Input and Output for the Tile Variables

The I/O implemented for the tile-variables in COSMO-5.0-clm9 is not practical with GRIB. A different method has now been implemented in COSMO-Model 5.05_urb1 for GRIB1 and for restart files (which uses GRIB1-like meta data).

A new namelist variable `lwrite_tiles` has been implemented in the namelist group `/GRIBOUT/`. If this variable is set to `.TRUE.`, all different tiles of a variable are written to output. To distinguish the different tiles, the additional element number is set to the number of the tile (in GRIB1 and in restart files). If writing a restart file, `lwrite_tiles` is set to `.TRUE.`, if `ntiles > 0`.

In order not to have to change the pointering in the module `src_setup_vartab.f90` we kept the *usual* arrays for the tile variables without the additional tile dimension, but put a "`z`" in front of the name, to make it different. In `src_input.f90` the fields are read into the fields

zvar and copied to the tile-variables tl_var afterwards.

In src_output.f90, all tile variables are added to the write_loop. If lwrite_tiles=.TRUE., a loop over all tiles is started to write all tile variables using the correct number of tile as additional element number. If lwrite_tiles=.FALSE., only tile 0 is written to output.

NOTE:

Implementation of all tile variables to NetCDF or GRIB2 is still ongoing.

4. Special Highlights of the Implementation in COSMO-Model 5.05_urb1

1. Implementation of the 2 new modules:

   - The module src_ahf has been named sfc_ahf. It contains one subroutine ahf. In COSMO-Model 5.04g_urb1 this routine is called in organize_physics.f90, after all parametrizations have been calculated and all data have been copied back to the ijk-data structure (because it is written for this data structure).
   - The module src_tile_approach.f90 has been named sfc_tile_approach.f90. It contains the subroutines
     - tile_define_urban_canopy:
     - tile_define_vegetation_canopy: These two routines are called in the module organize_data.f90 after reading the initial and the first two boundary data sets (not in src_input.f90 as in COSMO-5.0-clm9, because after the first boundary data set has been read, also the initial data can be modified again).
     - tile_filling: This new subroutine fills all tiles with the initial values and is also called in organize_data.f90, as the routines above.
     - tile_average_ground: This routine is written for the blocked data format now and is called just after TERRA.
     - tile_average_near_surface:
     - tile_average_near_surface_blocked: This routine is called after the call to the turbulence transfer scheme. It is now written with an argument list and is the blocked version of tile_average_near_surface.

2. The namelist variable tle has been renamed in ntiles (is a more "speaking name").

3. The external parameter data field for the total impervious surface-area index is called ISA in the version COSMO-5.0-clm9, but is now called FR_PAVED (similar to FR_LAND). This has already been implemented at DWD in the GRIB (shortNames) environment. The actual implementation in COSMO-Model 5.04g_urb1 accepts both names (but this is only a hack, because an extra GRIB 1 number is now used for ISA).

4. The new version of the turbulence scheme needs another external parameter SSO_STDH (from the SSO scheme). This parameter is not available in some test data set, therefore its usage has to be switched off, if necessary (modifications necessary in organize_physics and in organize_data.

5. In near_surface, a part "HSM" has been implemented, but only for itype_synd == 1, which is normally not used any more.
   This has not yet been implemented in COSMO-Model 5.04g_urb1.

6. In module `src_slow_tendencies_rk.f90`, a part has been implemented in subroutine `implicit_vert_diffusion_uvwt` for "additional security". In my opinion this is not necessary for COSMO-Model 5.05_urb1, because within TERRA and `tile_average_ground` all variables are only treated for landpoints.

7. Also in module `src_slow_tendencies_rk.f90`, the sensible heat flux is modified by substracting the field `ahf_now` when computing the vertical diffusion of the tendencies. With the new COSMO-ICON physics there is the possibility to compute this vertical diffusion after the physics. This is controlled with the namelist switch `itype_vdif`:

   -1: Vertical diffusion is computed in the dynamics (old behaviour)

   +1: Vertical diffusion is computed after the physics in the blocked data structure. Modification of the sensible heat flux with `ahf_now` is not yet implemented here (still have to think how to do it best).

5. Tests

A data set has been provided by Hendrik Wouters for 1st of July, 2012, for up to 15 hours in NetCDF data format. Tests have been performed with COSMO-5.0-clm9 and with COSMO-Model 5.04g_urb1. The following pictures show the 2m temperature computed by COSMO-5.0-clm9 (left) and by 5.04g_urb1 (right). This is just to show that the new version is running and not producing nonsense.

Runs have also been performed to test, whether the version COSMO-Model 5.04g_urb1 gives the same results as version COSMO-Model 5.04g without TERRA_URB. With the bug fix in `organize_physics.f90` (setting `zqv_s` in all time steps) this is now the case.

5.1 Problems with the Test Cases from Piemonte and Moscow

The version `cosmo_171113_5.04g_urb1` could not be used for test cases from Piemonte and Moscow. This model version crashes, no matter which configuration is used. These problems have been investigated:

5.2. Piemonte: Initial and Boundary Conditions derived from IFS Data

This data seems to be be problematic, because in the first few steps there are several grid points which have a negative value for the variable `QV_S`. This is also the case when using the former version COSMO-5.0-clm9, but this version does not crash, but silently ignores these values. Modifications in the computation of the 2m temperature now lead to crashes in such situations. This could be avoided using `itype_synd=1`.

We also prepared some ICON data for this test case, which did not show this behaviour regarding `QV_S`. But using the ICON data or the IFS data with `itype_synd=1` shows the same problems as the Moscow case.

5.3. Moscow: Initial Conditions without `SSO_STDH`

The new formulation of the turbulence scheme requires `SSO_STDH` as initial field, which was not present in the Moscow test data. To run this case two adaptations are necessary in the source code:

- `organize_data.f90`: Section 3.2, about line 1573: Comment the lines:

```
IF (itype_vdif > -2) THEN
  yvarini(nyvar_i + 1) = 'SSO_STDH  '
  nyvar_i = nyvar_i + 1
ENDIF
```

- `organize_physics.f90`: There are two calls to the subroutine `init_canopy`, in which you have to comment the lines with `d_pat` (line 1468 and 1702):

```
d_pat   = sso_stdh (:,j),     &
```

5.4. Analyzing the Problems

Depending on the configuration, the COSMO-Model shows a few different crashes:

- Crash in `turb_transfer` with negative values of `tl_qv_s` for tile 0.
- Crash in `gscp_graupel` with a negative value of `rho` or negative values of `tl_t_g`.

After some time of debugging, all crashes could be traced back to some calculations in the routine `tile_average_ground` in `sfc_tile_approach.f90`. This subroutine calculates the grid averages from the different tiles for all tile variables.

But for some variables not a grid averaged is used, but a new diagnosis is calculated. This is done for the sensible heat flux, the latent heat flux and the moisture flux. Also the variable `tl_qv_s` is computed again (and some variables necessary for that).

While these new computations seem to be ok for the old version COSMO-5.0-clm9, they seem to be problematic for the new version COSMO 5.05. Therefore we tested to use the fluxes as they are now computed in the physics from Version 5.05 and just aggregated `tl_qv_s` from the different tiles.

With this approach we could run the Piemonte and the Moscow cases without any problems using different configurations ("old" and "new" physics).

6. Major Changes between COSMO Versions 5.0 and 5.04g

6.1. Source Code

The following list gives the major changes in the COSMO-Model since version 5.0. Most of these changes had only a minor impact on the results. Only the bug fix in the dynamics for slope-dependent divergence damping coefficients showed clear differences in the results (with a better verification for our NWP tests).

The replacement of the turbulence and the soil and surface schemes by the ICON version has a major impact on the results, depending on the namelist configuration used (see Section A).

For a full list of changes for each version, please visit
`http://www.cosmo-model.org/content/model/releases/histories/default.htm`

Version 5.01:

- `src_slow_tendencies_rk.f90`: Use `t_g` instead of `t_s` for the flux computations.
- `pp_utilities.f90`: Optimization of the gamma-function.
- Removal of inconsistencies for the tracers
- Work in Dynamics:
  - targeted diffusion to avoid cold pools
  - reformulation of divergence damping coefficients in the new fast-waves solver
  - adaptation of the Runge-Kutta dynamical core to the SPPT (stochastic perturbation of physics tendencies)
- Modifications to lateral Davies relaxation

Version 5.02:

- Bug fix for computation of `kflat` (only when using GRIB2)
- Bug fix in use of MPI data types (only when using `ldatatypes=.TRUE.`

Version 5.03:

- Various bug fixes in the dynamics, TERRA and the radiation.

Version 5.04a:

- Bug fix in the dynamics for slope-dependent divergence damping coefficients

Version 5.04b:

- Introducing a new boundary condition module (only numerical changes)

Version 5.04a-g:

- Introducing ICON versions of parametrizations for turbulence, soil model, sea-ice scheme and FLake. But these schemes can be run in a configuration which reproduces the results from the corresponding COSMO schemes rather closely (see Section A).

6.2. Namelist Variables

The following namelist variables have been deleted or have changed their meaning (range, default value):

`/DYNCTL/`:

Name	Change	Comment
crltau	renamed	The new name now is crltau_inv and is just the inverse of crltau. Since the default is 1.0, this is not changed. Only if you used a different value, you have to adapt that now.
lexpl_lbc	deleted	No more explicit formulation of lateral boundary relaxation possible.
divdamp_slope	changed	This variable changed its default and the possible range (due to the bug fix). Before it was 10.0 < divdamp_slope <= 100.0 (with default 20.0). Now it is 0.1 < divdamp_slope <= 3.0 (with default 1.0).

/PHYCTL/:

In /PHYCTL/ the following namelist variables have been deleted, because now only the multi-layer version of TERRA is possible: lmulti_layer, nlgw, nlgw_ini, nlgw_bd

A few variables have been added for the COSMO-ICON physics: itype_vdif, ltkeshs, idiag_snowfrac, cwimax_ml

Please see the web site cited above for a description of these variables.

/TUNING/:

In /TUNING/ the following namelist variables have been deleted: wichfakt, securi

6.3. A Special Change for the Climate Mode

The treatment of statistically processed fields in the COSMO-Model is different for the NWP- or for the CLM-mode. This is especially true for fields that are accumulated, like the total precipitation TOT_PREC. In NWP-mode these fields are summed up from the beginning up to the end of the forecast, while in CLM-mode these fields are reset to 0.0 after every output step.

In COSMO-Model Version 5.04f we introduced special fields for cell tracking, which also have to be reset to 0.0 after every output. Therefore we had to change the handling of such fields and introduced additional namelist variables to control the way how and when statistically processed fields are reset.

We introduced 4 categories of statistically processed fields:

- Temperatures, e.g.: TMIN_2M, TMAX_2M
- Winds, e.g.: VMAX_10M, VABSMX_10M
- Summations, Averages, e.g.: TOT_PREC, ASHFL_S
- Cells, e.g.: LPI_MAX, TCOND_MAX

Resetting the variables for each category can now be controlled by the namelist variables

- ireset_temps
- ireset_winds

- `ireset_sums`
- `ireset_cells`

Possible values for these four variables are:

- `0`: no resetting at all (default for sums and averages)
- `1`: reset after given time interval (default for temps and winds)
- `2`: reset after every output (default for cells)

These defaults ensure the current behaviour of the COSMO-Model in NWP-mode.

In CLM Mode (`lbdclim=.TRUE.`), the namelist variable `ireset_sums = 2` has to be chosen to reset all summation variables after every output step!

7. Recommended Namelist Configurations for COSMO-Model 5.04g

At DWD we have problems when activating all new features in the COSMO-ICON physics, therefore it is difficult to recommend a special namelist configuration. We tested three different configurations:

- Old Settings: Turbulence and TERRA are run in a way to reproduce the results of the old COSMO-Versions as close as possible.
  These settings are now preferred at DWD.
- Conservative: The settings for the turbulence scheme activate the new parts of the code, while settings for TERRA still are for the old scheme. Alternatively, also some new features of TERRA can be activated (e.g. `itype_evsl=4`).
- Advanced: These settings come very close to the ICON settings, but COSMO results are not really satisfying. Please note that you need to run INT2LM also with special namelist settings:
  - `itype_aerosol = 2`
  - `itype_ndvi = 1`
  - `itype_rootdp = 4`
  - `lemiss = .TRUE.`
  - `lstomata = .TRUE.`

In addition to the namelist variables, that have to be set in a different way for the above configurations, there are also some hardcoded switches in the turbulence, that have to be different when reproducing the old COSMO-version of the turbulence. To be able to modify these switches at once, we implemented a new namelist switch `loldtur`. Per default `loldtur=.FALSE.` and the new way of running the turbulence is activated. To reproduce the old way, it has to be set to `.TRUE.` and all other namelist switches regarding turbulence have to be set for the "Old Settings".

The following table lists all namelist variables that have to be set for the three different configurations and specifies, which are related to turbulence, and which are not. Because

of ongoing problems with running the vertical diffusion after the physics, we only can recommend to use the former vertical diffusion in the dynamics. For this you have to set `itype_vdif=-1`:

Name	Old Settings	Conservative	Advanced
/TUNING/ (turbulence)			
tkhmin	0.4	0.75	0.75
tkmmin	0.4	0.75	0.75
rat_sea	20.0	7.5	7.5
patlen	500.0	750.0	750.0
turlen	150.0	500.0	500.0
a_hshr	0.2	2.0	2.0
c_soil	1.0	1.75	1.75
/PHYCTL/ (turbulence)			
loldtur	.TRUE.	.FALSE.	.FALSE.
itype_vdif	-1	-1	-1
ltkeshs	.FALSE.	.TRUE.	.TRUE.
itype_sher	1	0	0
imode_tran	1	0	0
imode_turb	1	1	1
icldm_tran	0	2	2
/PHYCTL/ (other)			
itype_aerosol	1	1	2
itype_root	1	1	2
itype_heatcond	1	3	3
itype_evsl	2	2	2
idiag_snowfrac	1	1	1
cwimax_ml	1.0E-6	0.0005	0.0005
lemiss	.FALSE.	.FALSE.	.TRUE.
lstomata	.FALSE.	.FALSE.	.TRUE.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Abstract

Model parameter uncertainty is a major source of errors in regional climate and NWP model simulations (Stephens et al., 1990; Knutti et al., 2002). State-of-the-art NWP models are commonly tuned using expert knowledge without following a well-defined strategy (Duan et al., 2006; Skamarock, 2004; Bayler et al., 2000). This is also the case for the COSMO model where expert tuning is typically made once during the development of the model, for a certain target area, and for a certain model configuration, and is difficult if not impossible to replicate. It is questionable whether such a calibration is still optimal for different target regions (e.g. with a different climate) or for other model configurations (e.g. with a finer grid resolution). Furthermore, the lack of an objective process to re-calibrate the model is often a major roadblock for the implementation of new model features. A practicable objective multi-variate calibration method has been proposed by Neelin et al. (2010) and applied to COSMO model for regional climate simulations (RCM) by Bellprat et al. (2012a and 2012b, 2016). The objective method has shown to be at least as good as an expert tuning. Based on these results, a COSMO priority project (CALMO) has been proposed and accepted, at the COSMO GM 2012 in Lugano, aiming to implement this method for NWP applications. CALMO project officially started on January 2013 and was completed at the end of December 2016. This COSMO priority project was assigned to Working Group 3b. During these 4 years about 6.5 FTEs have been invested. The scientists involved in the project were from 4 different institutions (HNMS, IMS, MeteoSwiss and ARPA-SIMC). Although not all tasks were successful (see Sec. 4 for details), the developments done during this project resulted in a working and robust calibration framework for NWP applications, well documented, including the calibration code (see http://www.cosmo-model.org/content/tasks/priorityProjects/calmo/default.htm).

Furthermore, substantial knowledge transfer took place between ETHZ and MeteoSwiss on one side, and HNMS and IMS on the other side, which is also a very positive side effect of this project. CALMO project was implemented in three phases. In the first phase of the project the method has been tested using COSMO-7 for three parameters over two 20 days periods; in the second phase, COSMO-2 and six parameters have been calibrated over an entire year, and in the third phase calibration of COSMO-1 and five parameters over a one month period has been performed. CALMO project has shown that the method used by Bellprat for COSMO-CLM can be adapted to NWP applications. After the proper re-design, the meta-model (MM, hereafter) is able to reasonably reproduce full COSMO model simulations, for all cases considered (Khain et al., 2015, 2017). Furthermore, the optimum set of model parameters improves a COSI-type score[1], for all tested configurations, and the results of an independent verification seem to indicate that the operational verification scores are also improved (see Sec. 7 and Sec. 8). It should be noted that the history of the soil, which may substantially impact the effect of the calibration, was only switched on for the third phase of the project, and that the calibration of COSMO-1 was limited to one month, namely January 2013. This is a serious limitation, reducing the robustness of the current analysis. Furthermore, the issue of reducing the computational cost of the method has not been tackled. Therefore, considering the huge potential of this calibration method, a follow-up project called CALMO-MAX (CALilbration of MOdel Method Applied on eXtremes) has been accepted by the COSMO Steering Committee, and will take place from 06.2017 to 09.2019. A successful CALMO-MAX will provide a permanent affordable COSMO framework for objective model calibration. All details are available at http://www.cosmo-model.org/content/tasks/priorityProjects/calmoMax/default.htm.

[1]COSI score is a universal verification score used by the COSMO consortium

Much documentation about CALMO already exists and will not be duplicated in this document. More specifically two COSMO Technical Reports, No 25 and 31 (Khain et al. 2015, 2017) provide a very detailed description of many aspects of the project. All this documentation is accessible on the COSMO web. In Sec. 2 of this report, a short introduction to the calibration method is proposed and the appropriate modifications required for adapting the methodology from RCM to NWP are presented. The roadmap of the project and the progress achieved within each CALMO task are presented in Sec. 3. A short description of the MM is made in Sec. 4, while Sec. 5 is focused on sensitivity experiments and a new strategy for fitting the MM. Sec. 6 summarizes the verification of the COSMO-2 simulations computed with the optimal set of parameters and with the default parameters, using the standard verification system of MeteoSwiss. Sec. 7 presents a case study using the calibrated parameters. Conclusions are made in Sec. 8. A full commented list of unconfined model parameters is available in Appendix 9, and the results of sensitivity experiments for different model parameters and for different regions are presented in Appendix 10.

2 Methodology

The main goal of the CALMO project was the implementation of the calibration method proposed by Bellprat et al. (2012b) for regional climate modelling to NWP applications. For N unconfined model parameters, the calibration process aims at finding the values of these parameters which optimize a selected performance score (a scalar measure of the model quality depending on a set of model fields and the associated observations). The basic idea of the proposed approach is to fit a set of significant model fields in parameters space via N-dimensional quadratic polynomial (for each model field, for each region and each day, separately), the significant model fields being the ones contributing to the performance score. This is the so-called meta-model (MM). Once the MM has been fitted, using full COSMO model simulations, both the effect of the parameter setting and of the parameter space used (i.e. the maximal range of optimal values) can be determined without the use of the full model, and the optimization of the performance score becomes feasible. It is important to realize that the calibration of the model is computed for a specific score, i.e. for a specific class of model applications; one derives the values of the unconfined model parameters which provide the best results for these applications. However, to avoid over fitting the model, it is also necessary to choose a score representing enough aspects of the model. Furthermore, it is necessary to choose a score with enough associated observations of good quality. One major difference with the RCM calibration is the type of measure used to quantify the quality of the model (performance score). Whereas RCM uses monthly mean values computed over climate regions, NWP uses scores reflecting the daily cycle and the day to day variability of the weather parameters. Furthermore, the spatial resolution of a NWP model, and the spatial scales of interest, are typically finer than the ones of a RCM. This has of course consequences on the choice of the most significant model parameters to use in the calibration process. It is widely known that there are numerous unconfined parameters in the COSMO model related to sub-grid scale turbulence, surface layer parameterization, grid-scale clouds and precipitation, moist and shallow convection, radiation and the soil scheme. The selection of parameters to be calibrated is made with respect to their influence on the variables associated with daily forecasts such as daily minimum and maximum 2m temperature as well as 24h accumulated precipitation. Comprehensive experiments have been conducted to measure this sensitivity and to support the final choice of the most relevant parameters for the calibration process (see Appendix 2). Note that some expert knowledge is needed to preselect the set of unconfined parameters and to define a plausibility range of values for each of these parameters. The CALMO project has been carried out in three phases of increasing

complexity. For convenience, to be able to tackle the knowledge accumulated at MeteoSwiss, all model configurations have been based on MeteoSwiss production configuration. In the first phase of the project, the model was operated with horizontal resolution of 0.0625° (approximately 7km) for a domain extending mainly over Western Europe as shown in Fig. 1. The model vertical extension reached 23.5 km (30hPa) with 60 model levels in the atmosphere. The calibration was computed for two 20-days periods in 2008 (winter and summer), for 3 model parameters: asymptotic turbulence length scale, tur_len, minimal diffusion coefficients for heat, tkhmin, and scalar resistance for the latent and sensible heat fluxes in the laminar surface layer, rlam_heat. In the second phase of the project, the model was operated with horizontal resolution of 0.02o (approximately 2.2km) for a domain covering the Alpine Arc, in particular Switzerland and Northern Italy, as shown in Fig. 2. The same vertical structure was used as in the first project phase. The calibration was computed for the full year 2013, for 6 model parameters; with respect to the first phase of the project, the following three additional parameters have been considered: c_soil, the surface-area index of the evaporating fraction of grid points over land, v0snow, the factor in the terminal velocity for snow, and entr_sc, the mean entrainment rate of boundary layer humidity into the shallow convection clouds. In the third phase of the project, the model was operated with a horizontal resolution of 0.01° (approximately 1.1km) for the same domain as in phase 2 (Fig. 2), with 80 instead of 60 vertical levels. This is the only phase of the project where the soil memory was considered. The calibration was computed for January 2013, for 5 model parameters: besides tkhmin, tur_len, entr_sc, c_soil, also crsmin, the minimum value of stomatal resistance used by the BATS scheme for the plant transpiration has been considered. The theoretical minimum required number of full COSMO simulations to fit the meta-model is [2*N + 0.5*N*(N 1) + 1], where N is the number of unconfined model parameters to calibrate; this relation has been tested, and it has been found that more simulations are required to obtain a robust calibration. This has as consequence to increase the minimal amount of computing resources required for the calibration. The length of the model integrations used for the calibration is also an important parameter; this is emphasized by the fact that a seasonal dependency on the optimum parameter values has been found. Once the optimum values of the parameters have been determined, a final COSMO simulation using these optimum parameters is performed to assess any quality gain against the reference model configuration, as measured by a standard verification procedure.

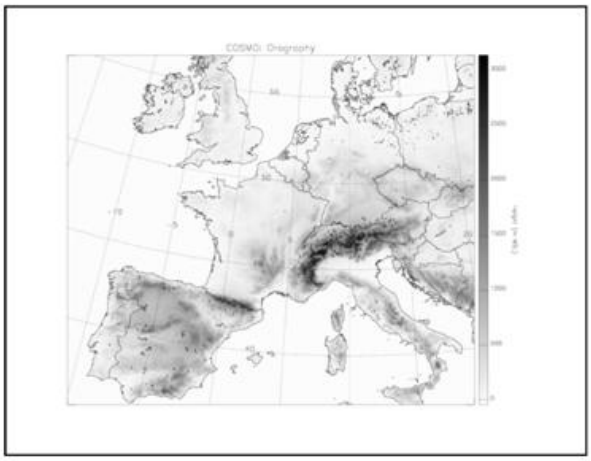

Figure 1: The simulation domain for the first phase of the project, with a 0.0625° grid size.

All necessary adaptations to transfer the calibration methodology from RCM to NWP have been performed in the framework of the CALMO project, which was defined with the following tasks:

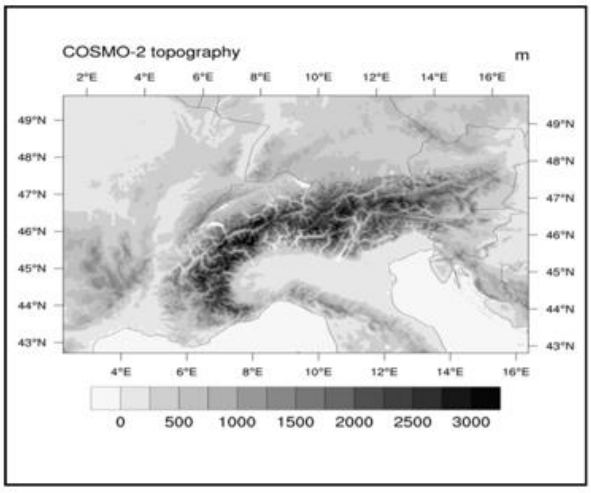

Figure 2: The simulation domain for the second and third phases of the project, with a grid size of 0.02°, respectively 0.01°.

- Preliminary work (e.g. acquire computing resources) (Task 1)
- Adaptation of the existing method for NWP applications (Task 2)
- Assessing the usefulness of the calibration method (Task 3)
- Define optimal methodology in terms of computing time and quality gain (Task 4)
- Documentation and dissemination of results (Task 5)

3 Tasks and achievements

A concise account of the tasks and achievements during the project is presented in this section.

Task 0: Administration and support

Due to the distributed nature of the project team (Greece, Switzerland, Israel and Italy), regular web conferences have been performed throughout the project to ensure the good information flow between all participants. The kick-off meeting took place in Zurich and three workshops have been successfully organized in Athens; additional workshops were also organized during the parallel sessions at the COSMO GM. The mailing list of the project (CALMO-ML, herein) has been widely used in order to support communication and information exchange between project participants (mailing list archive is available on-line). Although much effort has been invested to facilitate the communication within the project team, the rapid detection of critical problems and the timely solution of technical issues remained a real challenge due to the geographically distributed knowledge and team (as proven by the misunderstanding discussed in task 2.4). More in person meetings would certainly have been beneficial (but were difficult to realize due to the multiple tasks of the contributing scientists, including bench forecasting duties).

Task 1: Preliminary work

This task was divided into 4 subtasks, namely literature survey, knowledge transfer among contributing scientists, consolidation of CALMO methodology and technical infrastructure. The main deliverable of this task was the transfer of knowledge from RCM to NWP and

the working technical framework for performing the objective model calibration. Dr. Omar Bellprat / ETHZ, who contributed to the project in 2013, prepared an updated version of the calibration code, including minor changes to improve the MM estimation, and provided the appropriate documentation (see also sub-task 2.6). The entire project required significant computer resources for tasks 2 and 3. Computer resources were made available through a production project on the Piz Daint system hosted at the CSCS, using the GPU capable version of the COSMO model (the proposal is available at http://www.cosmo-model.org/content/tasks/priorityProjects/calmo/docs/CSCS_Proposal.pdf); more than one million node hours have been allocated to the CALMO project on this hybrid GPU system. In addition, a direct line has been established with the core model development team for the identification of key model parameters and for the variables to use in the performance score; discussions on this topic are available through the CALMO-ML.

Task 2: Adaptation of the method

Task 2 was divided into 8 subtasks, namely the documentation of the tuning parameters, the selection of a performance score, identification of key variables for NWP, setting up the experimental framework, collecting the appropriate data, modification of the meta model, computing and analyzing the results, and definition of a data thinning policy. The developments successfully performed in this task resulted in a working and robust calibration framework for NWP applications, well documented, including the calibration code. This task has also shown that a quadratic meta-model is able to reasonably reproduce full COSMO model simulations, for all cases considered.

2.1: Documentation of tuning parameters and choice of parameters subspace

A document listing most of the model tuning parameters, with a short documentation on their meaning, their default value, their allowed range, the associated model sensitivity, and other useful information (such as the code modules using the parameter) has been compiled and is available in Appendix 9 (note that this document is restricted to the physical parameterization schemes available in COSMO v.5.0). A selection of the parameters affecting turbulence, radiation, shallow convection, multilayer soil model, and diffusion parameterization schemes has been made and a set of sensitivity experiments have been performed by HNMS, discussed in Sec. 4 and, in more details, in Appendix 10. A shorter list of eight parameters to be considered for the optimization process at the time of the project was obtained: rlam_heat (the product of rlam_heat*rat_sea is kept constant), tkhmin (tkmmin= tkhmin, i.e. change tkmmin accordingly), tur_len, entr_sc, v0snow, crsmin, c_soil and kexpdec (f =2 in Decharme et al. 2006 formulation for hydraulic conductivity). Considering that one main goal of the calibration approach is to offer an alternative to the expert tuning, the list of tuning parameters should be kept up-to-date, and **this task should become a permanent task of COSMO**.

2.2: Selection of performance function(s)

A normalized RMSE, using both near surface daily minimum and maximum temperature and daily accumulated precipitation, suggested by IMS, described in Khain et al. (2015) and in Voudouri et al. (2017b), has been used as the performance score during the first stage of the project. It is known (Katz and Murthy, 1997) that several different measures have to be used for fully assessing the value of the forecast, in particular when considering precipitation. Therefore, more robust performance scores have been developed in the two last phases of the project: the normalized RMSE has been further improved and a COSI type score. All details are available in Khain et al (2017).

2.3: Identification of key-variables for NWP

The choice of key model variables used in the performance function is constrained by the accessibility of associated observations, with a good enough quality. Key variables used for daily weather forecasting, such as T2m daily minimum and maximum and daily accumulated precipitation, have been originally selected for the calibration. Besides their meteorological significance, observation based gridded analysis over Switzerland was also available for these variables. Additional variables have been introduced in the later phases of the project, such as the vertically integrated water vapor content, wind, temperature and humidity at significant levels, wind shear between significant levels, and stability indices, all evaluated at the location of upper air soundings stations. All details are available in Khain et al (2017).

2.4: Experimental set-up

The aim of this task was to define the exact configuration of the model simulations. The following aspects had to be considered: base model configuration (incl. grid resolution and set of physical parameterizations), domain size and location, set of external parameters, initial and boundary conditions (incl. soil initial conditions), type of simulation (e.g. hindcast, assimilation cycle and daily forecast), usage of additional analysis modules (e.g. soil moisture analysis, SST, snow pack), simulation length used for the calibration. The following paragraphs summarize the choices made in the three phases of the project.

CALMO first phase:

During the first phase of the project, the base model configuration is the COSMO-7 operational configuration operated at MeteoSwiss at the time. In particular, the model was operated on a horizontal grid with a grid size of 0.0625° (approximately 7km) for a domain extending mainly over Western Europe as shown in Fig. 1 above. Its vertical extension reached 23.5 km (30hPa) with 60 model levels in the atmosphere. The model was computed in forecast mode, with a daily 36-hour forecast starting from a fixed and prescribed analysis taken from the MeteoSwiss COSMO-7 operational archive. Lateral boundary conditions were also taken from the same MeteoSwiss operational archive. This means that the same sets of initial and lateral boundaries are used for all tests, including the reference simulation, independently from the set of unconfined model parameters values being tested. One consequence of this design is that the effect of a different set of model parameters values on the state of the soil are not propagated forward in time from one forecast to the next, or, in other words, the long-term memory of the soil is not active. According to WMO Annual Bulletin on the Climate, winter 2007/2008 was mild in Europe and, although summer 2008 has been warmer than usual, anomalies were confined in the normal range of variability of the thee recent years, without particularly strong and persistent departure from climatological averages (WMO, 2008). Therefore, 2008 was selected for the initial objective calibration approach as it was considered representative of a mean climatology over the area of interest. Two 20 days simulation periods, one during winter and one during summer, have been selected, namely 3-20.01.2008 (winter period) and 2-20.06.2008 (summer period). Although both periods are short, the forecast performance was evaluated over three different regions, yielding to a sample size which was considered adequate for this first phase of the project. The calibration of the model was restricted to the 12- to 36-hour lead time of the daily forecast, and to a limited domain covering Switzerland (verification domain), which is divided into three climatically unique areas, according to Frei (2013). The areas defined are: the area to the north of the Alpine crest, mostly coinciding with the Swiss Plateau; the area of Alpine crest, and the area to the south of the Alpine crest that mostly coincides with the Ticino region. Note that areas used by the meta-model should not be too small to avoid a noisy signal, which is not suited for a quadratic polynomial fit by the meta-model (this concerns in particular discontinuous fields like precipitation and CAPE). Finally, an additional simulation has been computed with the optimal set of unconfined parameters values, as provided by the meta-model, to

evaluate the impact of the calibration on the default model configuration.

CALMO second phase:

The base model configuration for the second phase is the COSMO-2 operational configuration operated at MeteoSwiss at the time of the project. The model was operated with a grid spacing of 0.02° (approximately 2.2km), for a domain covering the Alpine Arc, in particular Switzerland and Northern Italy, as shown in Fig. 2. Its vertical extension reached 23.5 km (30hPa) with 60 model levels in the atmosphere. As in the first phase of the project, the model was computed in forecast mode, with a daily 36-hour forecast starting from a fixed and prescribed analysis, meaning in particular that the long-term memory of the soil is again not active. In this phase of the project, the COSMO model was computed for a substantially longer period, considering the whole year of 2013 (from 01.01.2013 till 01.01.2014) instead of the 40 days period of the first phase of the project. The calibration was based on the 12- to 36-hour lead time of the daily forecast. In addition to Switzerland, Northern Italy was also added to the verification domain used for the calibration, and additional type of observations were considered. An additional experiment has also been computed with the optimal set of unconfined parameters values, to evaluate the impact of the calibration on the default model configuration.

CALMO third phase:

The base model configuration is the COSMO-1 operational configuration operated at MeteoSwiss at the time of the project (1.1 km grid mesh size, Alpine domain as in Fig. 2, 80 vertical levels). Unlike the two first phases of the project, the model was computed in hindcast mode (i.e. a free run without assimilation of observations) from 01.01.2013 till 01.02.2013, with prescribed lateral boundary conditions from the MeteoSwiss operational COSMO-7 archive. With this configuration, the impact of a new set of model parameters values on the state of the soil is propagated forward in time during the whole simulation period. The initial conditions of the soil model at the start of the hindcast run is derived from a three-year spin-up computed with a standalone soil model (so called TSA), for each set of unconfined model parameters which directly influences the soil parameterization. The advantages of computing a hindcast instead of a full assimilation cycle and a set of regular forecast, which would also keep the soil memory active, are the simplified configuration of the experiment and the reduced computational cost. Furthermore, studies have shown that, at least for a model domain of the size considered here, the differences between a hindcast and a full cycle are not significant, even after one year of simulation. In terms of computing resources, one day 1.1 km simulation costs approximately 10 times more than a similar one day 2.2 km simulation. The re-factored COSMO model version, capable of running on GPU-based hardware architectures, based on the version 5.0 of the COSMO model, was used in phases 2 and 3 of this project (Lapillonne and Fuhrer, 2013). Note also that the original plan was to use the same configurations for both the second and the third phase of the project (except for the resolution), both including the memory of the soil. However, misunderstanding between the PL and the WGC, which was realized too late, resulted in the configurations described here.

2.5: Collection of data

A gridded analysis of minimum and maximum daily 2-meter temperature, on a 2km grid, based only on observed 2m temperature at Swiss surface stations, is available over Switzerland (Frei, 2013). This analysis has been transformed to match the grid of the COSMO model, as described in the appendix A of Khain et al. 2015 (special care is needed due to the strong height dependency of the temperature field). A gridded product combining radar and rain gauges measurements has been used over Switzerland; 24-hours accumulated

precipitation have been derived from this product. All other observations, such as gridded T2m daily minimum and maximum over Northern Italy, gridded precipitation over Northern Italy, radio soundings, and gridded cloudy brightness temperature (MSG IR 10.8, and WV 6.2, not used) have been collected. The driving model used for the boundary conditions of all CALMO experiments is the operational COSMO-7 (7km resolution) computed at MeteoSwiss, and 3-hourly analysis available in the operational archive of MeteoSwiss have been used for that purpose. As already stated, an important issue that required careful consideration was the initialization of the soil, since multiple years are required for the deep soil to adapt itself to a change in the model climate (as induced e.g. by the choice of a different set of unconfined model parameters values). This is particularly crucial when considering unconfined parameter directly related to the parameterization of the soil. The approach adapted in this project was to compute a spin-up run with a much cheaper standalone soil, driven by prescribed atmospheric forcing, before starting each calibration experiment. Thus, TERRA standalone (TSA) has been consolidated to fulfill the requirements of the CALMO project. Systematic tests (sanity, performance) have been performed by IMS and soil initialization for CALMO experiments was computed. The consolidated TSA is now available through the COSMO web site (http://www.cosmo-model.org/content/support/software/default.htm).

2.6: Modifications on the meta-model

In the first phase, many adaptations of the original meta-model provided by Dr. Omar Bellprat have been performed to support the requirements for calibrating a NWP system instead of a RCM (e.g. the introduction of different statistical measures used as performance score, the manipulation of observational data sets). Significant work was then invested to improve the quadratic meta-model: defining a new set of regions, introducing an option not to average temperature extreme over regions, adding the support of atmospheric profiles, adjusting the RMSE-type performance score and introducing a new COSI performance score (Damrath, 2009), considering the conditions for a robust fit in parameter space, introducing a new method for logarithmic transformation of selected parameters, introducing a measure of model and observation uncertainties, developing an iterative method to obtain the optimal parameters via convergence in a n-dimensional parameter space of exceptional cardinality, and estimating the uncertainties on the optimal value of the model parameters. Sanity check of the meta-model has been performed, comparing the results of the meta-model with similar results of a full model run for a set of unconfined parameters not used in the calibration, both in the first and in the second phases of the project. All modifications and tests performed with the MM are discussed in details in Khain et al. 2017 and briefly described in Sec. 4 of this report. The MatLab code and the documentation is available at http://www.cosmo-model.org/content/support/software/default.htm#calmo.

2.7: Compute experiments and analyze results

This subtask was associated with the computation of at least [2*N + N *(N-1)/2 + 1] model simulations, each with a different set of model parameters values, each time over the selected time period, where N is the number of unconfined model parameters to calibrate. In the case of the COSMO-2 calibration, considering 6 model parameters, the minimum number of required simulations is 28. However, some additional simulations have been performed to better constrain the MM, and obtain a more robust set of optimum parameter values, resulting in a total of about 50 simulations, each simulation being computed over the entire year 2013. A control simulation has also been performed, using the optimum set of parameters, and the impact of the calibration on the model quality, compared with the configuration using the default parameters, is evaluated. The results of this verification are discussed in Sec. 6.

2.8 Data thinning policy and application

The standard amount of raw data produced by a one year COSMO-1 hindcast, i.e. for a single set of unconfined model parameters values, with hourly output, is of the order of 20 TB, whereas the allocated storage for the whole calibration project on Piz Daint was 70 TB. Consequently, an aggressive data thinning policy was required. Data thinning has been designed by HNMS and MeteoSwiss to provide all required data for standard verification on the full domain (SYNOP, upper air, radar composite), and to support the calibration based on minimum and maximum 2m temperature, radar composite, satellite brightness temperature and vertical profiles. Furthermore, a daily analysis was kept, in order to be able to restart a simulation from any day. Fieldextra was used for the data thinning. The data has been transferred from CSCS to ECMWF after the end of the project on Piz Daint. Although data thinning was applied, still a considerable amount of data is now being stored at the HNMS domain of ECMWF.

Task 3: Assessing the usefulness of the calibration method

The goal of this task was to show that the method is indeed able to improve the quality of the model. In addition, the sensitivity of the optimum with respect to the model resolution should have been investigated in this task, as well as the fair assessment of the impact of an improved resolution. The plan was to first calibrate the COSMO-2 configuration, and then a similar COSMO-1 configuration, both using a full year for the calibration. However, due to the many technical difficulties encountered during the project (see the Piz Daint allocation final report at
www.cosmo-model.org/content/tasks/priorityProjects/calmo/docs/CSCS_final_report.pdf), only the COSMO-2 calibration, without the memory of the soil, has been fully completed. Nevertheless, this task has shown that the optimum set of model parameters obtained with the calibration method improves a COSI-type score, for all tested configurations. More specifically, an improvement of the COSI-type score used by the MM of about 3-4% for the COSMO-2 configuration and of about 12% for the COSMO-1 configuration has been observed (all details are available in Khain et al. 2017). Interestingly, a strong seasonal dependency of the optimal parameters values has also been observed. Finally, the results of an independent verification indicate that the operational verification scores are also partly improved (see Sec. 6 for the COSMO-2 case).

3.1: Application of the method using COSMO-1

Calibration of COSMO-1 with five parameters has been performed (tkhmin, tur_len, entr_sc, c_soil, crsmin), but only for January 2013.

3.2: Analyse results

Analysis and discussion of the results have been made in Khain et al. 2015 and 2017, Voudouri et al. 2017c, and in the present report.

Task 4: Practicability of the method

An important objective of this project was to optimize the calibration procedure with respect to the required amount of computing resources, such that a model re-calibration can be computed on any reasonably powerful production system. As already mentioned under task 3, due to many technical problems met during the project, neither time nor human resources remained to tackle this issue. Instead of extending the project, it was decided to consolidate the goals already achieved, mainly a working and robust calibration framework for NWP applications, well documented, including the calibration code, and to design a follow-up project aiming at optimizing the method. The follow-up project, CALMO-MAX, has been accepted by the COSMO Steering Committee in spring 2017, and will take place from 06.2017 to 09.2019. The main goal of this new project is to provide a permanent afford-

able CALMO framework for objective model calibration. All details at http://www.cosmo-model.org/content/tasks/priorityProjects/calmoMax/default.htm.

Task 5: Documentation

A significant amount of documentation has been produced, and, in particular, the goal to make public the work performed within the COSMO Priority Project, not only to the COSMO members but also to the wider scientific community, has been achieved. A scientific paper focused on the preliminary results of this project has been published in Atmospheric Research (Voudouri et al., 2017b). Two papers (Voudouri et al., 2017a and Avgoustoglou et al., 2017) based on parts of the CALMO work have been presented at the 13th International Conference on Meteorology, Climatology and Atmospheric Physics (COMECAP 2016) which was held at Thessaloniki, in 19-21 September 2016; the contributions are included in the Conference Proceedings, published by Springer International Publisher AG as a book entitled: Perspectives on Atmospheric Sciences. Finally, a second manuscript summarizing the work using COSMO 2km has been submitted to Atmospheric Research. In addition, this final report and two COSMO technical reports are available. The documentation of the meta-model and a cookbook to facilitate its usage have also been prepared. All documentation is available on-line on the COSMO web site, at http://www.cosmo-model.org/content/tasks/priorityProjects/calmo/default.htm.

4 The Meta-model *(P. Khain, I. Carmona)*

The consolidation and extension of the MM is extensively discussed in Khain et al. 2015 and 2017, so only the basic ideas are described here. As in Neelin et al. (2010), the MM for a three model parameters combination, e.g. tur_len, tkhmin and rlam_heat, for a given day i and region r, states that the COSMO forecasted field $F_{i,r}$ (here Tmax, Tmin or Pr) may be approximated by a 3-dimensional polynomial of order 2:

$$F_{i,r} \cong F^d_{i,r} + c_{i,r} + \Sigma^3_{n=1} a^n_{i,r} x_n + \Sigma^3_{n=1} \Sigma^3_{m=1} B^{n,m}_{i,r} x_n x_m$$

where $x_{1,2,3}$ are the normalized parameters:

$$x_1 = \frac{rlam_heat - rlam_heat_d}{rlam_heat_{max} - rlam_heat_{min}}, x_2 = \frac{tkhmin - tkhmin_d}{tkhmin_{max} - tkhmin_{min}}, x_3 = \frac{tur_len - tur_len_d}{tur_len_{max} - tur_len_{min}}$$

The index d stands for the default unconfined parameter values. For default values of the 3 parameters, i.e. $(x_1 = 0, x_2 = 0, x_3 = 0)$, the approximated field should be close to $F^d_{i,r}$. The diagonal values of $B_{i,r}$ can be fitted along with the linear coefficients $a_{i,r}$ from the 2N end points of the $x_{1,2,3}$ ranges, along with the default case. Thus, an order-N first-fit procedure yields an estimate of the importance of quadratic non-linearity in addition to linear sensitivity. The off-diagonal $B_{i,r}$ coefficients can be evaluated from the corners of pairwise planes (or an equivalent number of suitably distributed points). Because the procedure is of order N2 it should in practice be done for a pruned subset of parameter directions. Thus, the minimum number of simulations to derive $c_{i,r}, a^{(n)}_{i,r}, B^{(n,m)}_{i,r}$ $(B^{(n,m)}_{i,r} = B^{(m,n)}_{i,r})$, with n,m=1,2,3, is equal to 2N + N(N-1)/2 + 1, which, for N=3, gives 10. Note that a different normalization of the unconfined model parameters than the linear transformation exemplified here with $x_{1,2,3}$ could be applied. In fact, it has been found that a logarithmic transformation provides a more robust fit when the default value of the concerned parameter is not centered in the parameter plausibility interval. It is important to realize that one polynomial is derived for each day i, for each region r, and for each meteorological field F, and that the MM is the collection of

all these polynomial functions. Once the MM has been fitted, the effect of any combination of the associated unconfined model parameters on the forecasted fields $F_{i,r}$ can be evaluated without the full NWP model. Once the MM is available, the calibration is based on the optimization of a performance score, function of the forecast fields $F_{i,r}$ and of the associated observations $O_{i,r}$. The RMSE-type performance score initially tested in CALMO first phase was adjusted, and a new **COSI performance score** was included based on the COSMO Index (COSI) developed by Ulrich Damrath (2009). The COSI score defined by user defined weights for the contributions of the various fields. In this project: $\omega_{Tmax} = 1, \omega_{Tmin} = 1, \omega_{Pr} = 1, \omega_{CAPE} = 0, \omega_{CIN} = 0$ (CAPE and CIN are usually noisy), $\omega_{TCWV} = 1$ (total column water vapor), $\omega_{WS1} = 0.33, \omega_{WS2} = 0.33, \omega_{WS3} = 0.33$ (wind shear between standard levels), $\omega_{T500} = 0.33, \omega_{T700} = 0.33, \omega_{T850} = 0.33, \omega_{RH500} = 0.33, \omega_{RH700} = 0.33, \omega_{RH850} = 0.33, \omega_{U500} = 0.2, \omega_{U700} = 0.2, \omega_{U850} = 0.2, \omega_{V500} = 0.2, \omega_{V700} = 0.2, \omega_{V850} = 0.2$ have been introduced. The adapted score for a combination of model parameters p is then defined by:

$$S_p = \frac{1}{12 \sum_{\Psi=1}^{18} \omega_\Psi} \left\{ \sum_{\Psi \neq 3} \omega_\Psi \sum_{mon=1}^{12} \left[1 - \frac{\sum_{\Psi regs} \sum_{\Psi days} (F_{\Psi,p,d,r,mon} - O_{\Psi,d,r,mon})^2}{\sum_{\Psi regs} \sum_{\Psi days} (O_{\Psi,d-1,r,mon} - O_{\Psi,d,r,mon})^2} \right] + \omega_3 \frac{\sum_{mon=1}^{12} \sum_{\Psi regs} \sum_{\Psi thr} ETS_{p,r,mon,thr}}{N_{\Psi days,mon} N_{\Psi regs,mon}} \right\}$$

where indices Ψ, r, mon, d refer to field, region, month and day of month mon, and where 1/3 < ETS < 1 (1 is the best) is the equitable threshold score for precipitation (region averaged precipitation with amounts thresholds thr of 0.1, 1, 3, 7.5, 10mm per 24h):

$$ETS_{p,r,mon,thresh} = \frac{H - \frac{(H+F)(H+M)}{N_{\Psi regs,mon}}}{H + M + F - \frac{(H+F)(H+M)}{N_{\Psi regs,mon}}}$$

where: H - Number of hits (i.e. both the model and the observations where above the given threshold); F - Number of false alarms; M - Number of misses. The result of the calibration procedure is the values of the parameters p which maximize (or minimize) the performance score S_p. To be able to solve this extreme problem on a standard computer in a reasonable amount of time, even for a large number of parameters p, an iterative method has been developed. In addition, the accuracy of the MM to represent COSMO results, has been examined both in the first phase for COSMO-7 and also in second phase for COSMO-2. In order to validate the quality of MM, an additional test simulation was performed for a parameter combination that was not used while fitting the MM. That allowed comparing the MM predictions for the specific parameters combination with the COSMO simulation results. These results are presented in Fig. 3 and Fig. 4 for COSMO-7 and COSMO-2 respectively. More specifically scatter plots for 24h accumulated precipitation (Pr) are presented for a 20-day interval during the calibration of COSMO-7 in Fig. 3. The y-axes show the MM estimation with respect to the reference (simulation with default parameters values), while the x-axes show the COSMO simulation results with respect to the reference. For Pr each point represents regions averages. The MM was constructed using the minimum number of simulations in Fig. 3a while in Fig. 3b the MM was constructed using additional "interaction" and "constrain" simulations. In both axes, the default simulation (REF) values were subtracted. The dots lying on the black straight lines show values for a region per day, which are accurately reproduced by the MM, the cloud of deviations from the line indicates MM error and the gray band shows the 95% percentile range of deviations. Reasonably high correlations R2 between COSMO forecasts and MM are observed. This is also the case in Fig. 4 for COSMO-2 where MM prediction of precipitation (Pr) for the tested parameter combination, vs COSMO-2 simulation results during the year 2013. The correlations given

in these figures represent a single parameter combination corresponding to one point in the 3- or 6-dimensional parameters space analyzed. However, it can be seen that regarding this tested parameter combination, the correlations R2 between the COSMO forecasts and the MM estimations are generally high. Consequently, the overall method seems to prove itself; one can use the MM to reproduce COSMO forecasts for various parameters combinations.

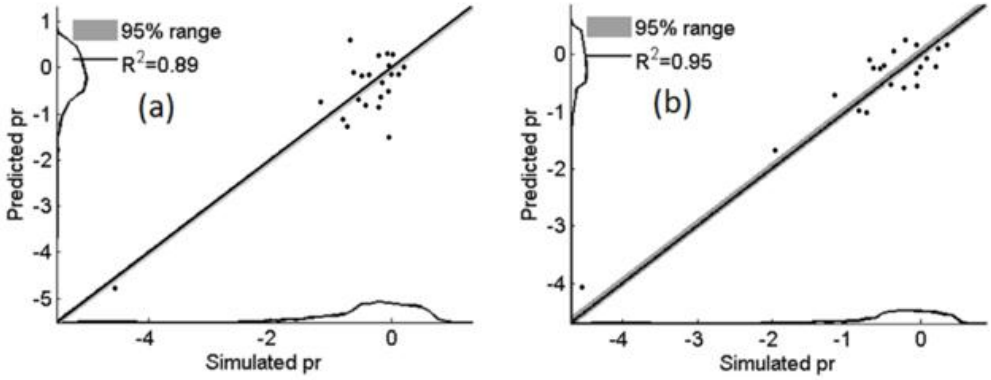

Figure 3: Estimating the MM quality for reproducing Pr field by comparing it with a test COSMO-7 simulation for the period 3-20.1.2008. (a) The MM was constructed using the minimum number of simulations; (b) the MM was constructed using additional "interaction" and "constrain" simulations. A slight improvement of the correlation is observed in this case. In both axes, the REF simulation values were subtracted.

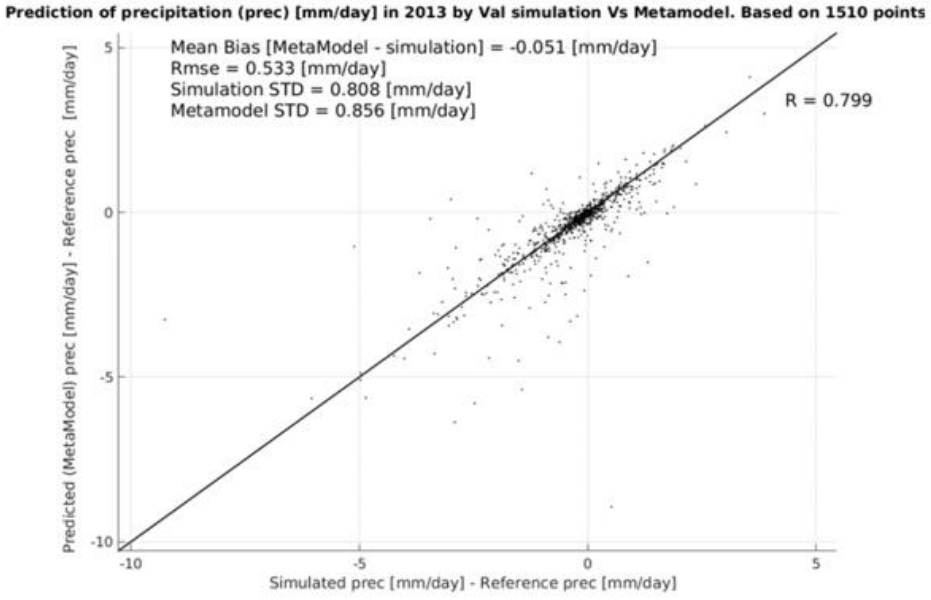

Figure 4: Pr Meta-Model prediction for the tested parameter combination, vs COSMO-2 simulation results during the year 2013. X axis presents the simulated Pr minus the reference simulation. Y axis presents the Meta-Model Pr minus the reference simulation.

5 Sensitivity experiments and fitting strategy *(E. Avgoustoglou)*

The goal of this effort was to gauge the sensitivity of COSMO model over a number of expected relatively high impact parameters. The list of parameters used for the sensitivity

experiments, extracted out of a wide list of free model parameters (shown in Appendix 9) and decided by CALMO project team over extensive communication and recommendations from COSMO experts. An extended set of parameters was tested over the wider Mediterranean area for a period of 62 dates from February, June, and December of 2013 with an emphasis over Switzerland. The sensitivity S with respect to a model variable P was estimated from the results of model runs for the two limits (min and max value) of the parameter selected, as well as for the default value, as follows:

$$S_{<P>}(\%) = \frac{< P >_{TEST} - < P >_{DEFAULT}}{< P >_{DEFAULT}} \bullet 100$$

$< P >$ stands for $< SNOWGSP >$ *or* $< TOTPREC >$ *or* $< CLCL >$ *or* $< CLCM >$ *or* $< CLCH >$ *or* $< CLCT >$

$$S_{\{\langle TOTPREC \rangle, \langle SNOWGSP \rangle, \langle CLCH \rangle, \langle CLCM \rangle, \langle CLCL \rangle\}} = \left|S_{\langle TOTPREC \rangle}\right| + \left|S_{\langle SNOWGSP \rangle}\right| + \left|S_{\langle CLCH \rangle}\right| + \left|S_{\langle CLCM \rangle}\right| + \left|S_{\langle CLCL \rangle}\right|$$

$$S_{\begin{bmatrix} TMIN\,2m \\ TMAX\,2m \end{bmatrix}} = \begin{bmatrix} < TMIN\,2m > \\ < TMAX\,2m > \end{bmatrix}_{TEST} - \begin{bmatrix} < TMIN\,2m > \\ < TMAX\,2m > \end{bmatrix}_{DEFAULT}$$

The results from the sensitivity experiments along with the highlights of this investigation are presented in Appendix 10 while an example is illustrated in Fig. 5. More details are available in Avgoustoglou et al., 2017. The impact for most of the parameters turned out to be important for all periods and domains. The weight of the parameter impact for the different domain, varies due to their climatological characteristics as expected. In principle, for almost all considered variables, at most 5 parameters show the greatest sensitivity and a choice among them should be expected to provide a sufficient kernel for the application of the MM. Towards the effort of model calibration and upon gauging the model sensitivity, when the number **n** of considered model parameters increases, the number of their pair combinations regarding their min and max values vastly increases $[O(2\mathbf{n})^2]$. **A methodology to help reduce the computing resources for fitting the meta-model is proposed here.** An efficient methodology to constrain the number of tests should be to indicate their impact according to some quantitative criteria and decide upon the resulting priority. The methodology is expected to be of practical value if two goals could be accomplished: (a) each test gets a priority number and (b) tests are performed according to it. If the number of tests becomes too expensive, the method should be flexible enough to be terminated at the priority that suits the available computational resources. The recommended truncation, however, needs to be supported by valid scientific arguments regarding the relative importance of the tests that will be included against those that will be omitted.

The specific steps followed in order to decide on the priority for model simulations needed to fit the MM is as follows: the first step is associated with the selection of the parameters to be used for calibration and decision on the model domain for which the MM will be used. The minimum number of simulations needed is [2N + N(N-1)/2 + 1] where N is the number of parameters selected including 1 simulation using default parameter value, 2 simulations using minimum and maximum value of each parameter and one simulation with an interaction terms between parameter pairs. **In order to decide on which interaction simulation per pair to use it is proposed to create a Priority Board Of Terms** (PBOT, see Fig. 6 below). It can easily be shown that the pair combinations for e.g. 7 parameters is 84. Consequently, the 84 empty white cells will be filled with priority numbers 1 to 84. Every empty white shell refers to a 2-parameters combination. The empty dark blue cells will not take any number due to single parameter assignment and due to double

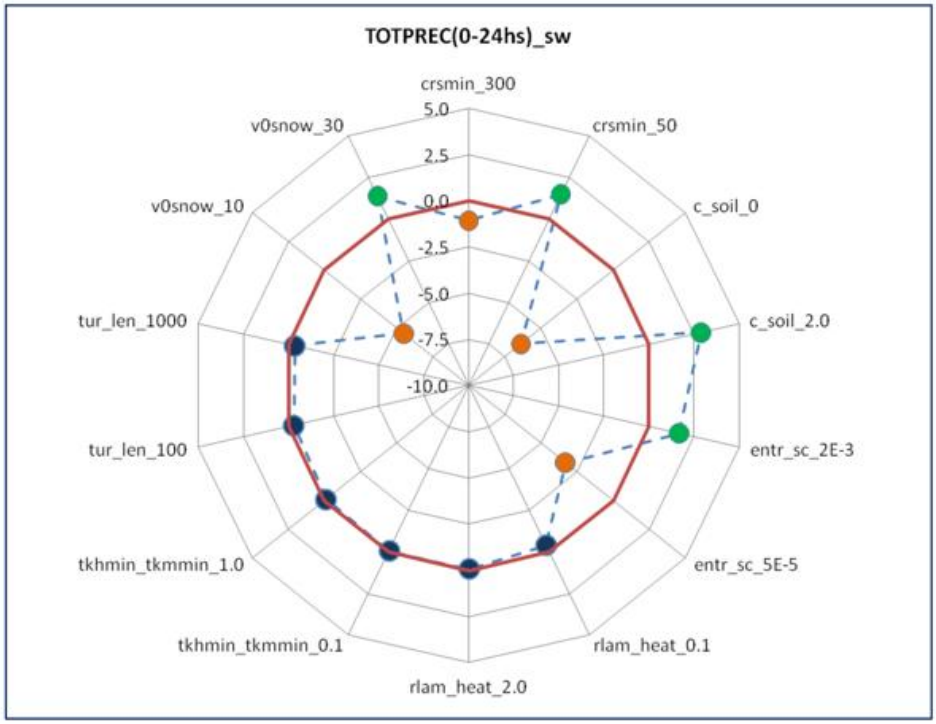

Figure 5: Spidertype graph for 24h accumulated precipitation.

counting in every test. Every number refers to the priority of the sensitivity run. For example, if the second empty white cell of the first line gets the number 5, the model runs with the combination will have priority 5, so 4 other parameter combinations have to be performed first. In addition, according to the importance of the model variables that will be used, a class is denoted in the PBOT (again, see Fig. 6 below). The subjective criteria on making this choice is discussed in detail in Avgoustoglou et al., 2017. The sensitivities (S) of the parameters used is defined and the sensitivity of the variable of the first priority class is presented in a **spider-type** graph, as shown for TOTPREC in Fig. 5. Once the spider type graph is created a set of priority numbers is given to fill the PBOT shown in Fig. 6. For example, the first set of priority numbers will be assigned to couple of parameters with opposite sensitivity, as shown by orange and green bullets on the spider graph, according to the radial distances between the orange and the green bullets. The second set of priority numbers will be assigned to PBOT according to the difference of the radial distances between couple of parameters with same sign sensitivity, etc. In more detail the methodology followed to perform the simulations needed to fit the MM can be found in:

http://www.cosmo-model.org/content/consortium/generalMeetings/general2015/parallel/WG3b_Euripides_Sept2015.pdf

and

http://www.cosmo-model.org/content/consortium/generalMeetings/general2016/wg3b/CALMO_Avgoustoglou.pdf

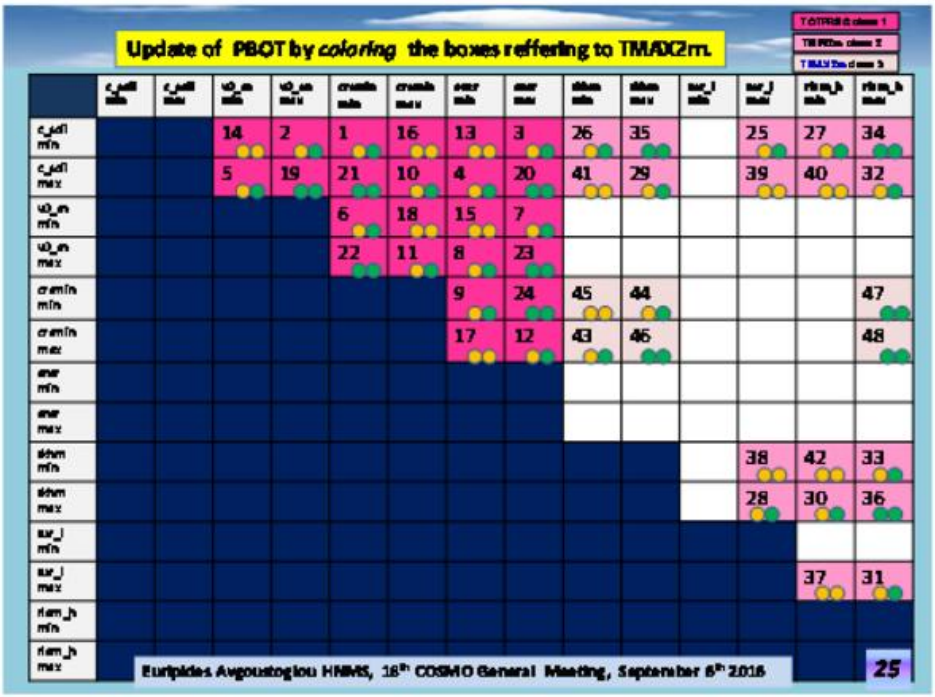

Figure 6: Final PBOT table indicating the hierarchy of interaction simulations to be performed for fitting the MM.

6 Verification of COSMO-2 calibration *(with the contribution of P. Kaufmann)*

By construction, the CALMO methodology provides a set of optimum values for unconfined model parameters, which optimizes a specified performance score (the COSI type score described in the previous section). In order to assess the robustness of this optimum, it is necessary to perform an independent verification of the simulation performed with the optimal set of parameters. A selection of verification plots produced with the standard MeteoSwiss verification system for the second phase of the CALMO project (COSMO-2 calibration) is presented in this section. Although limited in scope, this verification gives a first insight on the capacity of the CALMO methodology to provide a robust improvement of the quality of a specific model configuration. Simulations are performed over the entire year 2013, using default values (**DEF**) for 6 unconfined model parameters as well as using the optimum set of parameters (**BESTF2**) derived from the MM. The 6 parameters with their default and optimum values are summarized in Table 1. The optimum values are the ones obtained by using the COSI type performance score, with daily minimum and maximum of 2m temperature evaluated at grid points and not averaged (following the method 4 in Khain et al., 2017); a 3-4% improvement of the COSI type performance score has been obtained with BESTF2. The performance of the model for 2m temperature (T_2M), 2m dew point temperature (TD_2M), 10m wind speed (FF_10M), 12h accumulated precipitation (TOT_PREC12) and 1h accumulated precipitation (TOT_PREC1) is presented. All statistics are over the entire year 2013, the year which is also used for the calibration; all statistics are computed for Switzerland, using Swiss observing stations and the Swiss radar composite.

Diurnal cycle of mean model error in both cases DEF (blue line) and BESTF2 (red line) as well as mean model values and mean observation values (MOBS, black line) for **2m temperature** and **2m dew point temperature** are presented in Fig. 7 and Fig. 10. Improvement of 2m temperature mean error of about 0.2°C throughout the day is evident

Table 1: Calibration parameters and their values.

Parameter	Acronym	Default values	Optimum value (after method 4)
Factor for laminar resistance for heat	**rlam_heat**	1 (20 rat_sea)	1.273 (15.71092)
Minimal diffusion coefficient for heat	**tkhmin**	0.4	0.266
Maximal turbulent length scale (m)	**tur_len**	150	346.5
Entrainment rate for shallow convection	**entr_sc**	0.3e-3	0.1607e-3
Surface-area index of the evaporating fraction of grid points over land	**c_soil**	1	0.588
Factor for vertical velocity of snow	**v0snow**	20	12.3

in Fig. 7. This improvement is related to a warmer near surface temperature associated with BESTF2, which partly mitigates the cold bias observed with DEF over Switzerland. Considering the 2m dew point temperature, one observes a degradation of the mean error throughout the day associated with a drier surface layer, which increases the already dry bias observed with DEF. Left panel of Fig. 8 illustrates the mean 2m temperature model error for the optimum and the default cases, while mean observation and model values for all lead times during the entire year are shown in right panel. It is evident that model values obtained using the optimum set of parameters are closer to the observed ones. This is also supported by Fig. 9 where statistics for the whole 2013 are presented; incidentally, the overall minimum and maximum 2m temperature obtained with BESTF2 is closer to OBS than DEF (minimum observed is -30.9°C, with -28.9°C using BESTF2 and -28.8°C using DEF, while maximum observed is 37.1°C, with 37.9°C using BESTF2 and 38.1°C using DEF). For dew point 2m temperature, shown in Fig. 11 and Fig. 12, the observed mean value is equal to 2.13°C against 1.72°C using DEF and 1.47°C using BESTF2. It should be noted that the dew point temperature is not part of the performance score used to derive BESTF2.

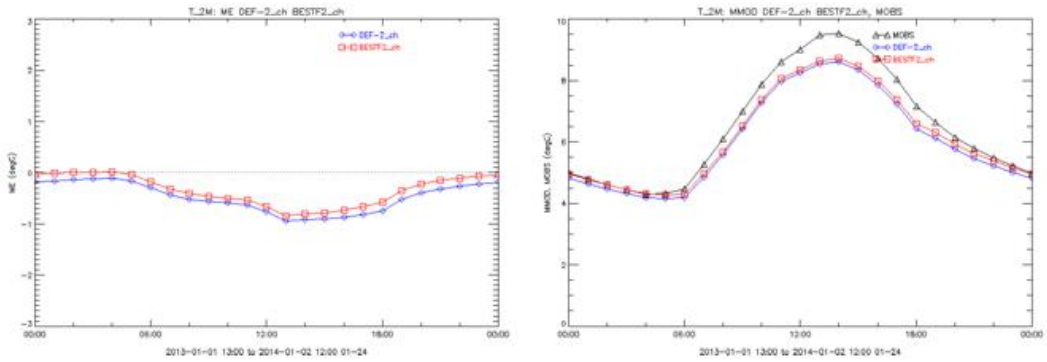

Figure 7: Verification of 2m temperature for 2013 over Switzerland. Diurnal cycle of mean model error (left panel) and mean model values compared to mean observations (right panel). An improvement of up to 0.2°C is observed.

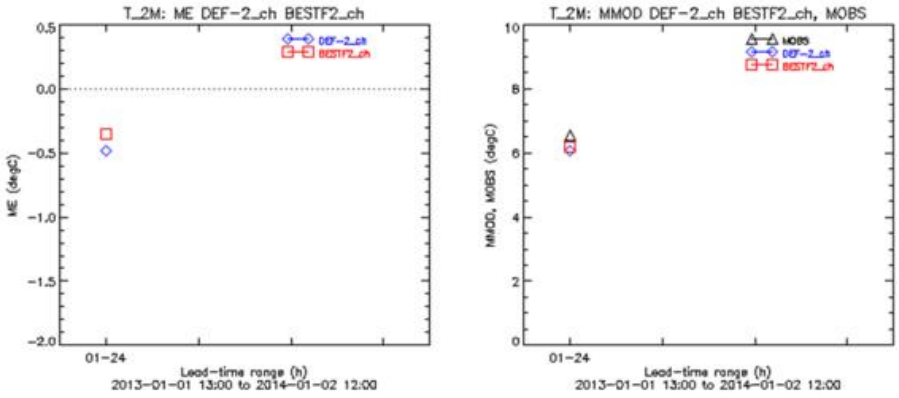

Figure 8: Verification of 2m temperature for 2013 over Switzerland. Mean model error (left panel) and mean model values compared to mean observations (right panel).

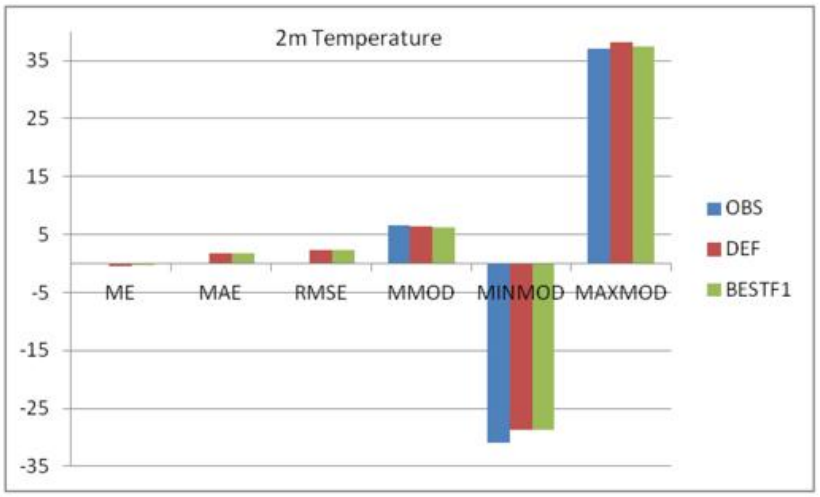

Figure 9: Statistics of 2m temperature for 2013 over Switzerland, showing observations (OBS) and model simulations using default parameter values (DEF) and optimum parameter values (BESTF2). The following quantities are shown: ME: mean error, MAE: mean absolute error, RMSE: root mean square, MMOD: mean value, MINMOD: minimal value, MAXMOD: maximal value.

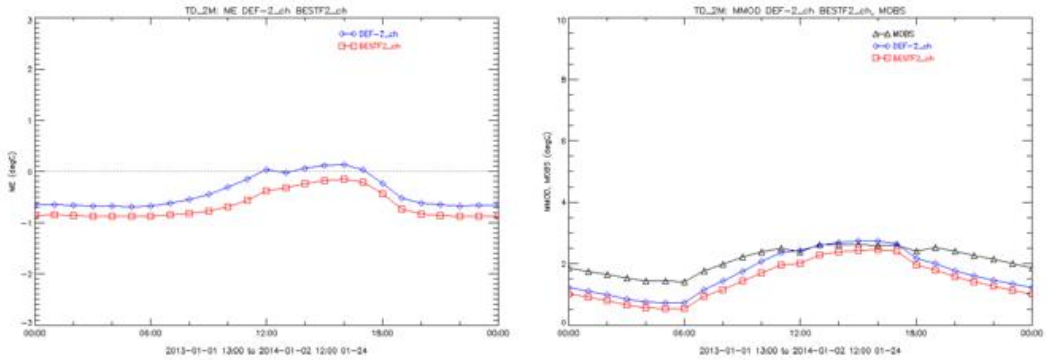

Figure 10: Verification of 2m dew point temperature for 2013 over Switzerland. Diurnal cycle of mean model error (left panel) and mean model values compared to mean observations (right panel).

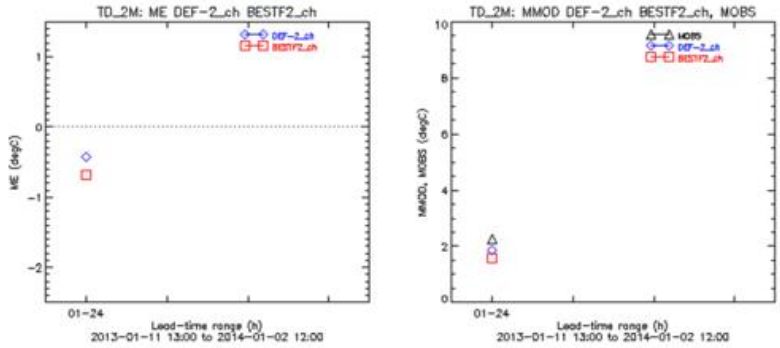

Figure 11: Verification of 2m dew point temperature for 2013 over Switzerland. Mean model error (left panel) and mean model values compared to mean observations (right panel) for dew point temperature.

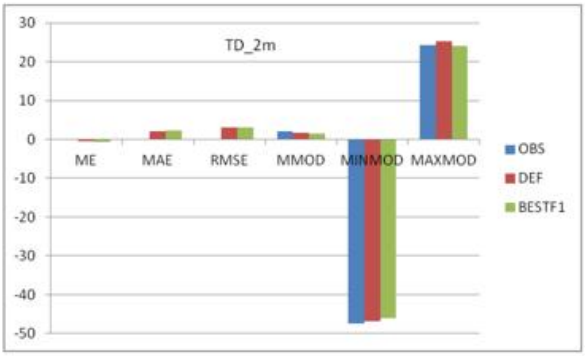

Figure 12: Statistics of 2m dew point temperature for 2013 over Switzerland, showing observations (OBS) and model simulations using default parameter values (DEF) and optimum parameter values (BESTF2). The following quantities are shown: ME: mean error, MAE: mean absolute error, RMSE: root mean square, MMOD: mean value, MINMOD: minimal value, MAXMOD: maximal value.

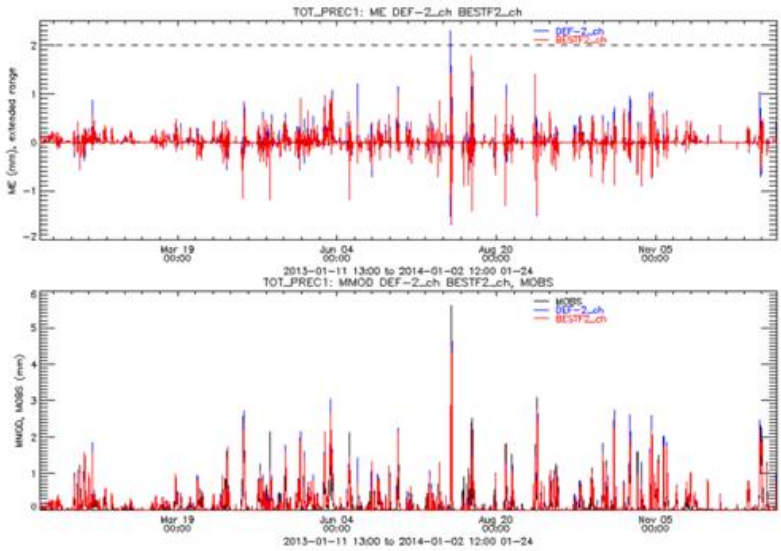

Figure 13: Time series of mean model error (upper panel) and mean model values compared to mean observations (lower panel) for hourly accumulated precipitation over Switzerland.

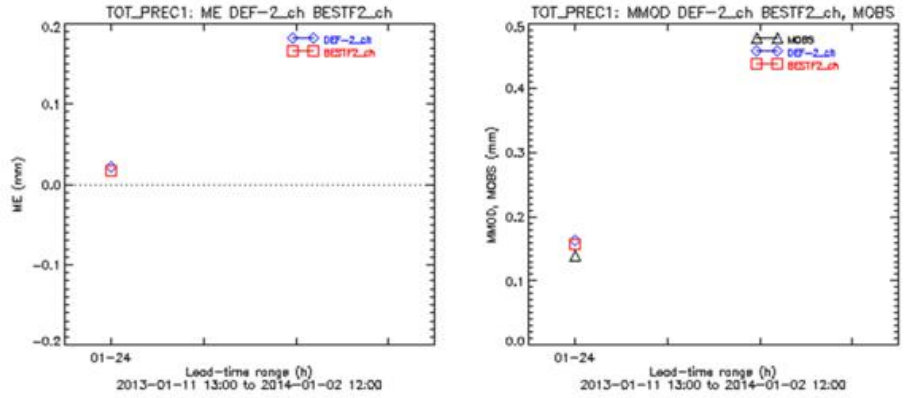

Figure 14: Mean model error (left panel) and mean model values compared to mean observations (right panel) for hourly accumulated precipitation over Switzerland.

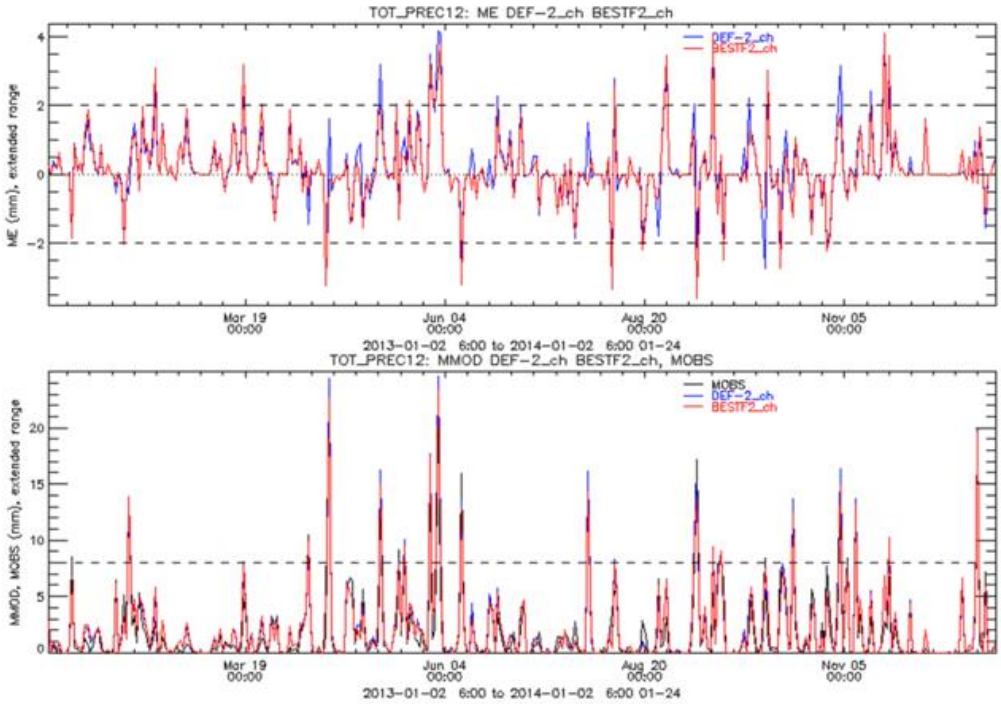

Figure 15: Time series of mean model error (upper panel) and mean model values compared to mean observations (lower panel) for 12-h accumulated precipitation over Switzerland.

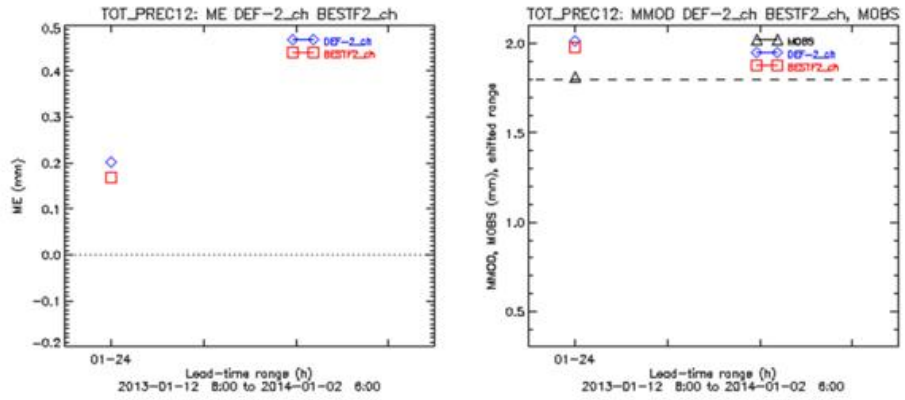

Figure 16: Mean model error (left panel) and mean model values compared to mean observations (right panel) for 12-h accumulated precipitation over Switzerland.

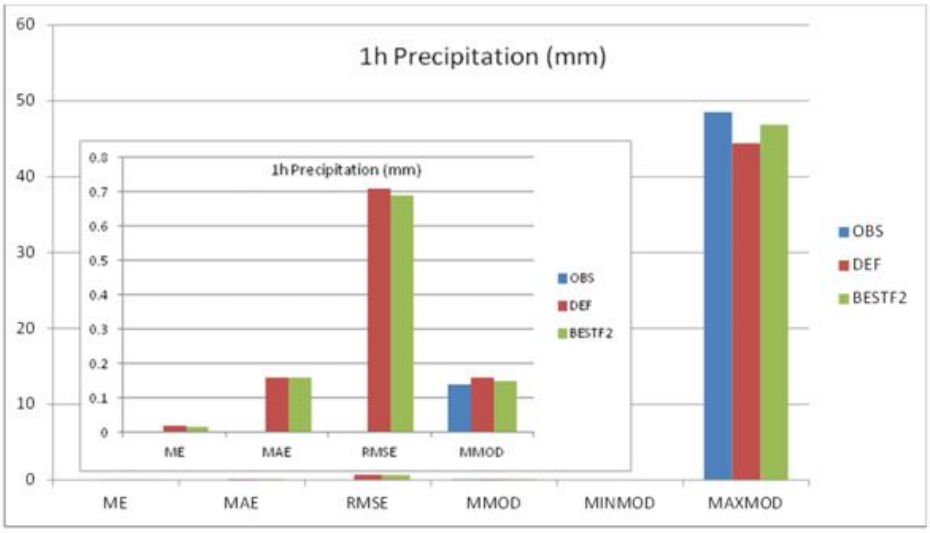

Figure 17: Statistics of hourly accumulated precipitation during entire 2013 over Switzerland, showing observations (OBS) and model simulations using default parameter values (DEF) and optimum parameter values (BESTF2). The following quantities are shown: ME: mean error, MAE: mean absolute error, RMSE: root mean square, MMOD: mean value, MINMOD: minimal value, MAXMOD: maximal value.

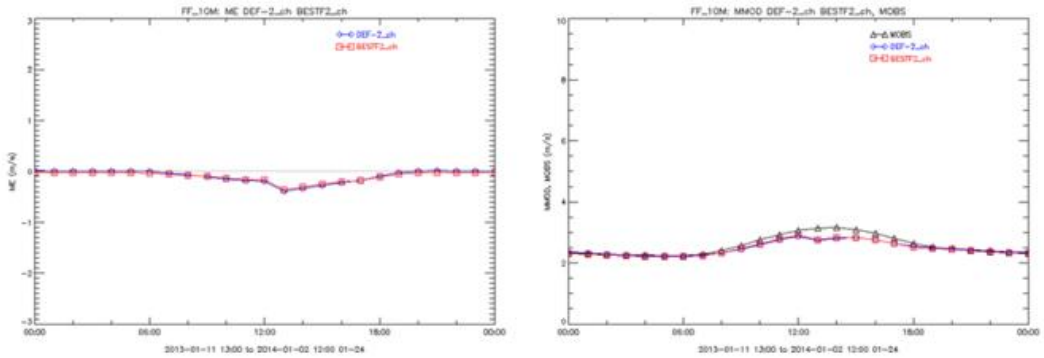

Figure 18: Verification of 10m wind speed for 2013 over Switzerland. Diurnal cycle of mean model error (left panel) and mean model values compared to mean observations (right panel).

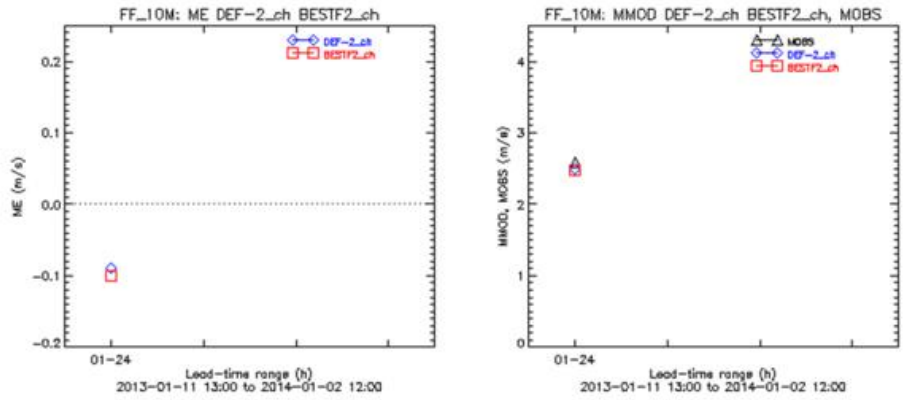

Figure 19: Verification of 10m wind speed for 2013 over Switzerland. Mean model error (left panel) and mean model values compared to mean observations (right panel).

Time series of mean model errors as well as mean model values, compared to mean observations for 12h and 1h accumulated precipitation are presented in Fig. 13 and Fig. 15 respectively. A slight improvement on mean error is visible for accumulated precipitation over the entire year, especially during the warm period of the year. Total scores for the diurnal cycle of the variable support this assertion, as shown in Fig. 14, Fig. 16 and Fig. 17: 1.79mm and 0.14mm mean observed values for 12h and 1h accumulated precipitation respectively, compared to 1.99mm and 0.16mm for the modeled values using default parameters and 1.96mm and 0.15mm using the optimum parameters.

Diurnal cycle of mean model error in both cases DEF (blue line) and BESTF2 (red line) as well as mean model values and mean observation values (MOBS, black line) for **10m wind speed** are presented in Fig. 18. Mean error total score and means for all lead times during the entire year for both model and observations is presented in Fig. 19. A very small degradation of the scores when using BESTF2 is observed (mean observed value 2.57 m/s, against 2.47 m/s using BESTF2 and 2.48 m/s using DEF).

7 A case study *(E. Bucchignani, P. Mercogliano, M. Milelli)*

The following case study illustrates the impact of using the CALMO calibrated values instead of the default parameters values. The interest of this study is that it uses the calibrated parameters with a different model configuration than the one used in the calibration, and for a different year. In the first half of July 2015, Piedmont region and Turin in particular experienced extreme temperature values and uncomfortable conditions for the population. In Turin, the maximum temperature since 1990 (38.5°C) has been recorded in July 2015. Ground stations data highlighted the presence of a UHI effect over Turin. This is the reason why this area and this period represent a suitable benchmark to test the capabilities of COSMO-CLM, and in particular of the urban parameterization. The computational domain considered is centered over Turin, discretized with 100 x 100 grid-points, employing a spatial resolution of 0.009° (about 1 km). The ECMWF IFS analysis at 0.075° have been used as forcing data. Three different simulations have been performed over the period 1 to 7 July 2015, respectively using the default set of control parameters **and two different sets of parameters derived from the COSMO-2 calibration performed in the CALMO project**[2], as listed in Table 2, in order to highlight the effects on the model results. Validation has been carried out against an observational dataset for daily values of temperature, provided by ARPA Piemonte. In the following, results related to Consolata station are shown, representative of an urban area. Table 3 shows the average observed T2m value, the average bias (model minus observation) over the simulated period and the maximum bias, obtained with the different configurations at Consolata. **Both calibrated configurations allow a significant reduction of the average bias. OPT2 allows also a reduction of the maximum bias.**

Table 2: Values of the control parameters for the three different configurations.

	Default	**OPT1**	**OPT2**
rlam_heat	1.0	0.74	1.24
tkhmin	0.4	0.176	0.233
tkmmin	0.4	0.4	0.233

entr_sc	0.003	0.00014	0.000267
c_soil	1	0.663	0.492
v0snow	20	17.8	12.1
rat_sea	20	20	16.12903

Table 3: Values of observed T2m value (°C), average bias (model minus observation) over the simulated period and the maximum bias, obtained with the different configurations.

	OBS	**BIAS URB_DEF**	**BIAS URB_OPT1**	**BIAS URB_OPT2**
Average bias	29.4	0.68	0.36	0.43
Maximum bias	29.4	5.5	5.0	4.9

[2]This case study has been conducted before the definitive values of the calibrated parameters were available. This is the reason why two different sets are present, both differing from the final values listed in Khain 2017; the OPT2 set is the one which is the nearest to the final values obtained by CALMO.

8 Conclusions

The CALMO project was a considerable step towards complementing the usual expert tuning with an objective calibration methodology. Expert tuning is typically done once during the development of the model, for a certain target area, and for a certain model configuration, and is often difficult if not impossible to replicate. This is the hope placed in this new methodology to support on-demand calibration by any COSMO member, e.g. to define an optimal calibration over the target area of interest, to introduce a seasonal dependency on some unconfined model parameters values, or for a re-calibration after major model changes (e.g. higher horizontal or vertical resolution). Furthermore, the CALMO methodology could also be used for an unbiased assessment of different modules (e.g. parameterization schemes), and for optimal perturbation of parameters when run in ensemble mode. Starting with a rough model resolution of 7km and a short calibration period of 40 days, the method was extended to a finer 2.2km resolution. The simulation period was significantly increased from 40 days of 2008 to the entire year of 2013, to consistently incorporates the weather development on a seasonal basis. The verification area was enlarged to also consider Northern Italy. The daily minimum and maximum 2m temperature and the 24h accumulated precipitation was complemented with vertical wind, temperature, and humidity profiles and with total water column at soundings locations. The number of calibrated model parameters was increased from 3 to 6. The meta-model was adapted and extended. A new COSI performance score was included to act as a performance metric for NWP models. A new method for logarithmic transformation for selected parameters was developed along with an iterative method to obtain the optimal parameters via convergence in a 6-dimensional parameter space of exceptional cardinality. An estimation of error bars on the optimal parameters values has been introduced. Following these adaptations, the calibration of COSMO-2 was performed and the optimal parameters combination was obtained. Using the COSI performance score to quantify the quality of the simulation, which is a combination of root mean square score for continuous fields and equitable thread score for precipitation, a performance gain of 2-4% was observed. An independent verification of the optimal configuration shows a small reduction of the 2m temperature and precipitation biases, but also a small increase of the 2m dew point bias. This small impact is expected, given that the chosen model configuration is very similar to the model configuration used by the COSMO core development team, which has undergone exceptional expert tuning over a period of almost two decades; arguably this small impact confirms the validity of the calibration method. However, the main learning from the CALMO project is that the meta-model is able to reasonably reproduce the dependency of the model on the unconfined parameters. This is illustrated in Fig. 6, where the meta-model prediction is compared with the full model prediction for the daily accumulated precipitation at different locations. Thanks to these developments, **the calibration methodology can now be readily applied to a NWP system and the reliability of the calibration results can be trusted**. However, a full assessment of the impact of the soil memory is not available; this is an important issue, because it is expected that the impact of a new set of model parameters can be substantially stronger through the accumulation of heat and humidity in the soil over the full simulation period, as indeed observed in a preliminary experiment with a 1.1 km configuration of the COSMO model (a performance gain measured by the COSI score exceeding 10% has been observed following a one month calibration). Furthermore, in order for this method to be used by the COSMO community, **it is essential to reduce the computing cost of the calibration**. For these reasons, a follow-up project CALMO-MAX has been defined. Finally, it should be noted that the selection of unconfined model parameters used in the calibration process is a crucial but also user-dependent step. More specifically the calibration of the model towards better scores could be associated with the user specific needs for a detailed representation

of specific model variables and phenomena. Additional parameterization development and new model implementations is always needed but **calibration is always meaningful in order to complement the expert tuning!**

9 Appendix: list of model parameters

The most interesting parameters for CALMO / COSMO-1 are highlighted:

in red: highest priority
in orange: medium priority
in yellow: lowest priority

Multilayer soil model

	name	description	value (min/max)	defined in	dependency on resolution, remarks
x	cdash	parameter for laminar conductance of heat and water vapour from leaves	0.05 $(m/s)^{1/2}$	data_soil	**not in use for COSMO-1 (aka itype_tran=2)**
x	cdmin	part of the tuning parameters for the maximum sustainable water flux in the soil	$2.5 \cdot 10^{-10} m^2/s$	data_soil	
x	cdsmin	minimum snow depth	0.01 m	data_soil	
x	cfinull	soil water suction at saturation	0.2 m	data_soil	
x	cf_snow	parameter for determination of fractional snow cover	0.015 m_{H2O}	data_soil	decrease cf_snow, if for smaller grid elements snow cover shall be increased, compare rhde for radiation
x	cf_w	parameter for determination of fractional water cover	0.001 m_{H2O}	data_soil	analogous to cf_snow
x	cik1	parameter for determination of maximum infiltration	0.02	data_soil	

	name	description	value (min/max)	defined in	dependency on resolution, remarks
x	ckrdi	scale for soil hydraulic conductivity	0.00001 m/s	data_soil	
x	cparcrit	scale for photosynthetically active radiation	100 W/m^2	data_soil	
x	crhosmax_ml	maximum density of snow	400 kg/m^3	data_soil	
x	crhosmin_ml	minimum density of snow	0.8	data_soil	
x	crhowm	fraction of saturated soil filled by water	50 kg/m^3	data_soil	
x	crsmax	maximum stomatal resistance	4000 s/m	data_soil	
x	crsmin	minimum stomatal resistance	150 s/m (50.0 – 300.0)	INPUT	
x	csatdef	scale for saturation deficit	4000 Pa	data_soil	
x	csvoro	parameter for influence of sub-grid scale orography on infiltration	1	data_soil	increase parameter for decreasing grid length to allow for more infiltration
x	ctau_i	time constant for drainage from interception store	1000 s	data_soil	modification in TERRA possible to avoid ctau_i $< 2\Delta$
x	ctend	maximum temperature for plant transpiration	313.15 K	data_soil	
x	cwimax_ml	parameter for determination of maximum interception store	0.000001 m	data_soil	
	kexpdec	hydraulic conductivity of soilr	2	src_soil_multlay.f90	

The soil model uses additional parameters which depend on the 8 soil types ice, rock, sand, sandy loam, loam, loamy clay, clay, and peat. Some additional values for sea water and for sea ice are given but not yet used in the model. All these parameters are defined in data_soil. Most of these parameters strongly effect the water and heat budgets at the soil surface. This in turn significantly effects the determination of the near surface values of temperature and humidity.

Turbulence (diffusion, vertical transport; atmosphere)

	name	description	value (min/max)	defined in	dependency on resolution, remarks
x	pat_len	length scale of subscale surface patterns over land	500 m (10.0 – 1000.0)		
x	c_diff	factor for turbulent diffusion of TKE	0.2 (0.01 – 10)		
x	a_stab	factor for stability correction of horizontal length scale	0		
x	a_heat	factor for turbulent heat transport	0.74		
x	a_mom	factor for turbulent momentum transport	0.92		
x	d_heat	Factor for turbulent heat dissipation	10.1 (12 – 15)		
x	d_mom	Factor for turbulent momentum dissipation	16.6 (12 – 15)		
x	tur_len	asymptotic maximal turbulent length scale	150 m (100 – 1000)		
x	tkesmot	time smoothing factor for TKE and diffusion coefficients	0.15		
x	tkmmin	Minimal diffusion coefficient for heat	$0.4m^2/s$(0.0 – 2.0)		
x	tkhmin	Minimal diffusion coefficient for momentum	$0.4m^2/s$(0.0 – 2.0)		

Turbulence (surface layer transfer)

	name	description	value (min/max)	defined in	dependency on resolution, remarks
x	rlam_mom	scaling factor of the laminar boundary layer for momentum	0.0		
x	rlam_heat	scaling factor of the laminar boundary layer for heat	1.0 (0.1 – 10.0)		
x	rat_lam	Ratio of laminar boundary thickness for q and h	1.0 (0.1 – 10.0)		
x	rat_can	Factor for canopy height	1.0 (0.0 – 10.0)		
x	rat_sea	ratio of laminar scaling factors for heat over sea and land	20 (1.0 – 100.0)		
x	c_lnd	surface area density of the roughness elements over land	2.0 (1.0 – 10.0)		
x	c_sea	surface area density of the waves over sea	1.5 (1.0 – 10.0)		
x	c_soil	surface area index of (evaporative) soil surfaces	1.0 (0.0 – 10.0)		
x	e_surf	Exponent to get the effective surface area	1.0 (0.1 – 10.0)		
x	z0m_dia	roughness length of a typical synoptic station	0.2 m (0.001 – 10.0)		

Grid scale precipitation

	name	description	value (min/max)	defined in	dependency on resolution, remarks
x	zaac	$zaac = \frac{3}{7}\frac{E_r}{\rho_w}(A_r B_r)^{2/9}$ $A_r = \rho_w \pi N_o^r$ $B_r = v_o^r \Gamma(4.5)/\Gamma(4)$ $E_r = 0.8$ $N_o^r = 8 \cdot 10^{-6} m^{-4}$ $v_o^r = 130 m^{1/2} s^{-1}$	1.72	hydor	parameter for the determination of the accretion rate
x	zaau	inverse of the time constant for autoconversion	$0.001 s^{-1}$	hydor	
x	zamc	parameter for the temperature dependent relation between mass and diameter of precipitation particles	$0.08 kg/m^2$	hydor	
x	zamelt	parameter for determination of melting of falling snow	$7.2 \cdot 10^{-6}$	hydor	
x	zamv	parameter for the temperature dependent relation between mass and diameter of precipitation particles	$0.02 kg/m^2$	hydor	
x	zanuc	inverse of the time constant for nucleation	$0.001 s^{-1}$	hydor	
x	zarim	$E_s \pi/4$ collection efficiency for snow particles	1.97	hydor	
x	zbdep	parameter β_{dep} (coef. for ice ventilation)	13	hydor	
x	zbev	parameter β_{ev} (coef. for drop ventilation)	8.05	hydor	
x	zbmelt	parameter β_{melt} (coef. for melting ice)	13	hydor	
x	zt1	parameter for the temperature dependent relation between mass and diameter of precipitation particles	253.15 K	hydor	
x	zt2	parameter for the temperature dependence of the distribution of water, ice, and mixed phase clouds	235.15 K	hydor	
x	v0snow	factor in the terminal velocity for snow	20 (10.0 – 30.0)		

	name	description	value (min/max)	defined in	dependency on resolution, remarks
x	rain_n0_fac	However, because on average, the parameterization of the frozen-phase growth processes in the current graupel scheme seems to be too inefficient to produce "enough" precipitation sized particles, we artificially reduce the evaporation of raindrops to get the "correct" rain amount at the surface, by tuning the N00 parameter with a factor rain_n0_factor ($\leqslant$ 1), N00_tuned = N00 $\cdot$ rain_n0_factor	1.0		
x	mu_rain		0		
x	qc0	cloud water threshold for autoconversion	0.0002 (0.0 – 0.01)		
x	qi0	cloud ice threshold for autoconversion	0.0 (0.0 – 0.01)		
	cloud_num	cloud droplet number concentration	5.0E8		
x	zxstar	separating mass between cloud and rain	separating mass between cloud and rain		

Radiation

	name	description	value (min/max)	defined in	dependency on resolution, remarks
x	csalb	solar albedo for dry soil	soil type dependent	data_soil	**Not in use for COSMO-1 (aka itype_albedo=3)**
x	csalb_snow	solar albedo for snow	0.7	data_soil	**Not in use for COSMO-1 (aka itype_albedo=3)**
x	csalb_p	solar albedo for plant covered soil	0.15	data_soil	**Not in use for COSMO-1 (aka itype_albedo=3)**
x	ctalb	thermal albedo for all soil types	0.004	data_soil	
x	ucl	determination of cloud cover in unsaturated conditions	1	constants	should be resolution dependent (ask Matthias how we can tune width of distribution!)
x	uc1	as ucl	0.8	constants	as ucl
x	uc2	as ucl	$sqrt(3)$	constants	as ucl
x	zclwfk	fraction of saturation humidity assumed for cloud liquid water content of convective clouds	0.01	organize_radiation	
x	zclwfs	as zclwfk, for non-convective sub-grid scale clouds	0.005	organize_radiation	**not used in code ?**
	IF (lzprog_qi) THEN zclws = 0.005_wp · zsex				
x	clc_diag	cloud cover at saturation in statistical cloud diagnostic	0.5 (0.2 – 0.8)		**not used by radiation, see turbulence**
x	q_crit	critical value for normalized oversaturation	1.6 (1.0 – 10.0)		**Not used by radiation, see turbulence (check why this is red!)**

Shallow convection

	name	description	value (min/max)	defined in	dependency on resolution, remarks
x	entr_sc	mean entrainment rate for shallow convection	3.0E-4 (5.0E-5 – 2.0E-3)		
x	thick_sc	limit for convective clouds to be "shallow" (in Pa)	2.5E4		

Sub-grid scale orographic drag

	name	description	value (min/max)	defined in	dependency on resolution, remarks
x	gkdrag	gravity wave drag constant	0.075		Not used in COSMO-1 (aka lsso=.false.)
x	gkwake	low level wake drag constant	0.5		Not used in COSMO-1 (aka lsso=.false.)

10 Appendix: highlights of sensitivity experiments

SELECTED DOMAINS

SENSITIVITY TESTS BLUEPRINT

13 parameters were considerd.

⊗

3 values/parameter including default.

⊗

The evaluation period consisted of 62 days from year 2013, i.e.: February 1-20, June 1-20, December 10-31.

‖

2418 runs based on COSMO.v5.0

- Horizontal grid size: 0.0625^0 (~7km).
- 649x393 grid points (wider mediterranean area), 60 levels.
- Integration time-step: 30 secs.
- Integration period: 48 hs.
- Boundary conditions : 6hr IFS Analysis.
- Computational Cost ~ 10^7 b.u. on Cray X C30 of ECMWF (gratis HNMS).

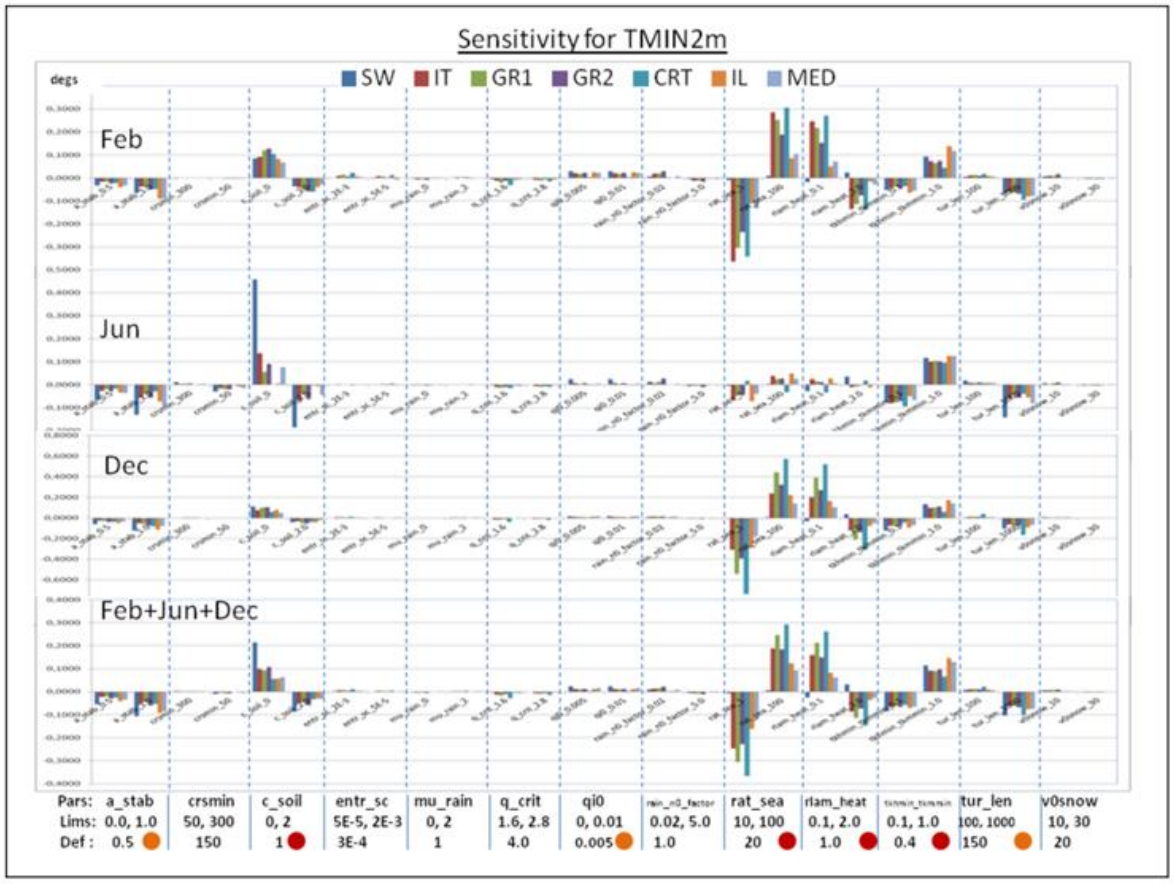
INVESTIGATED VARIABLES (AREA AVERAGES)

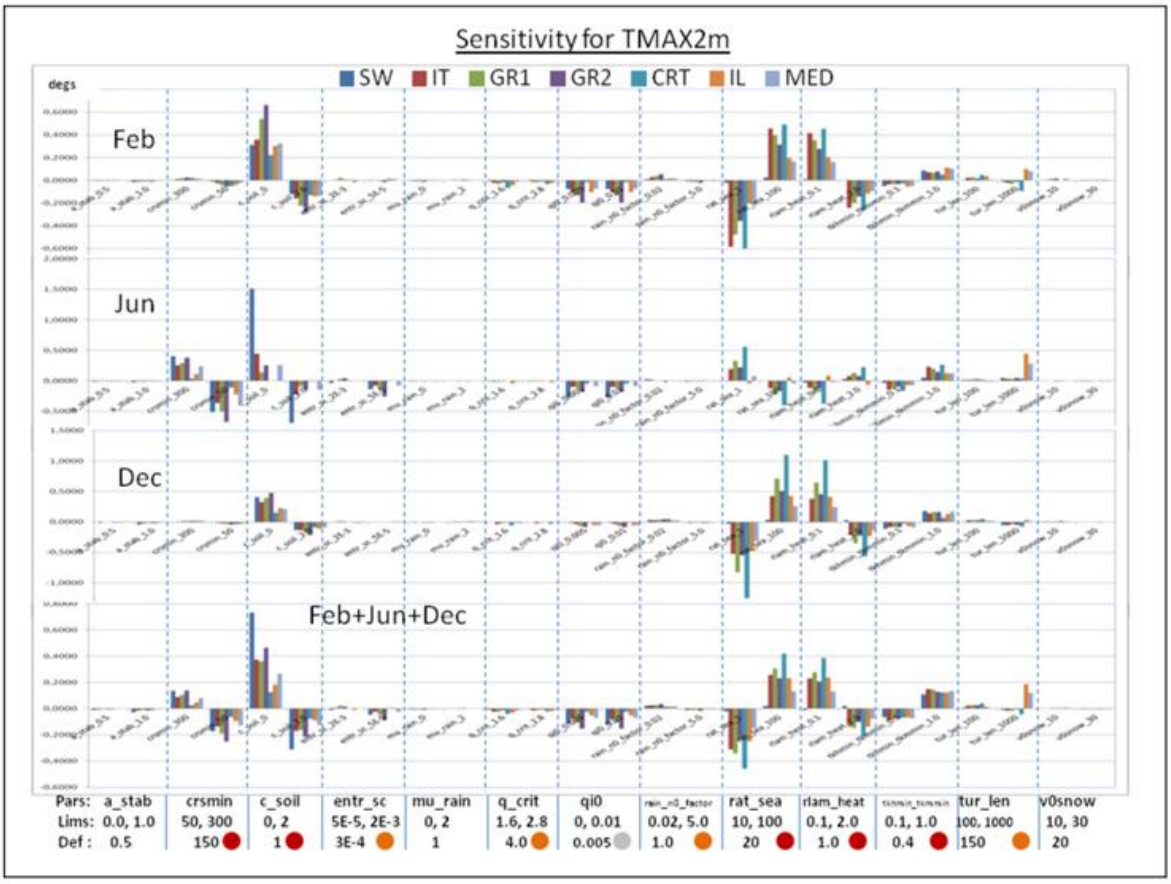
- **< TMAX2m >:** Maximum 2m temperature for 0-24 hr periods.
- **< TMIN2m >:** Minimum 2m temperature 0-24 hr periods.
- **< TOTPREC >:** 0-24 hr period accummulated precipitation (kg m^{-2}).
- **< SNOW_GSP >:** 0-24 hr periods accumulated grid-scale snow (kg m^{-2})
- **< CLCL >:** Low cloud cover (%) average of 3hr time steps 03-24 hs.
- **< CLCM >:** Medium cloud cover (%) average of 3hr time steps 03-24 hs.
- **< CLCH > :** High cloud cover (%) average of 3hr time steps 03-24 hs.
- **< CLCT > :** Total cloud cover (%) average of 3hr time steps 03-24 hs.

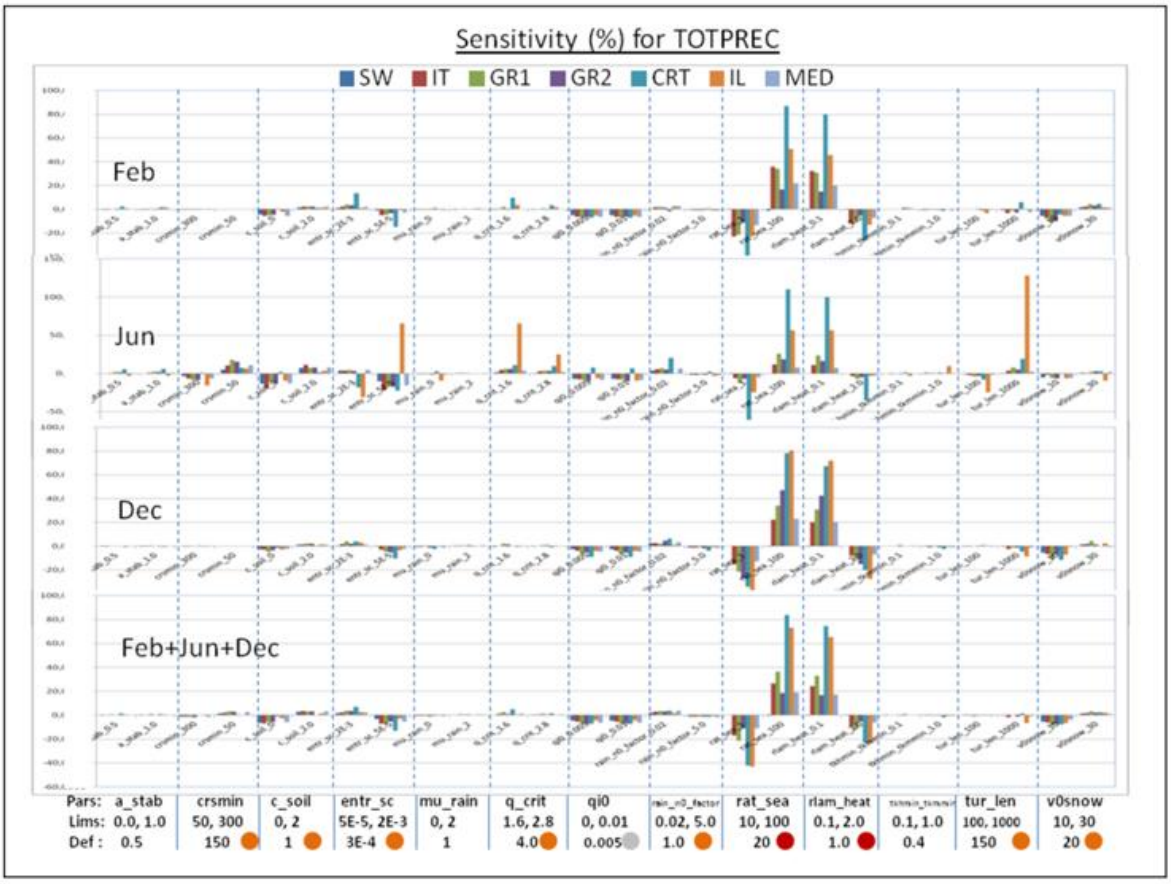
! The same investigation was performed for 24-48 hr periods with approximately the same performance.

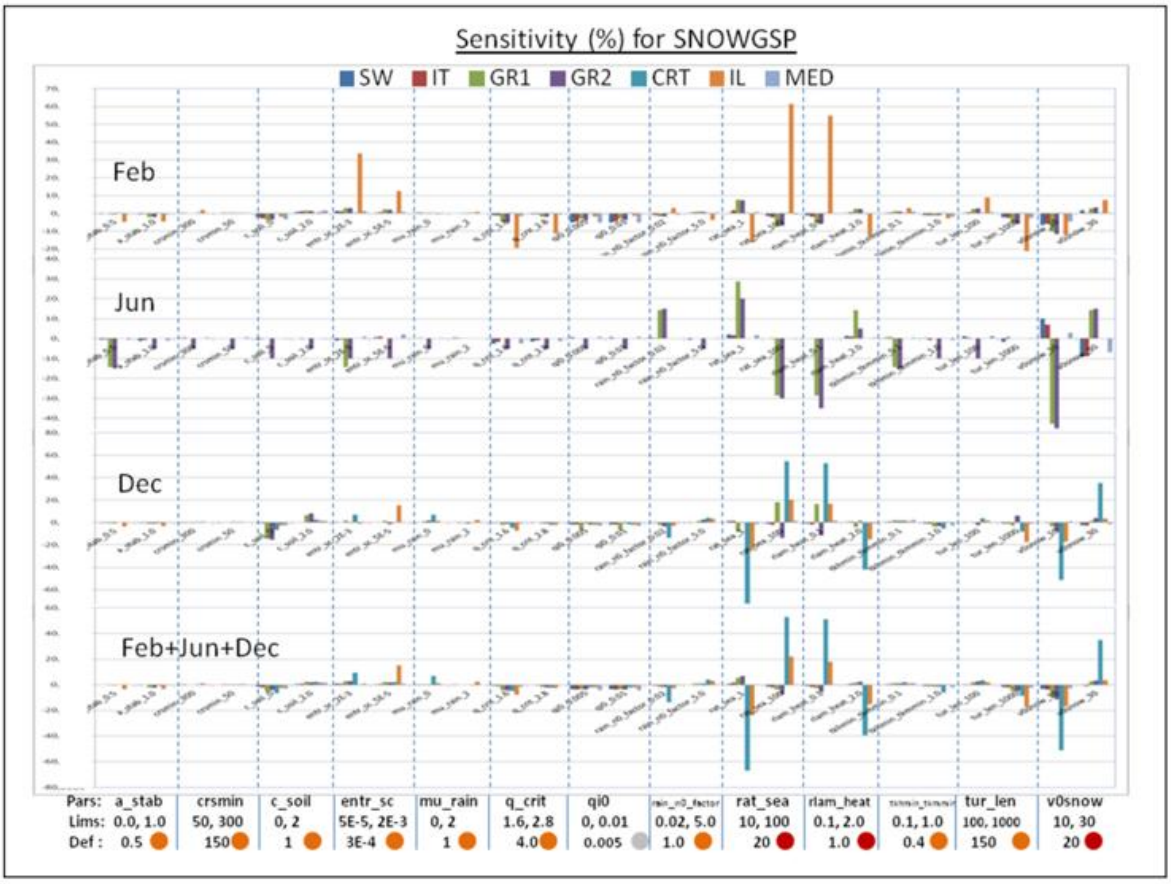
GRAPH FEATURES

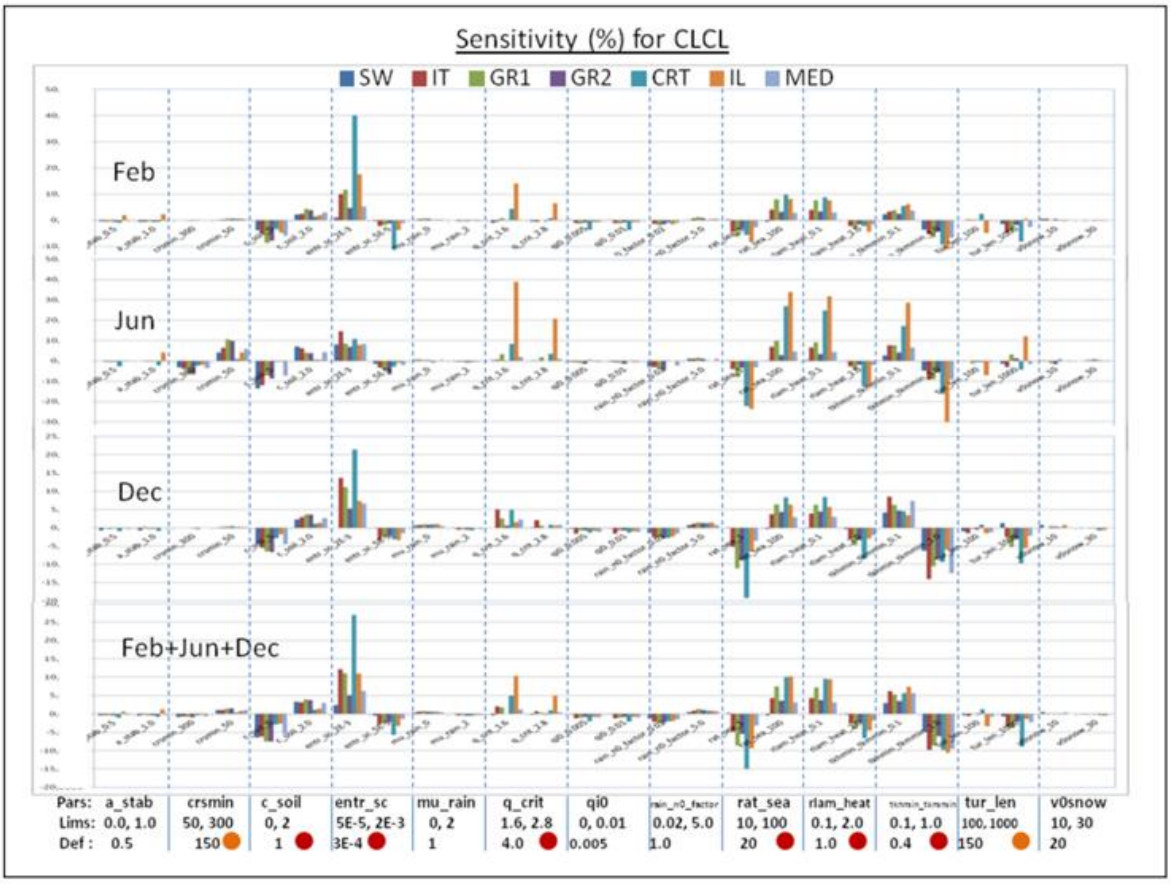
- The sensitivities of the considered variables are presented for every period as well as for the total number of days in succesive clustered column graphs: SW, IT, GR1, GR2, CRT, IL, MED.
- Domain color correspondance: SW IT GR1 GR2 CRT IL MED
- The idea behind the domain choices is to display the changes in sensitivities in reference to the relative location of the domains from the SouthEast (IL) to the NorthWest (SW) which is the focal domain of CALMO project at its present stage.
- On the horizonta axis, the sensitivities are presented for every pair of the parameter values under consideration.
- ● depicts the most sensitive parameters.
- ● depicts parameters with sensitivity of order 10% of ●.
- ● the sensitivity of **qi0** is displayed but not considered at this stage of the work.











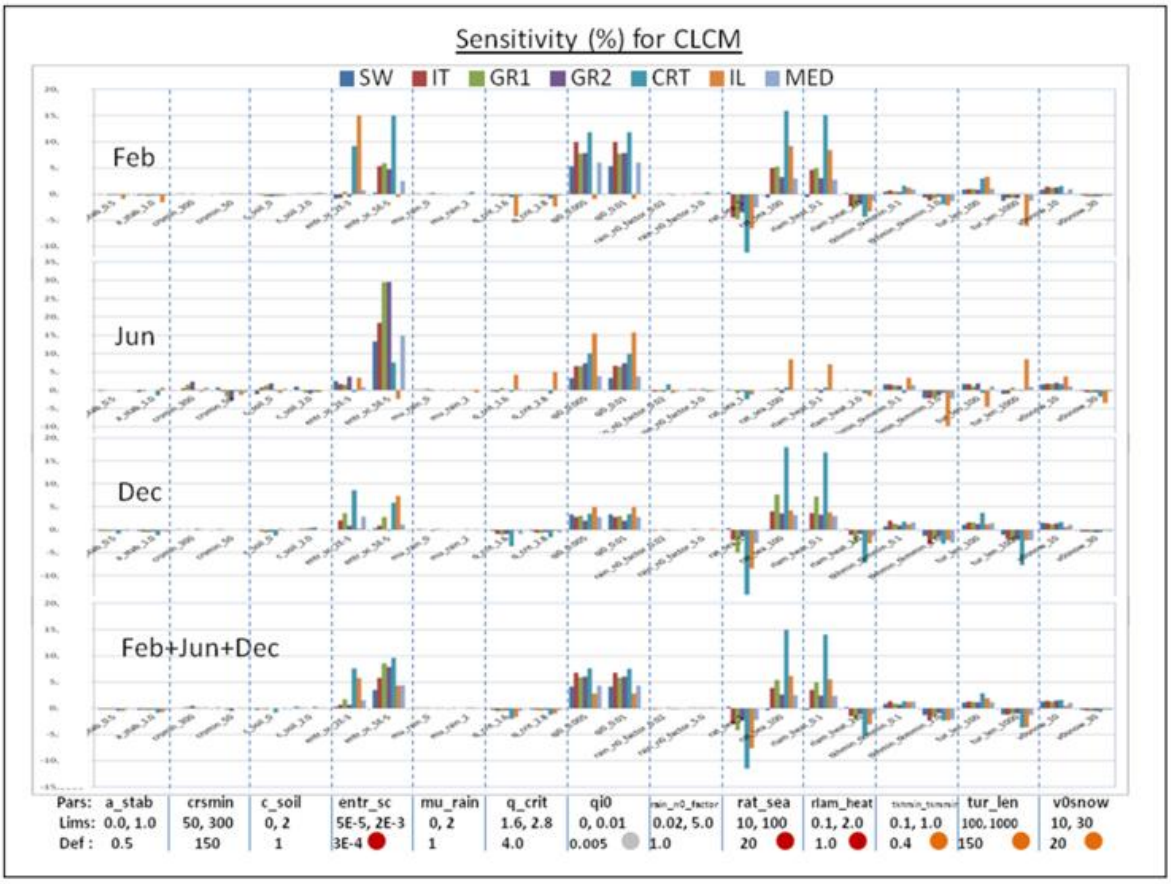


Figure 20: Description of parameter list. ∗c_lnd: Surface-area index of gridpoints over land (excluding leaf-area index). ∗∗The "gray" variable **qi0**, although its sensitivity will be shown, it is not accounted at this stage of our work due to caution regarding its use if different than its default value (communication with Axel Seifert).

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction - CALMO project

The CALMO project is based on the objective calibration method which was developed and implemented in regional climate model by Omar Bellprat and Christoph Schär (ETH). The purpose of the CALMO project is to implement the calibration method of Bellprat et al. (2012) to NWP model COSMO. Briefly, the calibration method is the following:

- First, define the parameters for tuning and their allowed ranges. The selected parameters have to be the most significant for the verified fields. For example, for the maximum 2m-temperature we may need to focus on soil and radiation schemes parameters, while for precipitation, we may need to consider also microphysical parameters, etc.
- Define the forecast fields to be verified. It is important to select many meteorologically important fields in order to better reflect the weather conditions. Otherwise there is a danger that the calibration procedure will improve specific fields while degrading the overall skill of the forecast.
- Define the time periods and geographical regions for calibration. The time periods and the regions should be chosen to represent a meaningful forecast.
- Define the parameters (combinations) values for performing the COSMO simulations. The minimum required number of simulations to be performed is 2N + 0.5N(N - 1) + 1, where N is the number of calibrated parameters.
- Define the method to perform the COSMO simulations, i.e. initial and boundary conditions and the forecasts time ranges. For soil-related parameters, long term spin-up simulations of the COSMO soil scheme are needed for preparing proper initial conditions.
- After the simulations are performed, the Meta-Models are constructed, i.e. the forecasted fields are interpolated in parameters space via N-dimensional quadratic polynomial (for each field, for each region and each day, separately). These interpolation formulas (the Meta-Models) allow estimating the forecasted field value for arbitrary parameter values (for each region and each day) without performing real COSMO simulation.
- At the next stage, the parameters space is filled by a large number of parameters combinations. For each parameter combination, a forecast field time series is produced (using the Meta-Models), compared with the observations, and evaluated using a performance score.
- Finally, the parameters combination which obtained the best score is selected.
- In principle, it is reasonable to perform a real COSMO simulation with the selected parameters combination, and verify whether the forecasts are indeed better (than with the default parameters combination).

2 Overview: different stages of the CALMO project

The CALMO project included three stages. At CALMO-stage-1 we have performed a preliminary calibration of COSMO-7km. The detailed description of that stage is presented in

	Stage-1	Stage-2	Stage-3
Resolution	7km	2.2km	1.1km
Simulations domain	[17W-22E, 35N-57N]	[0E-17E,42N-50N]	[0E-17E, 42N-50N]
Calibration area	Switzerland	Switzerland and north Italy	Switzerland and north Italy
Calibrated atmospheric fields	T2m-max; T2m-min; 24h-precipitation	T2m-max; T2m-min; 24h-precipitation; sounding profiles diagnostics: CAPE; CIN; total column water vapor; vector wind shears between the levels 500-700mb/700-850mb/850-1000mb; temperature, relative humidity and wind components at 850, 700 and 500mb	T2m-max; T2m-min; 24h-precipitation; sounding profiles diagnostics: CAPE; CIN; total column water vapor; vector wind shears between the levels 500-700mb/700-850mb/850-1000mb; temperature, relative humidity and wind components at 850, 700 and 500mb
Simulations period	1-20/1/2008, 1-20/6/2008	1/1/2013-31/12/2013	1/1/2013-1/2/2013
Tuning parameters	rlam_heat, tkhmin, tur_len	rlam_heat, tkhmin, tur_len, entr_sc, c_soil, v0snow	tkhmin, tur_len, entr_sc, c_soil, crsmin

Table 1: Overview: different stages of the CALMO project

Khain et al. (2015). At CALMO-stages 2 and 3 we have performed several improvements of the calibration process. The main characteristics of the 3 stages are summarized in Table 1.

3 Short overview of the tuned parameters

In Table 2 we present the parameters which were tuned during the different stages of the CALMO project, and briefly describe their physical meaning.

	Used at stages:	Brief physical meaning:	Min	Default	Max
rlam_heat	1,2	rlam_heat $[no-units]$ is the parameter which linearly determines the heat resistance length of laminar layer; so that the higher is rlam_heat the higher is the resistance of laminar layer for heat transfer, and consequently, the lower is the heat transfer between the surface and the lower atmosphere	0.1	1	2
tkhmin	1,2,3	tkhmin $[m^2/s]$ and tkmmin $[m^2/s]$ determine the minimum limits for the turbulence coefficients. tkhmin presence is evident when the turbulent diffusion coefficients (then the mixing) are small, which occurs in stable conditions, mainly at night near the surface	0.1	0.4	1
tur_len	1,2,3	tur_len $[m]$ is l_∞ in Blackadar formula (Blackadar, 1962) for the turbulence length. The higher is tur_len, the higher are the turbulent coefficients (both vertical and horizontal) in the middle-upper atmospheric levels, and consequently the higher are the turbulent fluxes (mixing) for all the variables and tracers	100	150	1000
entr_sc	2,3	entr_sc $[m^{-1}]$ is the mean entrainment rate of boundary layer humidity into the shallow convection clouds. The higher is entr_sc, the more effective is the shallow convection vertical mixing	0.05e-3	0.3e-3	2e-3
c_soil	2,3	c_soil $[no-units]$ is the surface-area index of the evaporating fraction of gridpoints over land: c_soil $\in$ [0, c_lnd=2]. The higher is c_soil, the higher is the surface evaporation	0	1	2
v0snow	2	v0snow $[no-units]$ is the factor in the terminal velocity for snow	10	20	30
crsmin	3	crsmin $[s/m]$ is the minimum value of stomatal resistance used by the BATS approach for vegetation transpiration	50	150	200

Table 2: COSMO parameters tuned at different stages of the CALMO project

4 Meta-Model

4.1 Overview

The Meta-Model was widely discussed in Khain et al. (2015), so here we briefly present its basic idea. Following the theory of Meta-Model construction (see Bellprat et al., 2012 and Neelin et al., 2010), for any parameters combination (for example N=3 parameters combination of rlam_heat, tkhmin, tur_len), for a given day i and a region r, the COSMO field F (for example Tmax, Tmin, Pr, etc.) may be approximated by 3-dimensional polynomial of order 2:

$$F_{i,r} \approx F_{di,r} + c_{i,r} + \sum_{n=1}^{N} a_{i,r}^{(n)} x_n + \sum_{n,m=1(n\neq m)}^{N} B_{i,r}^{(n,m)} x_n x_m \qquad (1)$$

where

$$x_1 = \frac{rlam_heat - rlam_heat_d}{rlam_heat_{max} - rlam_heat_{min}}, x_2 = \frac{tkhmin - tkhmin_d}{tkhmin_{max} - tkhmin_{min}}, x_3 = \frac{tur_len - tur_len_d}{tur_len_{max} - tur_len_{min}}$$

The index d stands for default. For default values of the N=3 parameters, i.e. $[x_1 = 0, x_2 = 0, x_3 = 0]$, the approximated field should be close to $F_{di,r}$. The constants $c_{i,r}$, $a_{i,r}^{(n)}$, $B_{i,r}^{(n,m)}$ are obtained using several COSMO simulations, as described in the following. Each simulation (for given parameters values) yields a set of forecasted values $F_{i,r}$. When sufficient number of simulations is performed, one can interpolate the different known values of as function of $[x_1, x_2, x_3]$ using the 3D polynomial in eq. 1 above. The sufficient number is 2N + 0.5N(N - 1) + 1, so that for N=3 the sufficient number of simulations to be performed is 10. Next we discuss the ways to increase the quality and the representativeness of such fit. The following factors are important for the interpolation to be realistic (to be able to replace the COSMO simulations):

- The choice of parameters values (combinations) for COSMO simulations should be specific. In this work the design is chosen according to Bellprat et al. (2012) (see also Khain et al. (2015)). Moreover, one should use as many as possible additional constrain simulations (for additional parameters combinations).
- The simulated COSMO field $F_{i,r}$ should not be noisy as function of the parameters. In other words, the sensitivity of $F_{i,r}$ on the parameters should be higher than the noise level. However, various COSMO fields are noisy for various parameters. That issue was discussed and solved in Khain et al. (2015).
- The time periods i and the regions r should be chosen to represent a meaningful forecast of the field $F_{i,r}$. In that work we have chosen typical periods of 24 hours (maximum and minimum daily temperature, 24h accumulated precipitation, etc.) and climatically distinguishable regions. The choice of the regions will be discussed in sections 4.2.1 and 4.2.2 below.
- It is important to select many meteorological important fields F in order to better reflect the weather conditions. Otherwise there is a danger that the calibration procedure will improve specific fields while degrading the overall skill of the forecast. At CALMO-stages 2 and 3 we have included optimization of meteorological profiles characteristics. That will be discussed in section 4.2.3 below.

- The default values of the parameters should be located close to the center of their allowed ranges. Otherwise, in the empty parameter ranges, the parabolic fit may reach very high (or very low) unrealistic peaks. The problem is, that the default values of rlam_heat, tur_len and entr_sc are significantly shifted from the centers of their allowed ranges: for $[0.1, 1, 10]$, $[100, 500, 10000]$, and $[0.05e-3, 0.3e-3, 2e-3]$, for rlam_heat, tur_len and entr_sc, respectively. That problem will be discussed and solved in section 4.2.4 below.

4.2 Adaptations to the Meta-Model

From CALMO-stage-1 (see Khain et al. (2015)) to CALMO-stages 2 and 3 we have performed several adaptations to the Meta-Model codes.

4.2.1 Option not to average Tmax/Tmin over regions

For observations over Switzerland we use Frei (2014) gridded data after correction to the elevations of model grid points. Over Italy we use the observations interpolated to the model grid (without correction to the elevations of model grid points), while only the grid points in vicinity of the stations get a value. At CALMO-stage-1 we have divided Switzerland area into 3 regions, and averaged the maximum and minimum 2m temperatures (Tmax and Tmin, respectively) and 24h accumulated precipitation (Pr) over these regions, before comparing with observations. While for precipitation, this averaging reduces the noise, for Tmax and Tmin we lost a lot of information. Just for example, Tmax errors at two different grid points can yield no error on average (see Fig. 1).

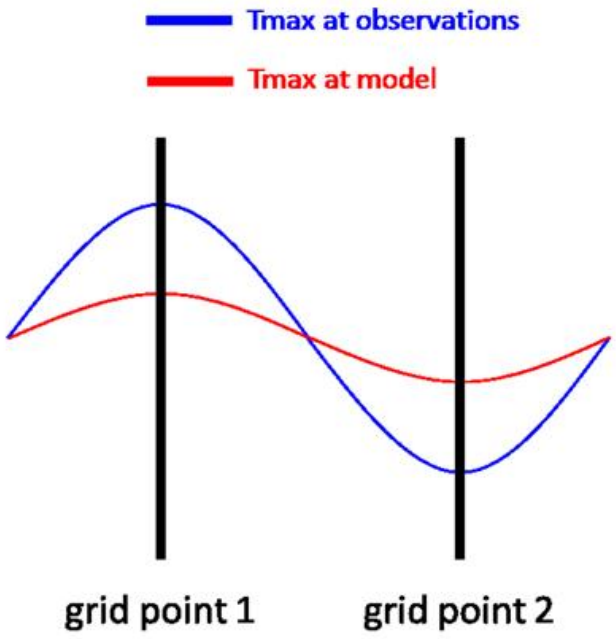

Figure 1: Schematic example for the reason not to average Tmax/Tmin over regions.

Moreover, at CALMO-stages 2 and 3 the Italian data are also analyzed. These data are not gridded (as Swiss ones), so that much less grid points are available for comparison of the model to the observations. In that case, region averaging would be based on much less points than over Switzerland. Therefore at CALMO-stages 2 and 3 we have added

the option (to the Meta-Model code) not to average Tmax and Tmin over regions, but to calculate the Meta-Model forecast for all the available grid-points in model and observations (about $N_{\Psi regs} \approx 10407$ for $\Psi = Tmax$ or $\Psi = Tmin$ for CALMO-stage-2, and similar number for CALMO-stage-3).

4.2.2 Defining new regions for averaging the 24h accumulated precipitation (optional also for Tmax, Tmin)

For observations over Switzerland we use the gridded MeteoSwiss radar composite (corrected by rain gauges) interpolated to the model grid. Over Italy we use the observations interpolated to the model grid, while only the grid points in vicinity of the stations get a value. In order to reduce the noise associated with precipitation fields, the precipitation model and observations values are averaged over $N_{Prregs,mon} = 6$ geographically unique regions, as presented in Fig. 2.

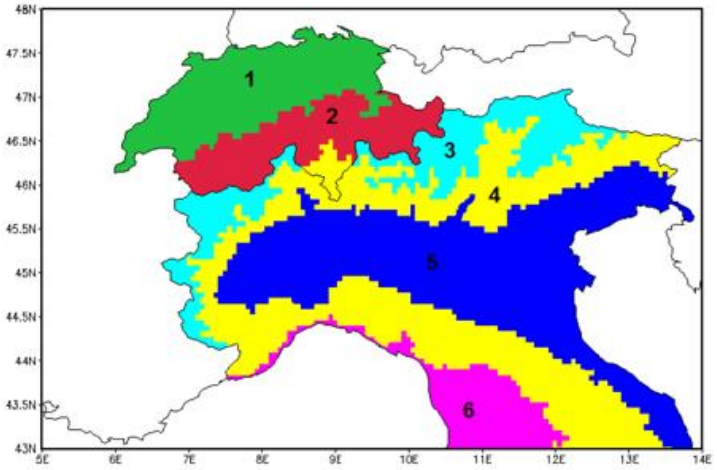

Figure 2: Geographically unique regions for precipitation averaging: 1-green: Swiss plateau (300m<h<1500m); 2-red: Swiss Alps (1500m<h); 3-cyan: Italian Alps (1500m<h); 4-yellow: Italian hills and Ticino (300m<h<1500m); 5-blue: Po Valley (h<300m); 6-magenta: Italian north-west coast (mainly h<300m).

4.2.3 Meta-Model predicts profiles characteristics

At CALMO-stage1 we have used the following fields: Ψ_1 - Daily maximum 2m temperature (Tmax); Ψ_2 - Daily minimum 2m temperature (Tmin); Ψ_3 - 24h accumulated precipitation (Pr). At CALMO-stages 2 and 3 we are using also the soundings data and the associated model profiles (at grid points near the soundings locations). The new verified fields are: Ψ_4 - Convective available potential energy (CAPE); Ψ_5 - Convective inhibition (CIN); Ψ_6 - Total column water vapor (TCWV); Ψ_7 - Vector wind shear between the levels of 500mb and 700mb (WS1); Ψ_8 - Vector wind shear between the levels of 700mb and 850mb (WS2); Ψ_9 - Vector wind shear between the levels of 850mb and 1000mb (WS3); $\Psi_{10,11,12}$ - Temperatures at 500mb (T500), 700mb (T700) and 850mb (T850) respectively; $\Psi_{13,14,15}$ - Relative humidity at 500mb (T500), 700mb (T700) and 850mb (T850) respectively; $\Psi_{16,17,18}$ - East-west wind component at 500mb (U500), 700mb (U700) and 850mb (U850) respectively; $\Psi_{19,20,21}$ - South-north wind component at 500mb (V500), 700mb (V700) and 850mb (V850) respectively. There are 11 available soundings at the CALMO-stages 2 and 3 domains, as presented in Fig. 3.

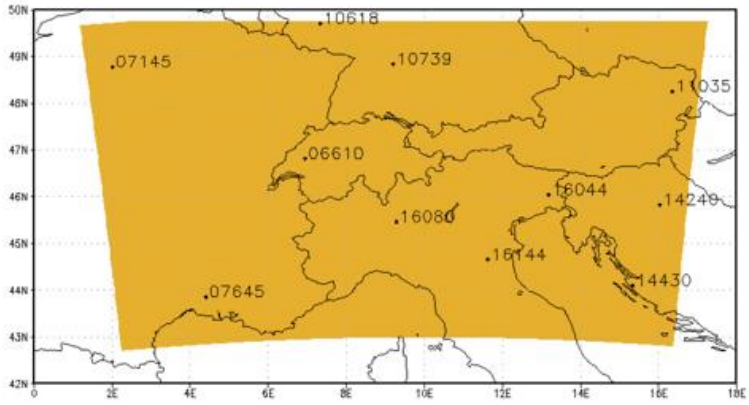

Figure 3: Available soundings inside CALMO-stages 2 and 3 domains.

Most of these soundings available twice per day, yielding about $N_{Prregs,mon} = 20{-}25$ (Ψ=any sounding field) profiles over the domain per day (depends on the sounding report quality).

4.2.4 Logarithmic transformation for some of the parameters

As discussed already in CALMO-stage 1 (Khain et al., 2015), the parabolic fit can accurately represent the dependency of the verified fields in parameters space only if the default values of the parameters are located close to the center of their allowed ranges. Otherwise, in the empty parameter ranges, the parabolic fit may reach very high (or very low) unrealistic peaks. The solution for that problem is transforming the problematic parameter/s to logarithm of the parameter/s. Such transformation brings the far away parameter values closer to the others, eliminating the empty parameter ranges, causing the parabolic fit to be more monotonic. In CALMO-stages 2 and 3, the problematic parameters are tur_len and entr_sc. Recently we have developed a method to objectively transform these parameters to logarithmic space:

$$x \rightarrow \hat{x} \equiv log(\alpha \frac{x - x_{min}}{x_{max} - x_{min}} + \beta).$$

The demand for the transformed default value to be exactly at the center between the minimum and maximum values, i.e. $\hat{x}_{max} - \hat{x}_d \stackrel{!}{=} \hat{x}_d - \hat{x}_{min}$ defines α and β. Applying the procedure yielded $\alpha = 72$, $\beta = 0.25$ for tur_len, and $\alpha = 9500$, $\beta = 210$ for entr_sc.

5 Performance scores

First, we have introduced user defined weights $\omega_{\Psi=1,...,21}$ (any positive numbers) for the contributions of various fields. For the results below, we have set: $\omega_{Tmax} = 1$, $\omega_{Tmin} = 1$, $\omega_{Pr} = 1$, $\omega_{CAPE} = 0$, $\omega_{CIN} = 0$, $\omega_{TCWV} = 1$, $\omega_{WS1} = 0.33$, $\omega_{WS2} = 0.33$, $\omega_{WS3} = 0.33$, $\omega_{T500} = 0.33$, $\omega_{T700} = 0.33$, $\omega_{T850} = 0.33$, $\omega_{RH500} = 0.33$, $\omega_{RH700} = 0.33$, $\omega_{RH850} = 0.33$, $\omega_{U500} = 0.2$, $\omega_{U700} = 0.2$, $\omega_{U850} = 0.2$, $\omega_{V500} = 0.2$, $\omega_{V700} = 0.2$, $\omega_{V850} = 0.2$. The fields CAPE and CIN (both observed and simulated) are generally noisy. Moreover, in the soundings data the number of reports (levels) is usually low, making the calculation of CAPE and CIN highly uncertain. Therefore at this work we set zero weights for these fields: $\omega_{CAPE} = 0$, $\omega_{CIN} = 0$. We have developed 2 optional performance scores for CALMO-stages 2 and 3, which are described below.

5.1 RMSE-type score

In contrast to CALMO-stage1, in stages 2 and 3 the number of regions (or grid-points) for comparing the model with observations very much depends on the forecasted field Ψ (and slightly depends on the month). Therefore the score for parameters combination p takes a more complicated form:

$$S_p = \left\{ \frac{1}{12 \sum_{\Psi=1}^{21} \omega_\Psi} \sum_{\Psi=1}^{21} \omega_\Psi \sum_{mon=1}^{12} \frac{1}{W_{\Psi,mon} N_{\Psi days,mon} N_{\Psi regs,mon}} \sum_{\Psi regs} \left[\frac{\sum_{\Psi days} (F_{\Psi,p,d,r,mon} - O_{\Psi,d,r,mon})^2}{\sigma^2_{\Psi,r,mon}} \right] \right\}^{1/2} \tag{2}$$

Where the fields Ψ_{1-21} where defined at Section 4.2.3 above.

5.1.1 Observations variability is defined per month

The quality of COSMO forecast strongly depends on the region and the season. For example, the forecast with Tmax error of 5K in the Alps at winter may be actually better than with error of 3K in the Swiss Plateau at summer. Therefore one needs to normalize the forecast errors by a value which reflects the forecast complexity for a given day and region. As at CALMO-stage 1, we normalize the forecast field Ψ errors by the observations standard deviation $\sigma_{\Psi,r,mon}$ at a given region (or grid-point) r over a period of a month $N_{\Psi days,mon} \approx 30$ (the period should not be too short in order to contain large enough sample, but not too long in order to represent the variability of a specific season):

$$\sigma_{\Psi,r,mon} = \sqrt{\frac{1}{N_{\Psi days,mon}} \sum_{\Psi days} (O_{\Psi,d,r,mon} - \overline{O}_{\Psi,d,r,mon})^2} \tag{3}$$

5.1.2 Normalization weights

Normalization weights are defined to set equal contributions for the various fields (N_p = 10000 - number of parameters combinations):

$$W_{\Psi,mon} = \frac{1}{N_p} \sum_{p=1}^{N_p} \frac{1}{N_{\Psi days,mon} N_{\Psi regs,mon}} \sum_{\Psi regs} \left[\frac{\sum_{\Psi days} (F_{\Psi,p,d,r,mon} - O_{\Psi,d,r,mon})^2}{\sigma^2_{\Psi,r,mon}} \right] \tag{4}$$

5.2 COSI-type score

The COSMO Index (COSI) was developed by Damrath (2009). We have adapted the score for CALMO use as following:

$$S_p = \frac{1}{12 \sum_{\Psi=1}^{18} \omega_\Psi} \left\{ \sum_{\Psi \neq 3} \omega_\Psi \sum_{mon=1}^{12} \left[1 - \frac{\sum_{\Psi regs} \sum_{\Psi days} (F_{\Psi,p,d,r,mon} - O_{\Psi,d,r,mon})^2}{\sum_{\Psi regs} \sum_{\Psi days} (O_{\Psi,d-1,r,mon} - O_{\Psi,d,r,mon})^2} \right] + \omega_3 \frac{\sum_{mon=1}^{12} \sum_{\Psi regs} \sum_{\Psi thr} ETS_{p,r,mon,thr}}{N_{\Psi days,mon} N_{\Psi regs,mon}} \right\} \tag{5}$$

where -1/3<ETS<1 (1 is the best) is the threshold dependent (we have chosen region averaged precipitation amounts thresholds of 0.1,1,3,7.5,10mm per 24h) precipitation score:

$$ETS_{p,r,mon,thresh} = \frac{H - \frac{(H+F)(H+M)}{N_{\Psi regs,mon}}}{H + M + F - \frac{(H+F)(H+M)}{N_{\Psi regs,mon}}} \tag{6}$$

where: H - Number of hits (i.e. both the model and the observations where above the given threshold); F - Number of false alarms; M - Number of misses.

6 Convergence to the optimal parameters combination

6.1 Method

After the Meta-Model is constructed we divide the parameters space into high number of points (parameters combinations), and calculate the score (see section 5) for each of the points in order to find the optimal one. In CALMO-stage 1, we have tuned 3 parameters, dividing the parameters space into 10000 points, i.e. roughly 21 bins for each of the parameters. In CALMO-stage 2, for example, the number of calibrated parameters is N=6, yielding huge number (about $21^6 \approx 10^8$) of points to be evaluated in order to find the optimal one. However, for computer time reasons it is not possible. Recently we have developed a method to overcome that problem and converge to the optimal parameters combination. At first iteration we sample 1000 points only and reveal the optimal regions in our N dimensional parameters space (according the uncertainty of the optimal 100 combinations). An example of the convergence after first iteration is presented in Fig. 4 below.

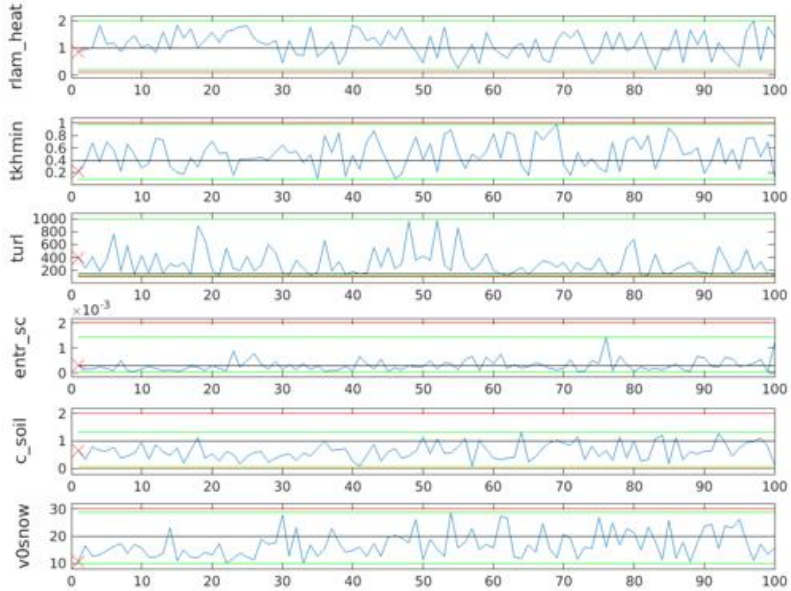

Figure 4: Example of convergence after first iteration. Each panel shows (in blue) the optimal 100 parameters values (in sorted order) among 1000 sampled combinations. The red lines represent the allowed ranges for each parameter, the green lines represent the uncertainty for each parameter after first iteration (following the optimal 100 values). Red crosses represent the best parameters combination after first iteration.

At second iteration we sample those regions (between the green lines in Fig. 4) by additional 1000 points, and reveal new, smaller, optimal regions (again according the uncertainty of the new optimal 100 combinations). We continue with these iterations until the solution converges to the optimal parameters combination. An example of the converged stage is presented in Fig. 5 below.

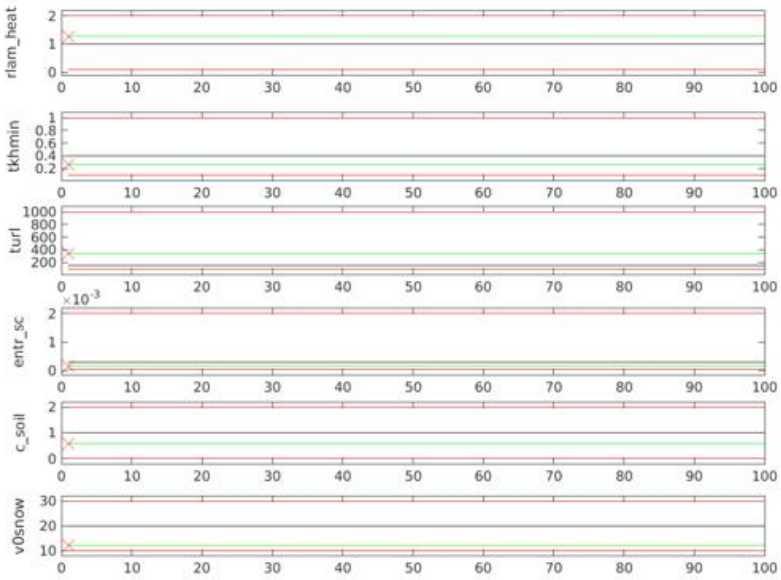

Figure 5: Example of convergence after last (35th) iteration.

6.2 Uncertainty of the optimal parameters combination

A question arises what is the uncertainty of the optimal parameters combination? In other words, what is the score sensitivity when slightly changing the parameters values with respect to the optimal parameters combination? To answer this question, we have followed the procedure described above, and determined the iteration at which the score reaches 90% of the optimal combination score. We define the parameters uncertainty (between the green lines in Fig. 4, for example) at that iteration as the uncertainty of the optimal parameters combination.

7 TERRA stand-alone

As part of CALMO-stages 2 and 3, among other parameters it was planned to tune also soil-scheme (TERRA) parameters (for example the hydraulic soil conductivity). In contrast to the regular COSMO parameters, the change in Terra parameters affects the COSMO forecasts with a significant delay (up to several years) via slow adaptation of the soil temperature and moisture profiles. Therefore, in order to tune TERRA parameters for specific year, one has to make the parameter changes several years earlier, and run the COSMO model in a cycle, slowly adapting the soil profiles to the parameter change. Moreover, errors in soil profiles caused by interpolation of soil fields from a coarse model disappear slowly, also on the scale of several years. Therefore, in order to obtain appropriate initial conditions in the soil (without interpolation errors), one again has to make the interpolation of soil fields several years earlier, and run the COSMO model in a cycle, slowly forgetting the interpolation errors. However, performing several years pre-run of the COSMO model (in a cycle mode)

is computationally expensive. Instead, it was decided to use the TERRA stand-alone (TSA) program driven by COSMO atmospheric analyses (from MeteoSwiss archive). The method was to initialize soil profiles from a coarse model interpolation, change the parameters of TSA (if needed), and run it for several years (prior to the tested year). Then, the obtained soil profiles were installed as initial soil conditions for the COSMO model runs (for the tested year). With we have run TSA for 3 years (2010-2012) with resolutions of 2.2 and 1.1 km, and prepared the soil initial conditions for the COSMO runs at 2013.

8 CALMO stage-2

8.1 Validation of CALMO stage-2 Meta-Model using arbitrary test simulation

In order to validate the Meta-Model quality, additional test simulation was performed for an arbitrary parameters combination [rlam_heat=1.24, tkmmin=0.233, tur_len=363.9, entr_sc=0.000267, c_soil=0.492 and v0snow=12.1], which was not used for building the Meta-Model. That allows comparing the Meta-Model prediction for this specific parameters combination with the real simulation results, over the entire 2013. Figs. 6-9 show scatter plots for maximum daily 2m-temperature (Tmax), minimum daily 2m-temperature (Tmin), 24h accumulated precipitation (Pr), and column integrated water vapor (TCWC), respectively. The y-axes show the Meta-Model estimation with respect to the reference (simulation with default parameters values), while the x-axes show the COSMO simulation results with respect to the reference. For Tmax and Tmin, each point represents grid-point comparison (according method IV as explained in section 8.2 below). For Pr each point represents regions averages. For TCWC each point represents a profile in one of the radiosondes locations.

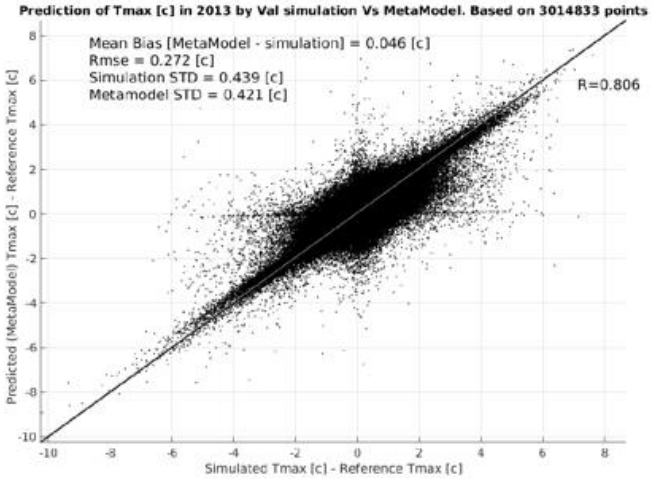

Figure 6: Tmax Meta-Model prediction for the tested parameter combination, vs COSMO simulation results during the year 2013. X axis presents the simulated Tmax minus the reference simulation. Y axis presents the Meta-Model Tmax minus the reference simulation.

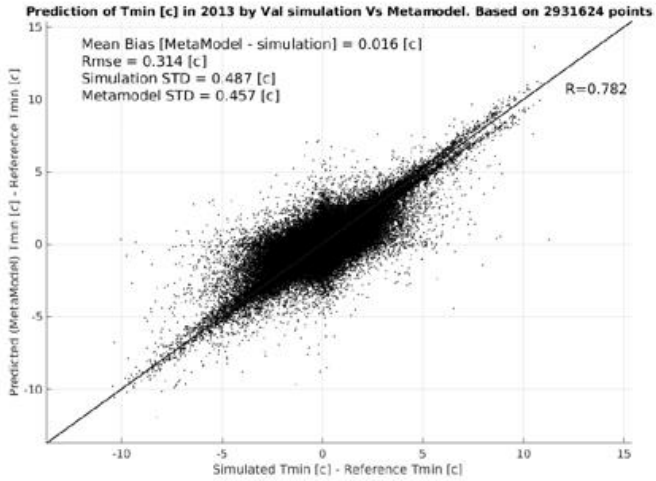

Figure 7: Tmin Meta-Model prediction for the tested parameter combination, vs COSMO simulation results during the year 2013. X axis presents the simulated Tmin minus the reference simulation. Y axis presents the Meta-Model Tmin minus the reference simulation.

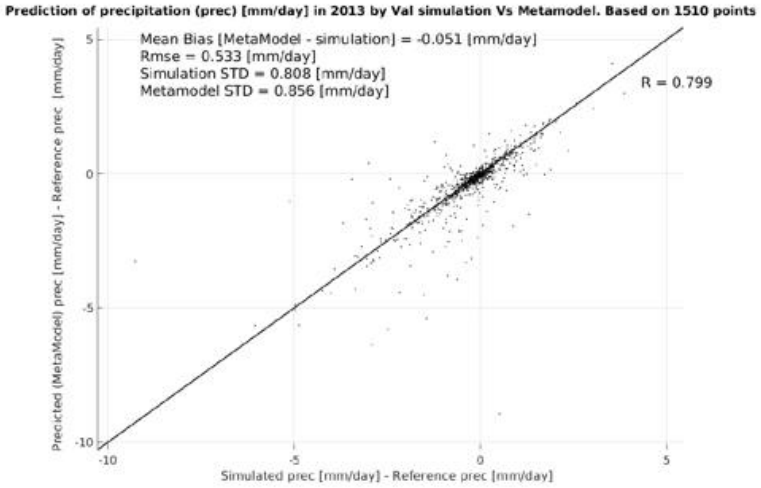

Figure 8: Pr Meta-Model prediction for the tested parameter combination, vs COSMO simulation results during the year 2013. X axis presents the simulated Pr minus the reference simulation. Y axis presents the Meta-Model Pr minus the reference simulation.

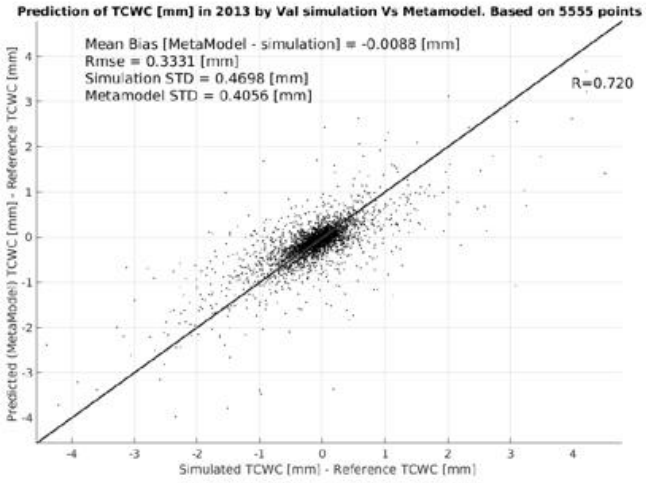

Figure 9: TCWC Meta-Model prediction for the tested parameter combination, vs COSMO simulation results during the year 2013. X axis presents the simulated TCWC minus the reference simulation. Y axis presents the Meta-Model TCWC minus the reference simulation.

Important to mention, that only one point (one parameters combination) in 6-dimensional parameters space was analyzed, so that correlations presented in Figs. 6-9 are not necessarily represent other possible parameters combinations. However, for the tested parameter combination, the correlations R between the COSMO forecasts and the Meta-Model estimations are generally high. Consequently, the overall method seems to prove itself: one can use the Meta-Model to reproduce COSMO forecasts for various parameters combinations.

8.2 Calibration results for entire year 2013

The calibration was performed using 4 different methods:

I Averaging Tmax and Tmin over regions (see Section 4.2.1 above), using RMSE-type score;

II Not averaging Tmax and Tmin over regions, using RMSE-type score;

III Averaging Tmax and Tmin over regions, using or the COSI score;

IV Not averaging Tmax and Tmin over regions, using the COSI score.

We have used the Meta-Model to calculate the overall score S_p (either RMSE-type (eq. 2) or COSI (eq. 5)) for any given parameters combination. Figs. 10-13 present the contours of S_p deviation, i.e. $S_p - \overline{S}_p$, for pairwise parameters combinations only, for the methods I,II,III,IV, respectively. Note that for RMSE-type score lower $S_p - \overline{S}_p$ means better parameters combination, while for COSI score, higher $S_p - \overline{S}_p$ is better. One can see that the optimal parameters regions are similar, regardless the method we used.

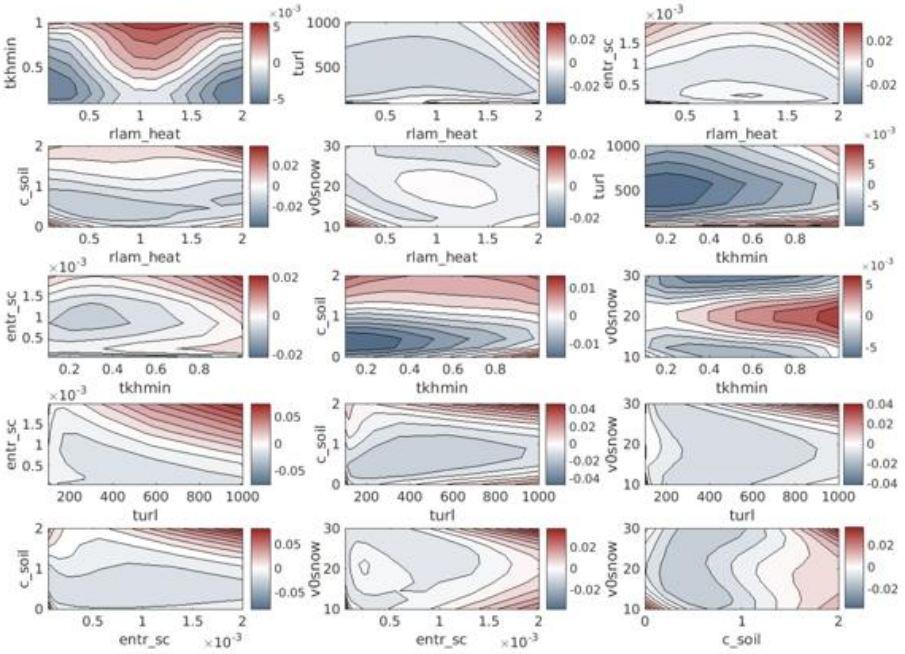

Figure 10: Method I - Contours of score deviation $S_p - \overline{S}_p$ (eq. 2), for pairwise parameters combinations. Lower $S_p - \overline{S}_p$ areas represent better parameters combinations.

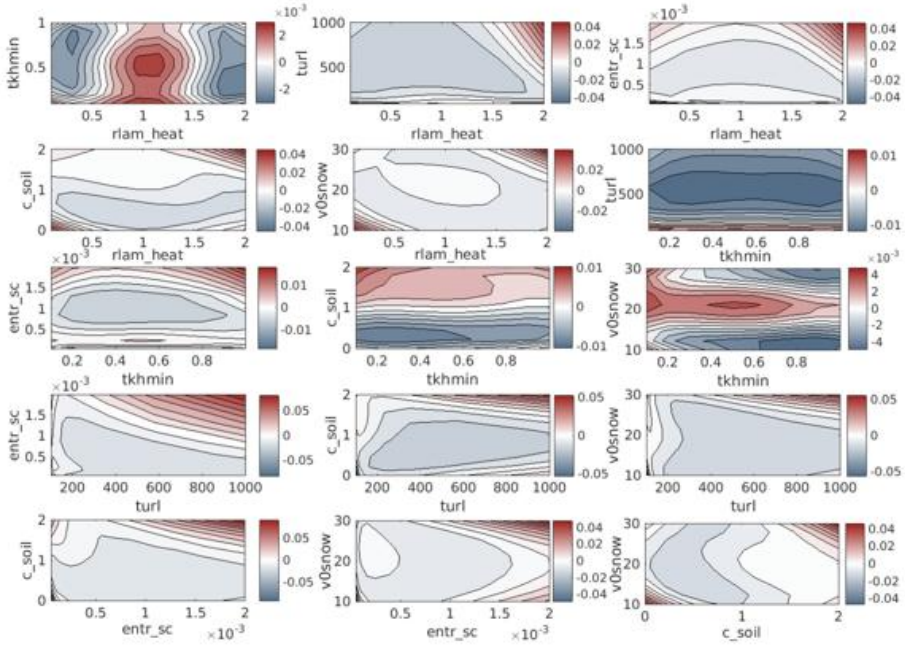

Figure 11: Method II - Contours of score deviation $S_p - \overline{S}_p$ (eq. 2), for pairwise parameters combinations. Lower $S_p - \overline{S}_p$ areas represent better parameters combinations.

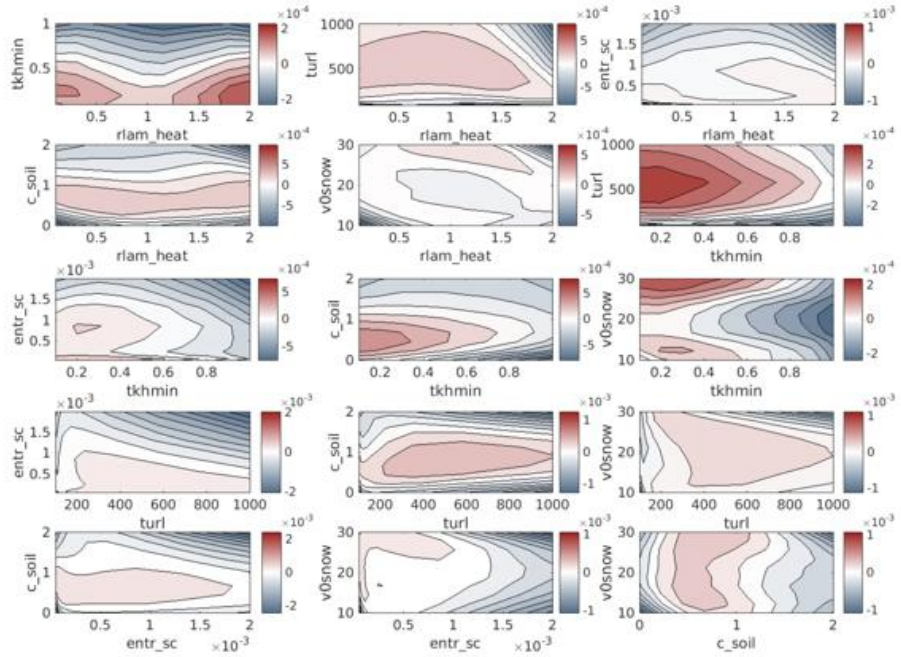

Figure 12: Method III - Contours of score deviation $S_p - \overline{S}_p$ (eq. 5), for pairwise parameters combinations. Lower $S_p - \overline{S}_p$ areas represent better parameters combinations.

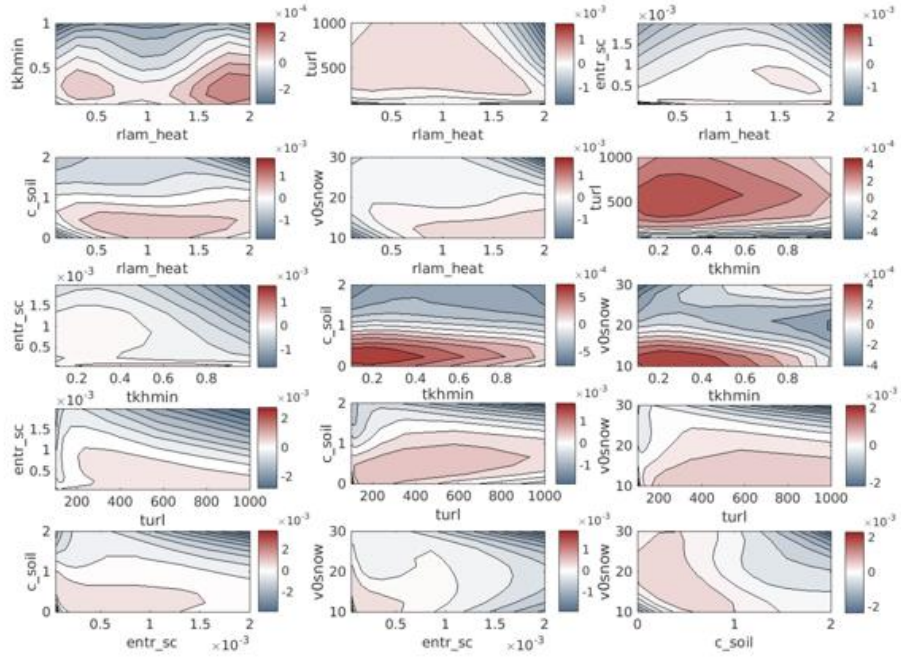

Figure 13: Method IV - Contours of score deviation $S_p - \overline{S}_p$ (eq. 5), for pairwise parameters combinations. Lower $S_p - \overline{S}_p$ areas represent better parameters combinations.

Figs. 14-15 present S_p scores distributions after first and last iterations, respectively (see Section 6 above), together with the score of the reference (REF) simulation, for methods I-IV.

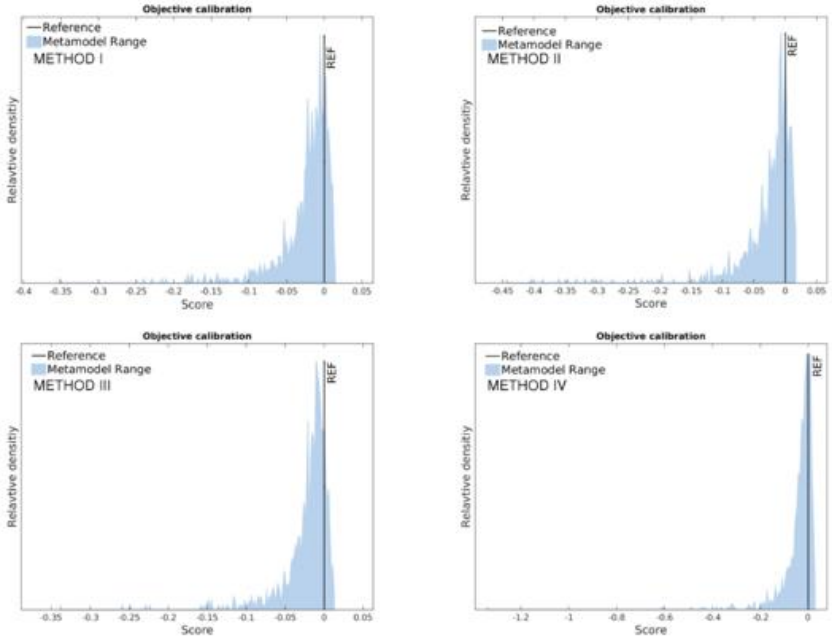

Figure 14: S_p scores distributions after **first** iteration, together with the score of the reference (REF) simulation, for methods I-IV. For convenience, the distributions are presented as function of $\widetilde{S}_p = 1 - S_p/S_{p,REF}$ for methods I, II and as function of $\widetilde{S}_p = S_p/S_{p,REF} - 1$ for methods III, IV. Therefore higher $\widetilde{S}_p > 0$ means better score with respect to the REF simulation.

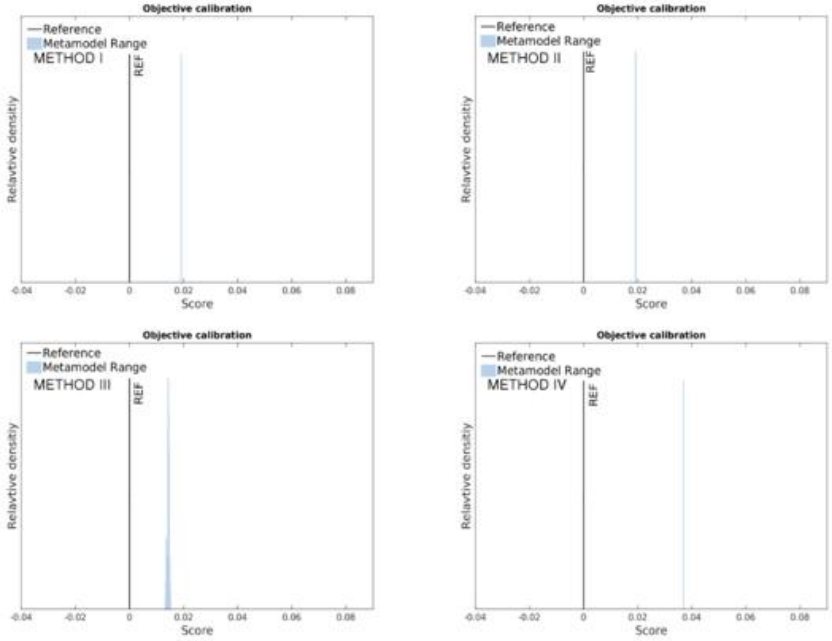

Figure 15: S_p scores distributions after **last** iteration, together with the score of the reference (REF) simulation, for methods I-IV. For convenience, the distributions are presented as function of $\widetilde{S}_p = 1 - S_p/S_{p,REF}$ for methods I, II and as function of $\widetilde{S}_p = S_p/S_{p,REF} - 1$ for methods III, IV. Therefore higher $\widetilde{S}_p > 0$ means better score with respect to the REF simulation.

Tables 3 and 4 present the optimal parameters combinations, as well as their uncertainties (see section 6.2) for the methods I-IV described above:

Method	rlam_heat	Tkhmin	tur_len
I	0.724 **0.835** 0.942 [-5.8% +5.6%]	0.179 **0.229** 0.282 [-5.6% +5.9%]	268.0 **309.3** 347.3 [-4.6% +4.2%]
II	0.836 **0.964** 1.077 [-6.7% +5.9%]	0.316 **0.372** 0.442 [-6.3% +7.8%]	390.2 **437.4** 503.9 [-5.2% +7.4%]
III*	**1.009**	**0.155**	**422.3**
IV	1.149 **1.273** 1.390 [-6.5% +6.2%]	0.205 **0.266** 0.351 [-6.8% +9.4%]	294.6 **346.5** 409.9 [-5.8% +7.0%]

Table 3: Optimal parameters combinations and their uncertainties for methods I-IV. *For method III there was no complete convergence to the optimal parameters combination, so the uncertainties are not presented.

Method	entr_sc (10^{-4})	c_soil	v0snow
I	0.643 **0.731** 0.866 [-4.5% +6.9%]	0.623 **0.681** 0.733 [-2.9% +2.6%]	18.7 **19.9** 21.2 [-6.0% +6.5%]
II	0.796 **0.798** 0.938 [-0.01% +0.7%]	0.679 **0.725** 0.760 [-2.3% 1.8%]	17.1 **18.5** 19.3 [-7.0% +4.0%]
III*	**0.832**	**0.735**	**18.8**
IV	1.261 **1.607** 2.104 [-1.8% +2.5%]	0.515 **0.588** 0.664 [-3.7% +3.8%]	11.6 **12.3** 13.3 [-3.5% +5.0%]

Table 4: Optimal parameters combinations and their uncertainties for methods I-IV. *For method III there was no complete convergence to the optimal parameters combination, so the uncertainties are not presented.

Assuming method IV as the most reasonable, the final optimal parameters combination with its uncertainty is:

- rlam_heat=1.273 instead of the default 1.0. Uncertainty: [1.149 1.390];
- tkhmin=0.266 instead of the default 0.4; Uncertainty: [0.205 0.351];
- tur_len=346.5 instead of the default 150; Uncertainty: [294.6 409.9];
- entr_sc=0.0001607 instead of the default 0.003; Uncertainty: [0.0001261 0.0002104];
- c_soil=0.588 instead of the default 1.0; Uncertainty: [0.515 0.664];
- v0snow=12.3 instead of the default 20; Uncertainty: [11.6 13.3].

8.3 Calibration results - seasonal dependence

In this section we analyzed the seasonal dependence of the optimal parameters combination during 2013. For that purpose we have performed parameters calibration for summer 2013 (Jul, Aug and Sep) and winter 2013 (Jan, Feb and Mar), separately. The results for the optimal parameters combinations, as well as their uncertainties are presented in Tables 5-6.

Cases	rlam_heat	Tkhmin	tur_len
Entire 2013	1.149 **1.273** 1.390 [-6.5% +6.2%]	0.205 **0.266** 0.351 [-6.8% +9.4%]	294.6 **346.5** 409.9 [-5.8% +7.0%]
Summer 2013	0.954 **1.071** 1.164 [-6.2% +4.9%]	0.186 **0.221** 0.270 [-3.9% +5.4%]	352.2 **357.5** 398.9 [-0.6% +4.6%]
Winter 2013	0.982 **1.112** 1.232 [-6.8% +6.3%]	0.791 **0.891** 0.929 [-11.1% +4.2%]	109.8 **117.2** 127.9 [-0.8% +1.2%]

Table 5: CALMO stage-2 optimal parameters combinations, as well as their uncertainties for method IV for the following cases: all months in 2013, summer 2013 (Jul, Aug and Sep) and winter 2013 (Jan, Feb and Mar).

Cases	entr_sc (10^{-4})	c_soil	v0snow
Entire 2013	1.261 **1.607** 2.104 [-1.8% +2.5%]	0.515 **0.588** 0.664 [-3.7% +3.8%]	11.6 **12.3** 13.3 [-3.5% +5.0%]
Summer 2013	4.439 **4.890** 5.495 [-2.3% +3.1%]	1.090 **1.150** 1.205 [-3.0% +2.8%]	20.2 **21.2** 22.3 [-5.5% +5.0%]
Winter 2013	1.387 **1.714** 2.076 [-1.7% +1.9%]	0.0 **0.041** 0.134 [-2.1% +4.7%]	29.2 **30.0** 30.0 [-4.0% +0.0%]

Table 6: CALMO stage-2 optimal parameters combinations, as well as their uncertainties for method IV for the following cases: all months in 2013, summer 2013 (Jul, Aug and Sep) and winter 2013 (Jan, Feb and Mar).

One can see significant differences at the optimal parameters combinations for summer and winter. This fact reflects different biases of atmospheric fields between the seasons (see for example the first CALMO progress report (Khain et al., 2015)). However, figuring out the atmospheric fields responsible for this behavior is beyond the scope of this report.

9 CALMO stage-3

9.1 Calibration results for January 2013

CALMO-stage-3 calibration was performed using method IV, i.e. not averaging Tmax and Tmin over regions, using the COSI score. As can be seen in Table 1, at that stage we have tuned 5 parameters: tkhmin, tur_len, entr_sc, c_soil, crsmin, for the period 1/1/2013 1/2/2013. As at CALMO-stage 2, we have used the Meta-Model to calculate the overall COSI score S_p (eq. 5) for any given parameters combination. Before presenting the results for the optimal 5-parameters combination, we first investigate the importance of each of the 5 parameters. This is done by performing the calibration several times, each time excluding one of the parameters. Figs. 16-20 present the contours of deviation, i.e. $S_p - \overline{S}_p$ (higher $S_p - \overline{S}_p$ is better), for pairwise parameters combinations only, in the following order:

- Case 1: Tuning parameters tkhmin, tur_len, entr_sc, c_soil (excluding crsmin) see Fig. 16;
- Case 2: Tuning parameters tkhmin, tur_len, entr_sc, crsmin (excluding c_soil) see Fig. 17;

- Case 3: Tuning parameters tkhmin, tur_len, c_soil, crsmin (excluding entr_sc) see Fig. 18;
- Case 4: Tuning parameters tkhmin, entr_sc, c_soil, crsmin (excluding tur_len) see Fig. 19;
- Case 5: Tuning parameters tur_len, entr_sc, c_soil, crsmin (excluding tkhmin) see Fig. 20.

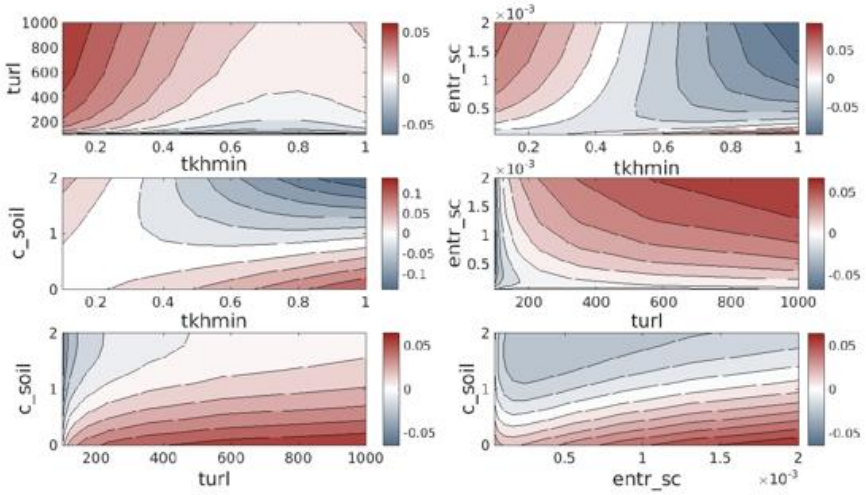

Figure 16: Contours of score deviation for method IV (eq. 5), for pairwise parameters combinations. Higher $S_p - \overline{S}_p$ areas represent better parameters combinations. The tuning is performed for parameters tkhmin, tur_len, entr_sc, c_soil (excluding crsmin) - case 1. Period: 1/1/2013-6/2/2013.

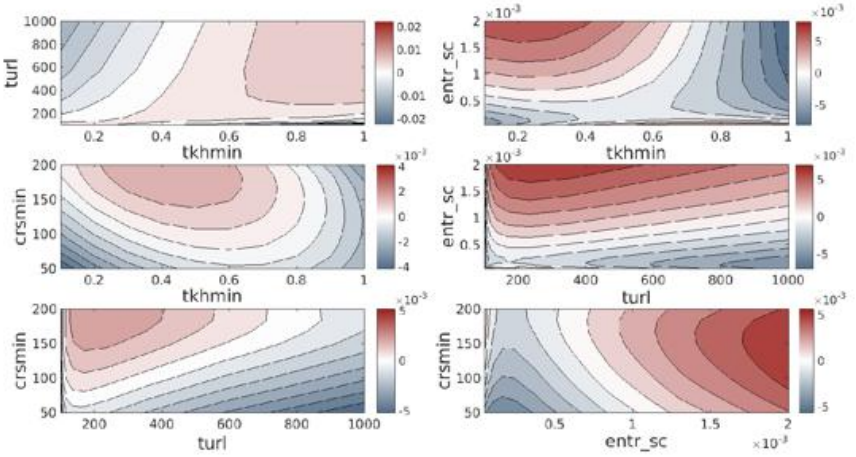

Figure 17: Contours of score deviation for method IV (eq. 5), for pairwise parameters combinations. Higher $S_p - \overline{S}_p$ areas represent better parameters combinations. The tuning is performed for parameters tkhmin, tur_len, entr_sc, crsmin (excluding c_soil) - case 2. Period: 1/1/2013-1/2/2013.

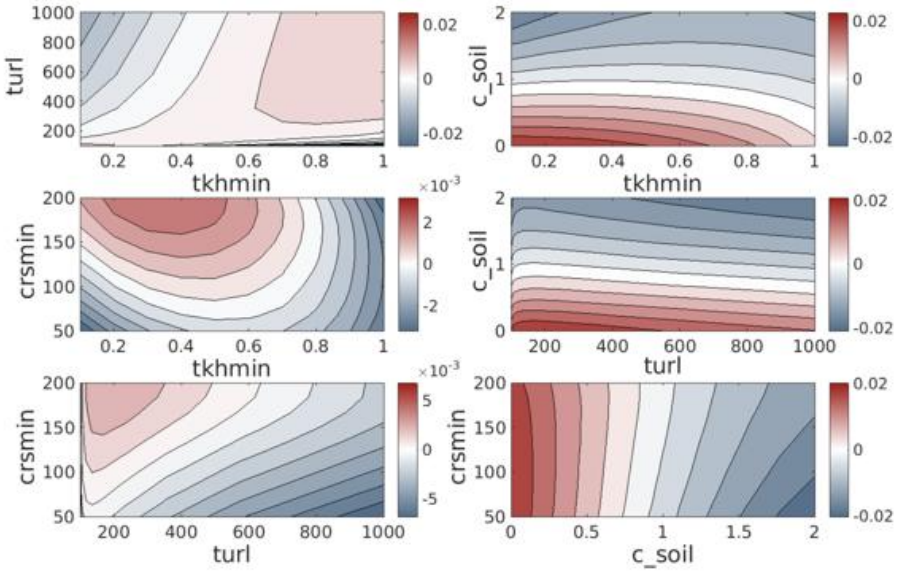

Figure 18: Contours of score deviation for method IV (eq. 5), for pairwise parameters combinations. Higher $S_p - \overline{S}_p$ areas represent better parameters combinations. The tuning is performed for parameters tkhmin, tur_len, c_soil , crsmin (excluding entr_sc) - case 3. Period: 1/1/2013-1/2/2013.

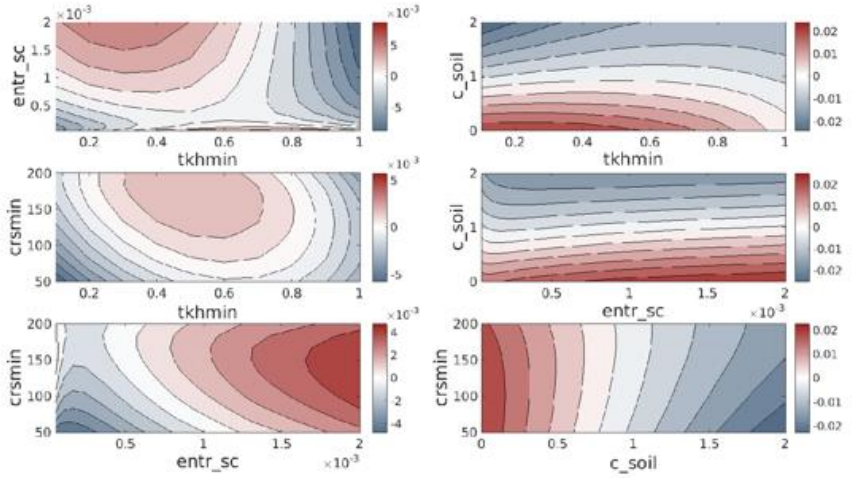

Figure 19: Contours of score deviation for method IV (eq. 5), for pairwise parameters combinations. Higher $S_p - \overline{S}_p$ areas represent better parameters combinations. The tuning is performed for parameters tkhmin, entr_sc, c_soil , crsmin (excluding tur_len) - case 4. Period: 1/1/2013-3/2/2013.

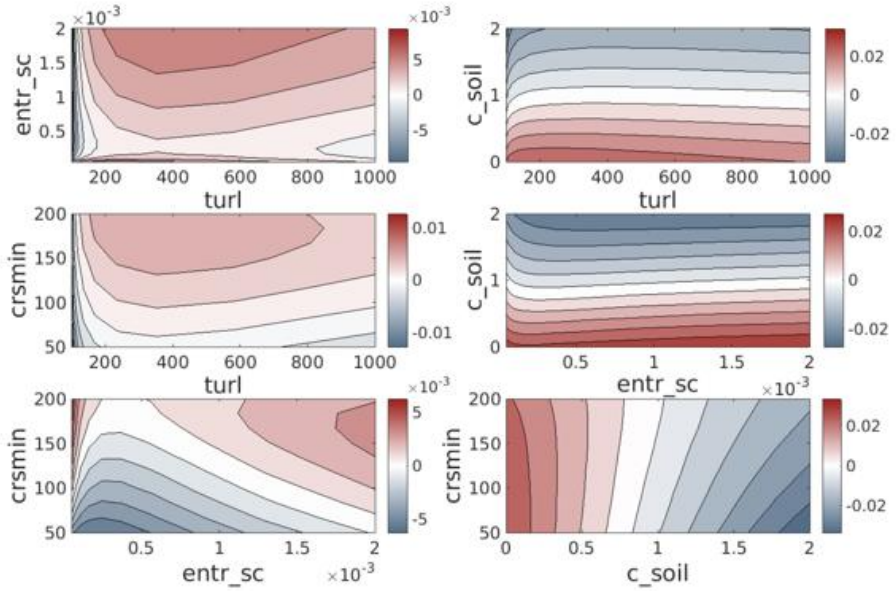

Figure 20: Contours of score deviation for method IV (eq. 5), for pairwise parameters combinations. Higher $S_p - \overline{S}_p$ areas represent better parameters combinations. The tuning is performed for parameters tur_len, entr_sc, c_soil , crsmin (excluding tkhmin) - case 5. Period: 1/1/2013-1/2/2013.

As can be seen from Figs. 16-20, the optimal and worst areas in parameters space differ between the 5 cases. This can be explained by an importance of parameters interactions (fourth term in eq. 1) with respect to the first order parameters variation (third term in eq. 1). However, the main reason for such behavior can be too small sample (for example, only 48% of the regions were rainy during the 32 days period). Following the analysis above, we have performed the calibration taking into account all the 5 parameters tkhmin, tur_len, entr_sc, c_soil, crsmin. Fig. 21 presents the contours of S_p deviation, i.e. $S_p - \overline{S}_p$ (higher $S_p - \overline{S}_p$ is better), for pairwise parameters combinations only.

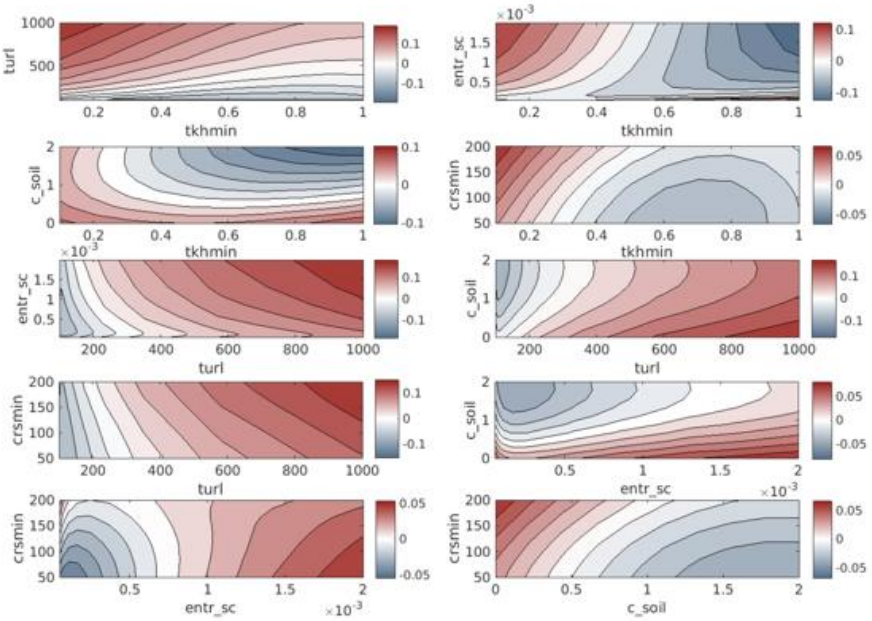

Figure 21: Contours of score deviation for method IV (eq. 5), for pairwise parameters combinations. Higher $S_p - \overline{S}_p$ areas represent better parameters combinations. The tuning is performed for all the 5 parameters tkhmin, tur_len, entr_sc, c_soil, crsmin. Period: 1/1/2013-1/2/2013.

Fig. 22 presents S_p scores distributions after first (left panel) and last (right panel) iterations, together with the score of the reference (REF) simulation.

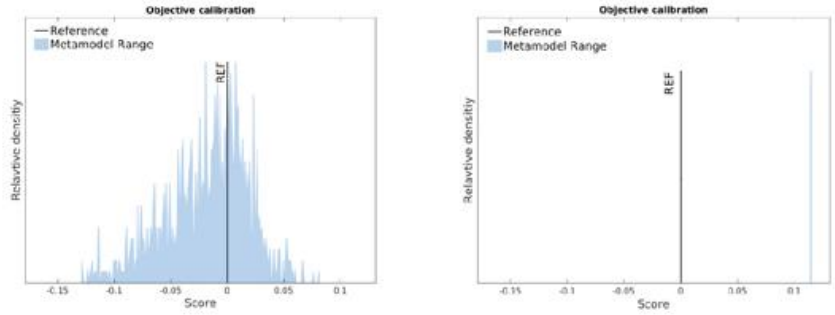

Figure 22: S_p scores distributions after **first** iteration (left) and **last** iteration (right), together with the scores of the reference (REF) simulation. For convenience, the distributions are presented as function of $\widetilde{S}_p = S_p/S_{p,REF} - 1$. Higher $\widetilde{S}_p > 0$ means better score with respect to the REF simulation.

Table 7 presents the optimal parameters combinations, as well as their uncertainties (see section 6.2), when calibrating 4 parameters (eliminating one parameter each time according cases 1-5 described above) and for the full calibration analysis, tuning all the 5 parameters:

Cases	tkhmin	tur_len	entr_sc (10^{-4})	c_soil	crsmin
1	0.986 **1.000** 1.000 [0.0% +1.6%]	100.0 **100.0** 101.0 [-0% +0.1%]	18.0 **20.0** 20.0 [1.0% +0.0%]	1.957 **2.000** 2.000 [2.0% +0.0%]	———
2	0.988 **1.000** 1.000 [-1.3% +0%]	100.0 **100.0** 100.2 [-0% +1.9%]	7.401 **8.985** 9.012 [-8.1% +0.1%]	———	150.1 **171.2** 171.6 [-8.4% +0.2%]
3*	**0.101**	**815.2**	———	**1.793**	**60.0**
4	0.100 **0.100** 0.111 [-0.0% +1.2%]	———	0.702 **0.704** 0.904 [-0.01% +1.0%]	1.978 **2.000** 2.000 [-1.1% +0%]	50.0 **50.0** 54.2 [-0.0% +1.7%]
5	———	100.0 **100.0** 100.3 [0.0% +0.03%]	4.284 **20.0** 20.0 [-8.1% +0.0%]	1.971 **2.000** 2.000 [-1.5% +0%]	50.0 **50.0** 54.3 [-0.0% +1.7%]
all 5 par.	0.983 **1.000** 1.000 [-1.9% +0.0%]	104.3 **109.3** 117.2 [-0.6% +0.9%]	18.0 **20.0** 20.0 [-10.3% +0.0%]	1.937 **2.000** 2.000 [-3.2% +0.0%]	186.3 **200.0** 200.0 [-5.5% +0.0%]

Table 7: Optimal parameters combinations and their uncertainties. *For case 3 there was no complete convergence to the optimal parameters combination, so the uncertainties are not presented

Taking into account the uncertainties using also cases 1-5, the final optimal parameters combination (with its uncertainty) is:

- tkhmin=**1** instead of the default 0.4; Uncertainty: [0.983 1];
- tur_len=**109.3** instead of the default 150; Uncertainty: [104.3 117.2];
- entr_sc=**0.002** instead of the default 0.003; Uncertainty: [0.0018 0.002];
- c_soil=**2** instead of the default 1.0; Uncertainty: [1.937 2];
- crsmin=**200** instead of the default 150; Uncertainty: [186.3 200].

One can see, that all the five parameters get their optimal values on the edges of their allowed ranges. As mentioned before, that can be explained by short calibration period i.e. too small sample (for example, only 48% of the regions were rainy during the 32 days period). In addition, more simulations have to be performed to validate the results. In CALMO-stage-3 only one interaction simulation was performed (in addition to the minimum required), while in CALMO-stage-2 13 additional interaction simulations were performed.

9.2 CALMO-2km vs CALMO-1km optimal parameters for January 2013

At this section we addressed the question does the optimal parameters combination changes with the model resolution, or more specifically, from CALMO-2km to CALMO-1km? As CALMO-1km results are available for January 2013 only, we have calibrated the parameters for CALMO-2km again but this time for January 2013. Tables 8 and 9 presents the CALMO-2km (Stage-2) and CALMO-1km (Stage-3) optimal parameters combinations, as well as their uncertainties for January 2013.

CALMO Stage	rlam_heat	Tkhmin	tur_len
Stage-2 Entire 2013	1.149 1.273 1.390 [-6.5% +6.2%]	0.205 0.266 0.351 [-6.8% +9.4%]	294.6 346.5 409.9 [-5.8% +7.0%]
Stage-2 Jan 2013	0.845 0.935 1.002 [-4.7% +3.5%]	0.191 0.220 0.262 [-3.2% +4.7%]	559.8 653.3 753.0 [-10.4% +11.1%]
Stage-3 Jan 2013	Default value*	0.983 1.000 1.000 [-1.9% +0.0%]	104.3 109.3 117.2 [-0.6% +0.9%]

Table 8: CALMO-2km (Stage-2) and CALMO-1km (Stage-3) optimal parameters combinations, as well as their uncertainties for method IV for January 2013 (in comparison with CALMO-2km for entire 2013 in the first row). *Note that in CALMO-1km the calibrated parameters are 'tkhmin', 'tur_len', 'entr_sc', 'c_soil' and 'crsmin'

CALMO Stage	entr_sc (10^{-4})	c_soil	v0snow
Stage-2 Entire 2013	1.261 1.607 2.104 [-1.8% +2.5%]	0.515 0.588 0.664 [-3.7% +3.8%]	11.6 12.3 13.3 [-3.5% +5.0%]
Stage-2 Jan 2013	2.346 2.764 3.242 [-2.1% +2.5%]	0.653 0.756 0.841 [-5.2% +4.3%]	11.2 11.8 12.3 [-3.0% +2.5%]
Stage-3 Jan 2013	18.0 20.0 20.0 [-10.3% +0.0%]	1.937 2.000 2.000 [-3.2% +0.0%]	Default value*

Table 9: CALMO-2km (Stage-2) and CALMO-1km (Stage-3) optimal parameters combinations, as well as their uncertainties for method IV for January 2013 (in comparison with CALMO-2km for entire 2013 in the first row). *Note that in CALMO-1km the calibrated parameters are ' tkhmin', 'tur_len', 'entr_sc', 'c_soil' and 'crsmin'

As can be seen from Tables 8 and 9, the optimal parameters for CALMO-2km and CALMO-1km are completely different. We see 4 possible reasons for that:

- The results are not statistically significant due to short calibration period (one month only).
- Different parameters combinations were analyzed in stages-2 and 3. In stage-2 we have tuned the combination of rlam_heat, tkhmin, tur_len, entr_sc, c_soil and v0snow while in stage-1 we have tuned the combination of tkhmin, tur_len, entr_sc, c_soil and crsmin. Parameters interactions might be significant, so that tuning part of parameters keeping others default is different from tuning them all together. Therefore we cannot state that the comparison performed in table 6 is a clean experiment.
- CALMO stage-2 and stage-1 simulations were performed in different ways. Stage-2 runs were initialized every 24 hours, while in stage-1 we have initialized the runs once at 1/1/2013 (using Terra-Standalone pre-runs), and performed single long runs keeping the soil memory. This soil memory may have a big influence on the model forecasts and the optimal parameters combinations.
- Physical reasons related to the change in resolution from 2.2km (stage-2) to 1.1km (stage-1) are probably significant, but at that stage we cannot state how much.

10 Summary

The CALMO project has several important achievements. In general, we have proved that the CALMO calibration method allows tuning parameters of NWP model. In order to adapt

the calibration method of Bellprat et al (2012) to NWP model, we have significantly improved the Meta-Model codes. The main developments are listed below:

- added the option not to average 2m-temperature over regions;
- added prediction of profiles characteristics;
- added quality control to the observed and simulated fields;
- added clever interpolation of observed 2m-temperature fields to the model grid;
- developed the RMSE-type and COSI scores;
- developed new method for logarithmic transformation for selected parameters;
- developed a method to converge to optimal parameters combination in huge N-dimensional parameters space;
- analyzed the uncertainty of the optimal parameters combination.

These new developments, mainly in the Meta-Model, performance score and the optimization algorithm (sections 4, 5, 6 above and Khain et al. (2015)) highly increased the reliability of the calibration results. As part of the CALMO project, we have calibrated the COSMO model in resolutions of 7km, 2.2km and 1.1km. For 2.2km and 1.1km resolutions we have used wide verification area, which included Switzerland and north of Italy. We have validated the model performance over many meteorological fields. Moreover, for 2.2km resolution, the calibration period was very long (entire 2013) and the number of the tuned parameters was high (six). These achievements yielded highly qualitative calibration analysis, making the calibration results especially reliable. Future study may have a lot of interesting and important directions. Using the Meta-Model, one can perform more specific calibrations:

- focusing on specific types of weather conditions (rain, extreme events, stable stratified nights, fogs, etc.);
- focusing on seasons (season-dependent parameters tuning);
- reducing the noise of the calibration method by matching specific parameters to related fields and weather situations, and performing the tuning for these matches only;
- analyzing the relative importance of constrain and interaction simulations for various parameters.

A Appendix: Meta-Model code

A.1 Algorithm

In order to execute the program, one has to execute main.m. First it reads the user defined definitions from namelist.m. Then it divides the calibration period to several short (10 day) sub-periods (to save matlab memory) and executes ReadData_and_MetaModel.m for every period, to read observations and simulations data and build the meta-model regressions. After that stage is performed for all the sub-periods, it executes PostProc.m which performs the post-processing and saves the calibration results in .mat format files.

A.1.1 ReadData_and_MetaModel.m

First the observations data is read (via **read_calmo_obs.m**) into datamatrix.obsdata and datamatrix_so.obsdata structures, for near surface fields and sounding derived fields, respectively. The Swiss 2m-temperature (Tmax and Tmin) fields are interpolated to the model grid (via **build_temp_obs.m**) using several optional methods (including the one which takes into account the local observed 2m-temperature profile in the vicinity of the model grid point). Next, the 24-hours precipitation is interpolated to the model grid (via **build_rain_obs.m**). In addition, soundings data is read (via **read_sounding_obs.m**), followed by reading the Italian Tmax, Tmin and precipitation data (from netcdf files). After reading the observations, the simulations data is read (via **read_calmo_sim.m**), while the profiles data is read via **read_profiles_mod.m**. There are several types of simulations data: reference (default parameters combination) simulation is read into datamatrix.refdata structure for near surface fields (and datamatrix_so.refdata for profiles derived fields); min-max simulations (where one of the parameters gets its maximum or minimum value, while the others kept default) are read into datamatrix.moddata structure for near surface fields (and datamatrix_so.moddata for profiles derived fields); interaction simulations (where pair of parameters get their maximum or minimum value, while the others kept default) are read for near surface fields into datamatrix.moddata structure as well (and datamatrix_so.moddata for profiles derived fields); constrain simulations (where one of parameters gets some intermediate value, while the others kept default) are read into datamatrix.constrain structure for near surface fields (and datamatrix_so.constrain for profiles derived fields); validate simulation (where all the parameters get some intermediate value - needed for validating the meta-model at an arbitrary point in parameters space) is read into datamatrix.valdata structure for near surface fields (and datamatrix_so.valdata for profiles derived fields). After the observations and simulations data is read, there is an option (via avg_T parameter) to average part of the fields over regions (regions are defined in **regions_bmp.m**, similarly to definition of regions in Frei (2014) for Switzerland) so that the Meta-Model will be built to predict region-averaged fields, rather than the fields at every grid point. The averaging over regions is performed in **Frei_regions.m**. Next, we redefine data arrays to have the structure (fields,days,regions,simulations) (via **gpts_series.m**) and finally delete unrealistic sounding/profiles data (via **del_bad_sounding.m**). Next, the Meta-Models are created via **neelin_e.m** which uses **polyfitn.m** for performing the forecasts fits in N-dimensional parameters space. In case only precipitation is averaged over regions (avg_T=0), the Meta-Model structures metamodel_tmax, metamodel_tmin and metamodel_pr are created, while if temperature data is also averaged (avg_T=1), the Meta-Model structure metamodel_new includes all the data (for temperature and precipitation). In addition, the profiles Meta-Models are written into the structure metamodel_so (see definitions of the Meta-Model structures in the description of **neelin_e.m** function below). Finally, the Meta-Model structures are

saved in .mat format.

A.1.2 PostProc.m

First, the Meta-Model structures are loaded for all the periods. Then we calculate the weights for different fields via **weights_calc.m**, needed to equalize their contributions to the final score (see eq. 4). The weights calculation uses **neelin_p.m**. This function calculates pseudo-forecast using the Meta-Models, for an arbitrary parameters combination. Then a big structure "main_data" is created (and saved in .mat format), which includes all the model and observations structures, as well as the Meta-Model structures and the fields weights. Next, the function **planes.m** is called, which plot performance scores for pair-wise parameters cross sections. For that, it uses **neelin_p.m**, as well as the scores calculation **rmse_calc.m** and **cosi_calc.m**, for rmse-type and cosi-type scores, respectively. This is followed by the iterations loop, aimed to converge to the optimal parameters combination (see section 6). At each iteration, the function **lhopt.m** is called which uses **neelin_p.m** to calculate the scores distribution for a specific part of the parameters space (which is getting smaller from iteration to iteration). This distribution is plotted via **histplot.m**. In case the process converged to the optimal parameters combination, or the iterations number reached a predefined maximum ("iterations_num"), the loop is broken. Next, the "good enough" iteration is determined (parameter "iteration_goodenough") as the iteration at which the score reaches 90% of the optimal combination score. We define the parameters uncertainty (between the green lines at Fig. 4, for example) at that iteration as the uncertainty of the optimal parameters combination. Next **optparam.m** is called to plot the optimal parameters combination (before transforming parameters back from the log representation). In case some of the parameters were transformed to log space (see section 4.2.4), the optimal parameters combination and the uncertainties values are transformed back to the real parameters space via **log_turlen_entrsc.m**. Finally, the uncertainty ranges are saved in UB_reg.mat and LB_reg.mat, and the optimal parameters combination is saved in popt_reg.txt.

A.2 Structure

The Meta-Model code is written in Matlab and uses its Statistical Toolbox. It consists of 33 Matlab (.m) files, which are called in the following order:

1	main.m % main program to be called
2	ReadData_and_MetaModel.m % Read observations and simulations data, then fit the Meta-Models
3	namelist.m % read namelist
4	sims_def.m % choose parameters to be tuned
5	expval_inter_combs.m
6	**% stage A: Reading observations and simulations data:**
7	read_calmo_obs.m % Read observations data
8	build_temp_obs.m % Interpolate 2m-temperature observations grid to model grid
9	
10	build_rain_obs.m % Interpolate rain observations grid to model grid
11	var_meta_calmo.m % correct fields units
12	read_sounding_obs.m % Read sounding observations
13	get_press_levs.m
14	read_calmo_sim.m % Read simulations data
15	var_meta_calmo.m % correct fields units
16	read_profiles_mod.m % Read simulations data
17	get_press_levs.m
18	Frei_regions.m % Average part of the fields over predefined big regions
19	regions_bmp.m % Definition of regions over Switzerland and north Italy
20	gpts_series.m % Redefine data arrays to the following structure: (fields,days,regions,simulations)
21	del_bad_sounding.m % delete unrealistic sounding/profiles data
22	corr_so.m
23	**% stage B: create Meta-Models:**
24	neelin_e.m % create Meta-Models - forecasts fits in N-dimensional parameters space
25	allcomb.m
26	polyfitn.m % N-dimensional 2-nd order polynomial fit
27	**% stage C: Post-processing:**
28	PostProc.m % Post-processing: plot analysis results and calculate the optimal parameters combination
29	namelist.m % read namelist
30	sims_def.m % read parameters to be tuned
31	weights_calc.m % calculate weights for different fields, to equalize their contributions to the final score (assuming user defined weights are uniform)
32	neelin_p.m % calculate pseudo-forecast using the Meta-Models
33	ETS.m % calculate rain part of COSI score (in case weights are calculated for COSI score also)
34	planes.m % plot performance scores for pair-wise parameters cross sections
35	allcomb.m
36	divisor.m
37	neelin_p.m % calculate pseudo-forecast using the Meta-Models
38	rmse_calc.m % calculate RMSE-type score
39	cosi_calc.m % calculate COSI-type score
40	ETS.m % calculate rain part of COSI score
41	lhopt.m % calculate scores distribution as part of the iterative convergence algorithm
42	neelin_p.m % calculate pseudo-forecast using the Meta-Models
43	histplot.m % plot scores distribution as part of the iterative convergence algorithm
44	optparam.m % plot optimal parameters combination (before transforming parameters back from the log representation)
45	allcomb.m
46	log_turlen_entrsc.m % transforming tur_len and entr_sc parameters back from the log representation

A.3 Subroutines

The Meta-Model code includes the following subroutines:

```
function main()

% NAME
% main
% PURPOSE
% main program of the CALMO parameters tuning method
% NOTE
% Set main definitions at namelist.m file
% RUN
% from Bash: "matlab -nodesktop -nosplash -r main"
% from Matlab: F5 inside main.m
% INPUT
% -
% OUTPUT
% calibration results saved in .mat format
% AUTHORS
% Pavel Khain (pavelkh_il@yahoo.com)
% Itsik Carmona (carmonai@ims.gov.il)
% Originally: Omar Bellprat (omar.bellprat@gmail.com)

function ReadData_and_MetaModel(date_min,date_max)

% NAME
% ReadData_and_MetaModel
% PURPOSE
% Read observations and simulations data, then fit the Meta-Models
% INPUTS
% time period: from date_min 'dd-mmm-yyyy' to date_max 'dd-mmm-yyyy'
% OUTPUTS
% saved (in .mat format) observations and simulations fields as well as
% the Meta-Models coefficients

function [maindir simuldir obsdir extdir vars vars_2d avg_T vars_sound sims_opt ml score
w_user lhacc iterations_num best_percent date_min date_max]=namelist()

% NAME
% namelist
% PURPOSE
% Namelist of the calibration analysis
% INPUTS
% -
% OUTPUTS
% maindir - main directory
% simuldir - "maindir/simuldir": path to simulations files
% obsdir - "maindir/obsdir": path to observations files
% extdir - "maindir/extdir": path to "external data" files
% vars - calibrated fields groups. Can be any combinations of:
% 't2m_max','t2m_min','pr','sound'
```

```
% vars_2d - calibrated 2D fields. Can be any combinations of:
% 't2m_max','t2m_min','pr'
% avg_T - region average over Precipitation only (avg_T=0), or over
% Precipitation, Tmax and Tmin (avg_T=1)
% vars_sound - calibrated profiles fields:
% 'CAPE','CIN','TCWC','WSHEAR1','WSHEAR2','WSHEAR3','T850mb',
% 'T700mb','T500mb','RH850mb','RH700mb','RH500mb','U850mb',
% 'U700mb','U500mb','V850mb','V700mb','V500mb'
% sims_opt - Choose parameters to callibrate and the simulations to use. The
% possible values for sims_opt and their meaning appear in sims_def.m
% file
% ml - Minimum number of days (during given period) for valid soundings data. If
% less - current sounding fields are not analyzed
% score - 'rmse' or 'cosi' for RMSE-type and COSI-type scores, respectively
% w_user - array of user defined weights (for simlicity - from 0 to 1) for
% calibrated fields:
% tmax tmin pr cape cin ws1 ws2 ws3 T850mb T700mb T500mb RH850mb
% RH700mb R500mb U850mb U700mb U500mb V850 V700mb V500mb
% lhacc - Number of experiments to sample parameter space at each iteration
% iterations_num - Maximum number of iterations
% best_percent - "winners" percent of lhacc which is used to define the
% parameters space for the next iteration
% date_min - beginning of calibration period
% date_max - end of calibration period

function [paramn,paramnt,range,default,expval,valval,simval,sims_reg,sims_inter,
sims_con,valcon,param_log,date_min,date_max]=sims_def(sims_opt)

% NAME
% sims_def
% PURPOSE
% Choose parameters to tune and the simulations to use
% INPUTS
% sims_opt - defined by 5-digits number: sims_opt=ABCDE, where:
% A - number of parameters to calibrate (1,2,3,4,5,6,)
% B - serial number of combination for given A
% C - number of ADDITIONAL (to the minimum required) interaction
% parameter simulations (interaction terms)
% D - number of "constrain" 1D simulations (additional simulations
% where only one parameter is changed from default)
% E - number of parameters (among A) which are transformed to LOG
% space
% OUTPUTS
% paramn - Parameter names
% paramnt - Parameter names (for TEX interpreter)
% range - Parameters ranges (min and max)
% default - Parameters defaults
% sims_reg - Names of max-min simulations (where only 1 parameter is shifted to
% its max/min value)
% sims_inter - Names of interaction simulations (where 2 parameters are shifted
```

```
% to their max/min values)
% expval - Parameters values for max-min and interaction simulations
% simval - Name of "val" simulation (where all the parameters are shifted from
% their default values, in order to validate the Meta-Models)
% valval - Parameters values for "val" simulation
% sims_con - Name of "constrain" simulations (where each time one parameter is
% shifted from its default value, but not to its max/min values)
% valcon - Parameters values for "constrain" simulations
% param_log - Array of 0/1 numbers (having length of paramn), where ones stand
% for parameters which are transformed to log space
% date_min - The earliest allowed start date ('dd-mmm-yyyy') for chosen sims_opt
% date_max - The latest allowed end date ('dd-mmm-yyyy') for chosen sims_opt

function [VectorValues]=expval_inter_combs(temp_inter,range,default,paramn)

% NAME
% expval_inter_combs
% PURPOSE
% fill expval matrix for sims_def.m
% INPUTS
% temp_inter - one of the interaction simulations
% range - Parameters ranges (min and max)
% default - Parameters defaults
% paramn - Parameter names
% OUTPUTS
% expval matrix for sims_def.m

function [odata odata_s sound_exist]=read_calmo_obs(vars,date_lim,avg_type, size_vars_sound)

% NAME
% read_calmo_obs
% PURPOSE
% Read observations data from Switzerland and north Italy, as well as soundings
% data, for specified period
% INPUTS
% vars - calibrated fields groups. See namelist.m
% date_lim - Structure which includes the dates range of simulations to be read
% avg_type - Interpolation method of observations data to model grid. Can be:
% 'near_neighb','simple_mean','weight_mean','clever_mean'
% size_vars_sound - length(vars_sound) - number of soundings fields
% OUTPUTS
% odata - Data matrix with dimensions [Field,Day,1,Lon,Lat] (field can be
% Tmax,Tmin,Pr)
% odatas - Data matrix for profileswith dimensions [Field,Day,1,Hour,Sounding
% location]
% sound_exist - binary matrix [Day,Hour,Sounding location] with ones where the
% sounding data exist

function build_temp_obs(avg_type,maxminavg)

% NAME
```

```
% build_temp_obs
% PURPOSE
% This function interpolates the gridded temperature observations (by C. Frei) to the model
grid.
% METHOD
% When comparing smoothed topography model-grid 2m-temperature whith the
% observed 2m temperature, one shoud "correct" the observed
% 2m-temperature to correspond the model grid elevation. The correction may be
% performed using the neighboring grid points 2m-temperature profile,
% according the recommendation of C. Frei
% Steps:
% 1. Read any simulation file to obtain the model grid lat/lon
% (ex:aggregated_LTUR_2013011000.nc)
% 2. Read any simulation file to obtain the model grid altitude
% (ex:laf2013111600_filtered.nc)
% 3. Read any observations file to obtain the observations grid lat/lon (ex:
% TmaxD_ch01r.swisscors_201301010000_201302010000.nc)
% 4. Read gridded observations altitude ( ex: topo.swiss1_ch01r.swisscors.nc)
% 5. Interpolate the gridded observations to the model grid using one of the
% possible methods
% INPUTS
% avg_type - one of the interpolation methods:
% 'near_neighb','simple_mean','weight_mean','clever_mean'
% maxminavg - Which field to interpolate: 'Tmax','Tmin','Tavg'
% OUTPUTS
% saved (in .mat format) interpolated temperature observations

function build_rain_obs()

% NAME
% build_rain_obs
% PURPOSE
% This function interpolates the gridded rain observations to the model grid.
% METHOD
% 1. Read any simulation file to obtain the model grid lat/lon
% (ex:aggregated_LTUR_2013011000.nc)
% 2. Read gridded rain observations you need to interpolate (ex:
% CPCH_201301080000_01440_c2.nc)
% 3. Interpolate the gridded observations to the model grid using nearest
% neighbor
% INPUTS
% -
% OUTPUTS
% saved (in .mat format) interpolated precipitation observations
% AUTHOR
% Pavel Khain (pavelkh_il@yahoo.com)

% Definition of regions over Switzerland and north Italy
% METHOD
% Analyze image file (regions_italy_swiss_for_matlab.bmp) where each region has
```

```
% its color
% INPUTS
% lat - latitude
% lon - longitude
% img - image file (regions_italy_swiss_for_matlab.bmp) where each region has
% its color
% unify_regions - array that defines which regions (out of 1-7) to unify (option
% to unify several regions into one bigger)
% OUTPUTS
% area - region number to which lat lon belong

function datamatrix_t = gpts_series(datamatrix,vars,var)

% NAME
% gpts_series
% PURPOSE
% Redefine data arrays (which were not averaged over regions) to the following
% structure: (fields,days,regions,simulations)
% INPUTS
% datamatrix - Structure which includes observations and simulations data
% for surface fields ('t2m_max','t2m_min','pr'). Dimensions:
% [Field,Day,simulation,Lon,Lat]
% vars - calibrated fields groups. Can be any combinations of:
% 't2m_max','t2m_min','pr','sound'
% var - specific field group (one of vars)
% OUTPUTS
% datamatrix_new - Structure which includes observations and simulations
% data for surface fields ('t2m_max','t2m_min','pr').
% Dimensions: [Field,Day,region,simulation]

function datatemp=del_bad_sounding(datamatrix_so,ml,sims_reg,sims_inter, sims_con,simval,vars_sound)

% NAME
% del_bad_sounding
% PURPOSE
% delete unrealistic sounding/profiles data
% INPUTS
% datamatrix_so - Data matrix for profiles. Dimensions:
% [Field,Day,region,simulation]
% ml - Minimum number of days (during given period) for valid soundings data. If
% less - current sounding fields are not analyzed.
% sims_reg - Names of max-min simulations (where only 1 parameter is shifted to
% its max/min value)
% sims_inter - Names of interaction simulations (where 2 parameters are shifted
% to their max/min values)
% sims_con - Name of "constrain" simulations (where each time one parameter is
% shifted from its default value, but not to its max/min values)
% simval - Name of "val" simulation (where all the parameters are shifted from
% their default values, in order to validate the Meta-Models)
% vars_sound - calibrated profiles fields: 'CAPE','CIN','TCWC','WSHEAR1',
% 'WSHEAR2','WSHEAR3','T850mb','T700mb','T500mb','RH850mb',
```

```
% 'RH700mb','RH500mb','U850mb','U700mb','U500mb',
% 'V850mb','V700mb','V500mb'
% OUTPUTS
% datatemp - Data matrix for profiles. Dimensions: [Field,Day,region,simulation]

function metamodel=neelin_e(parameters, datamatrix_test,vars_2d)

% Quadratic regression metamodel as described in Neelin et al. (2010) PNAS and
% Bellprat (2012)
% NAME
% neelin_e
% PURPOSE
% Fit a mutlivariate quadratic quadratic regressions (metamodels)
% INPUTS
% From the structure parameters and datamatrix the following fields are
% processed
% parameters.experiments:
% Parameter values for each experiment with the dimension of [N,
% 2*N+N*(N-1)/2]
% The structure NEEDS to be as follows. Example for 2 parameters
% (p1,p2):
% [p1_l dp2 ] ! Low parameter value for p1 default dp2
% [p1_h dp2 ] ! High parameter value for p1 default dp2
% [dp1 p2_l] ! Low parameter value for p2 default dp1
% [dp1 p2_h] ! Hihg parameter value for p2 default dp1
% [p1_l p2_h] ! Experiments with interaction (no default)
% ! Additional experiments used to constrain interaction
% terms
% parameters.range:
% Range of values for each parameter to normalize the scale
% parameters.default:
% Default values of parameters to center the scale
% datamatrix_test.moddata:
% Modeldata corresponding to the dimensions of parameter.experiments
% datamatrix_test.refdata:
% Modeldata when using default parameter values to center the
% datamatrix fitted
% vars_2d - calibrated 2D fields. Can be any combinations of:
% 't2m_max','t2m_min','pr'
% OUTPUT
% structure metamodel.
% a: Metamodel parameter for linear terms [N,1]
% B: Metamodel parameter for quadratic and interaction terms
% [N,N]. Quadratic terms in the diagonal, interaction terms
% in the off-diagonal. Matrix symmetric, B(i,j)=B(j,i).
% c: Metamodel parameter for zero order (constant)

function PostProc(period)

% NAME
% PostProc
```

```
% PURPOSE
% plot analysis results and calculate the optimal parameters combination
% INPUTS
% time periods array (more precisely - initial dates of the periods):
% 'dd-mmm-yyyy','dd-mmm-yyyy',...
% OUTPUTS
% saved (in .mat format) analysis results

function [W_fin]=weights_calc(parameters,datamatrix_tmp,metamodel_tmp, w_user,score,fields)

% NAME
% weights_calc
% PURPOSE
% calculate weights for different fields, to equalize their contributions to the
% final score (assuming user defined weights are uniform).
% INPUTS
% parameters - structure parameters (see definitions in
% ReadData_and_MetaModel.m)
% datamatrix_tmp - structure datamatrix (see definitions in
% ReadData_and_MetaModel.m)
% metamodel_tmp - structure metamodel (see definitions in neelin_e.m)
% w_user - array of user defined weights (for simlicity - from 0 to 1) for
% calibrated fields:
% score - 'rmse' or 'cosi' for RMSE-type and COSI-type scores, respectively
% fields - field name (can be 't2m_max','t2m_min','pr',vars_sound)
% OUTPUT
% W_fin - weights array for different fields

function [dmatrix]=neelin_p(metamodel,parameters,datamatrix,pvector)

% NAME
% neelin_p
% PURPOSE
% Forecast using regression metamodel as described in Neelin et al. (2010) PNAS
% and Bellprat et al. (2012).
% METHOD
% Predict data using the metamodel for a parameter matrix
% INPUTS
% From the structure metamodel, parameters and datamatrix the following fields
% are
% processed (mind the same naming in the input)
% metamodel.a:
% Vector of linear terms of the metamodel [...,N,1] additional
% data dimensions possible (ex:a [Regions,Variables,Time,N,1])
% metamodel.B:
% Matrix of quadratic and interactions terms [...,N,N] additional
% data dimensions possible (ex:a [Regions,Variables,Time,N,N])
% metamodel.c: Metamodel parameter for zero order (constant)
% parameters.range:
% Range of values for each paramter to normalize the scale.
% parameters.default:
```

```
% Default values of parameters to center the scale
% datamatrix.reffdata:
% Modeldata of when using default parameter values to center the
% datamatrix
% pvector: Parameter values for one experiment with the
% dimension of [N,1] N=Number parameters
% OUTPUT
% dmatrix: Predicted data for parameter experiment

function ets = ETS (Obs,Model,thresrain)

% NAME
% ETS
% PURPOSE
% rain forecast. Answers the question: How well did the forecast "yes" events correspond
% to the observed "yes" events (accounting for hits that would be expected by chance)
% Range: -1/3 to 1; 0 indicates no skill. Perfect score: 1.
% NOTE
% be carefull with 0/0 when there is no rain both in nature and model (ex:
% "summer in Israel") !!!
% INPUTS
% parameters - structure parameters (see definitions in
% ReadData_and_MetaModel.m)
% datamatrix_tmp - structure datamatrix (see definitions in
% ReadData_and_MetaModel.m)
% metamodel_tmp - structure metamodel (see definitions in neelin_e.m)
% w_user - array of user defined weights (for simlicity - from 0 to 1) for
% calibrated fields:
% score - 'rmse' or 'cosi' for RMSE-type and COSI-type scores, respectively
% fields - field name (can be 't2m_max','t2m_min','pr',vars_sound)
% OUTPUT
% ets - rain forecast score

function planes(main_data,parameters,w_user,score,new_calc,predir,param_log)

% NAME
% planes
% PURPOSE
% Plot performance scores for pair-wise parameters cross sections
% INPUTS
% main_data - big structure, which includes the sub-structures:
% main_data.data - datamatrix structure
% main_data.metamodel metamodel structure
% main_data.field - field names
% main_data.W - weights array for different fields
% parameters structure:
% parameters.range:
% Range of values for each paramter to normalize the scale.
% parameters.default:
% Default values of parameters to center the scale
% datamatrix.reffdata:
```

```
% Modeldata of when using default parameter values to center the
% datamatrix
% w_user - array of user defined weights (for simlicity - from 0 to 1) for
% calibrated fields:
% tmax tmin pr cape cin ws1 ws2 ws3 T850mb T700mb T500mb RH850mb
% RH700mb R500mb U850mb U700mb U500mb V850 V700mb V500mb
% score - 'rmse' or 'cosi' for RMSE-type and COSI-type scores, respectively
% new_calc - 0 or 1: 0 by default, when main_data is devided into cells over
% periods. 1 - otherwise
% predir - path for saving output planes figures
% param_log - Array of 0/1 numbers (having length of paramn), where ones stand
% for parameters which are transformed to log space
% OUTPUT
% saved planes figures

function score=rmse_score(qfit,obsdata,W,w_user,new_calc)

% NAME
% rmse_score
% PURPOSE
% calculate RMSE-type score for Meta-Model predictions (regressions estimations)
% INPUTS
% qfit - metamodel predictions for given parameter combination
% obsdata - observations data
% W - weights for different fields, to equalize their contributions to the final
% score
% w_user - array of user defined weights (for simlicity - from 0 to 1) for
% calibrated fields
% new_calc - 0 or 1: 0 by default, when main_data is devided into cells over
% periods. 1 - otherwise
% OUTPUT
% score - RMSE-type score

function score=cosi_score(qfit,obsdata,W,w_user,new_calc)

% NAME
% cosi_score
% PURPOSE
% calculate COSI score for Meta-Model predictions (regressions
% estimations). Defined on the basis of the COSI score by Ulrich Damrath (DWD)
% INPUTS
% qfit - metamodel predictions for given parameter combination
% obsdata - observations data
% W - weights for different fields, to equalize their contributions to the final
% score
% w_user - array of user defined weights (for simlicity - from 0 to 1) for
% calibrated fields
% new_calc - 0 or 1: 0 by default, when main_data is devided into cells over
% periods. 1 - otherwise
% OUTPUT
% score - COSI score
```

```
function [Sopt,xstar,xopt,sc_stat,UB_next,LB_next]=lhopt(main_data,
parameters,w_user,score,new_calc,lhacc,tmp_str,iteration,
best_percent,UB_new,LB_new,param_log)

% NAME
% lhopt
% PURPOSE
% Optimise model parameters using a latin hypercube sampling. See Bellprat et al. (2012)
% METHOD
% Create a sample of parameters using a latin hypercube design
% and predict the model performance of the sample using the metamodel.
% INPUTS
% main_data - big structure, which includes the sub-structures:
% main_data.data - datamatrix structure
% main_data.metamodel metamodel structure
% main_data.field - field names
% main_data.W - weights array for different fields
% parameters structure:
% parameters.range:
% Range of values for each paramter to normalize the scale.
% parameters.default:
% Default values of parameters to center the scale
% w_user - array of user defined weights (for simlicity - from 0 to 1) for
% calibrated fields:
% tmax tmin pr cape cin ws1 ws2 ws3 T850mb T700mb T500mb RH850mb
% RH700mb R500mb U850mb U700mb U500mb V850 V700mb V500mb
% score - 'rmse' or 'cosi' for RMSE-type and COSI-type scores, respectively
% new_calc - 0 or 1: 0 by default, when main_data is devided into cells over
% periods. 1 - otherwise
% lhacc - Number of experiments to sample parameter space at each iteration
% tmp_str - path to the calibration results
% iteration - iteration number (of convergence process to the optimal parameters
% combination)
% best_percent - "winners" percent of lhacc which is used to define the
% parameters space for the next iteration
% UB_new - upper limit of parameters range at given iteration
% LB_new - lower limit of parameters range at given iteration
% param_log - Array of 0/1 numbers (having length of paramn), where ones stand
% for parameters which are transformed to log space
% OUTPUTS
% Sopt - Scores for all experiments at given iteration
% xstar - Latin hypercube parameter experiments at given iteration
% xopt - Parameter setting with highest score at given iteration
% sc_stat - score statistics at given iteration
% UB_next - upper limit of parameters range at NEXT iteration
% LB_next - lower limit of parameters range at NEXT iteration

function histplot(lhscore,score,best,predir,iteration)

% NAME
% histplot
```

```
% PURPOSE
% plot histogram of SCORES for meta-models predictions
% INPUTS
% lhscore - Scores for all experiments at given iteration
% score - 'rmse' or 'cosi' for RMSE-type and COSI-type scores, respectively
% best - 0 or 1: o by default, 1 if a special simulation exists and verified
% predir - path for saving output planes figures
% iteration - iteration number (of convergence process to the optimal parameters combination)
% OUTPUTS
% saved scores histogram for specific iteration

function optparam(parameters,lhscore,lhexp,popt,errm)

% NAME
% optparam
% PURPOSE
% Plot optimal parameters combination
% NOTE: not checked or adapted since early stage of the CALMO project !
% INPUTS
% parameters - parameters structure
% lhscore - Scores for all experiments (at last iteration)
% lhexp - Latin hypercube parameter experiments (at last iteration)
% popt - Parameter setting with highest score (at last iteration)
% errm - error of metamodel, set to 0.001 ???
% OUTPUTS
% Plot optimal parameters combination

function xnolog=log_turlen_entrsc(xlog,paramname)

% NAME
% log_turlen_entrsc
% PURPOSE
% convert the optimal parameters (tur_len and entr_sc) values from log-space
% back to the regular space
% INPUTS
% xlog - input vector of paramaeters values in log space
% paramname - parameter names
% OUTPUT
% xnolog - output vector of paramaeters values (tur_len and entr_sc) in regular
% space
```

The COSMO Priority Project 'COLOBOC': Final Report.

No. 28: Ulrich Blahak (2016):
RADAR_MIE_LM and RADAR_MIELIB - Calculation of Radar Reflectivity from Model Output.

No. 29: M. Tsyrulnikov and D. Gayfulin (2016):
A Stochastic Pattern Generator for ensemble applications.

No. 30: D. Mironov and E. Machulskaya (2017):
A Turbulence Kinetic Energy – Scalar Variance Turbulence Parameterization Scheme.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Summary

The Priority Project Runge-Kutta started in October 2005 and ended after 3 years in September 2008. The starting point was an implementation of the Runge-Kutta (RK) method (Wicker and Skamarock 1998, Wicker and Skamarock 2002, Skamarock et al. 2005) into the COSMO-model at DWD beginning mid 2003 as the basic time integration scheme for use in high resolution applications. The aim was to replace the Klemp and Wilhelmson (1978) leapfrog-scheme later on. The Runge-Kutta method offers a substantial gain in accuracy at no additional costs. At the beginning of the Priority Project 10 tasks were defined (in a rather arbitrary order). During the project 4 additional tasks arose. These tasks can roughly be grouped into 3 classes:

- Repair detected model deficiencies:

  1 - Looking at pressure bias

  4 - Advection of moisture quantities in conservation form

  6 - Deep valleys

  7 - Different filter options for orography

  14 - DFI for RK

- New developments:

  8 - Higher order discretization in the vertical

  9 - Physics coupling scheme

  10 - Testing of alternative fast wave scheme

  13 - Divergence damping in a truly 3D-version

- Tool development:

  2 - Continue RK case studies

  3 - Conservation tool

  5 - Investigation of convergence

The two tasks

11 - Development of a more conservative dynamics

12 - Development of an efficient semi-implicit solver in combination with RK time integration scheme

were found to be too ambitious to be handled into this project. Indeed task 11 will evolve into an entirely new Priority Project ('Conservative Dynamical Core (CDC)').

Fortunately the tasks (1, 4, 6, 7, 14) which handle detected model deficiencies could be treated and came to a satisfactory end. This holds in particular for the rather tenacious problem of the pressure bias, task 1, which could be solved by a combination of several measures. The new moisture transport schemes are probably the main responsible for the improvements of the precipitation forecast, which were detected in the Priority Project 'Quantitative precipitation forecast' by comparing the old and new dynamical core (Leapfrog vs. RK). Also the tool development tasks (3, 5) could fulfil all the required deliverables.

The integration tool is now applied e.g. at the MPI Hamburg for budget inspections of moisture. A solver for analytic solutions for mountain flows is available, which was developed in particular for model validation. The tools for measuring the convergence rate are also available now. Task 2 had no concrete deliverables but accompanied the project by verifying the efforts of the projects by case studies and by identifying possible new problems of the dynamical core (e.g. the stability problem of thin layers near the ground). From the 'new development' tasks, task 9 is merely in an intermediate state. Task 8 (implicit vertical advection) could be brought to a satisfactory state some months after the official end of the project. At least, the necessary methodologies (needed efficient linear equation solver, model configuration items) are delivered and several studies were performed. Task 13 (3D-divergence) could not be treated at all. There was some time invested into task 10 to bring this version into a state for operational use. All in all it was found that some ideas contained there were promising, but a bigger effort is required to solve some more fundamental questions before it could be used.

2 Project report

2.1 Task 1: Looking at pressure bias

The pressure bias problem in RK core was pointed out in Torrisi (2005). Objective verification results using SYNOP observations showed a difference in mean sea-level pressure (MSLP) bias behaviour between 7 km Runge Kutta (RK) and LeapFrog (LF) runs (Fig. 1)

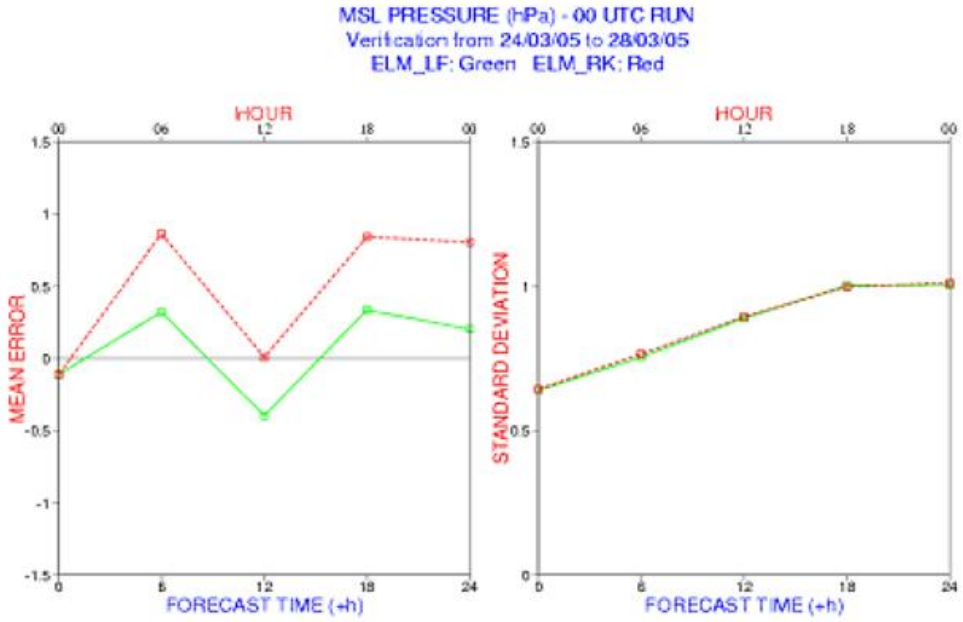

Figure 1: The pressure bias problem in the RK-dynamical core compared to the Leapfrog-scheme.

The pressure bias for RK runs, typically positive, tends to be larger (especially increasing

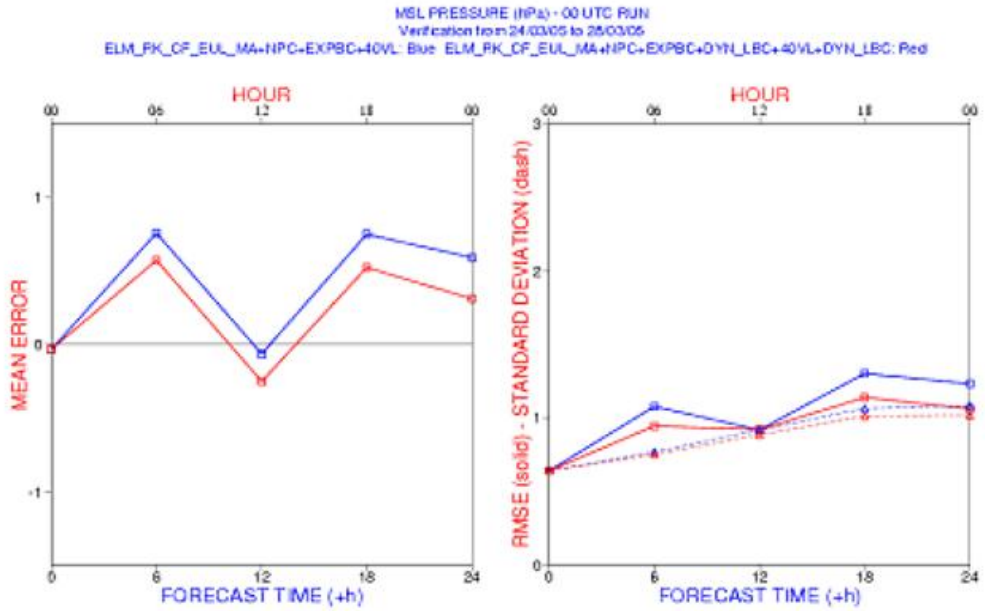

Figure 2: Positive effect of the dynamical bottom boundary condition on the PMSL.

with forecast time) leading to a worse RMSE. The implementation of the Gassmann formulation of the dynamical bottom boundary condition in the vertical pressure gradient term of the horizontal momentum equations brought an improvement in pressure bias behaviour for the RK dynamics (Fig. 2). Other work was done on RK core (change in metric term discretization, change in vertical average on half levels, etc), but no significant positive impact on the pressure bias was found. Objective verification results for the winter period 20 Jan - 04 Feb 2008 showed that 7 km RK/LF differences in pressure bias for COSMO-ME are almost negligible (Fig. 3). Generally, small RK/LF bias differences using 2.8/7 km grid spacing (depending on season, domain, location, etc) are still found (RK larger bias). RK/LF differences in MSLP bias are very big (especially at longer forecast times) using a 14 km grid spacing.

Other experiments showed that the pressure bias problem is not only present by changing the dynamical core (RK/LF), but it is evident also by using very large domain size and particularly clear using a 14 km grid spacing when compared to hydrostatic model runs (HRM). Objective verification results showed a difference in MSLP bias behaviour in 7 km RK (and LF) COSMO runs having domains of different sizes (the larger domain, the greater the bias difference - Fig. 4). Moreover, a large pressure bias difference was also found between 14 km COSMO and HRM runs on a Euro-Atlantic domain (Fig. 5). COSMO LF/RK runs have a larger bias increasing with forecast time. The pressure bias is a characteristics of COSMO model and is probably related to the model formulation. For this reason the effects on the pressure bias of two changes in the model formulation were addressed:

- Gassmann and Herzog (2006) reconsidered the derivation of prognostic temperature and pressure equations to remove some inconsistencies in the formulation of these equations;
- Zängl proposed a new reference atmosphere to overcome the problem of limitation in vertical extent of the model domain using the default reference atmosphere (model implementation in COSMO 4.5, September 2008).

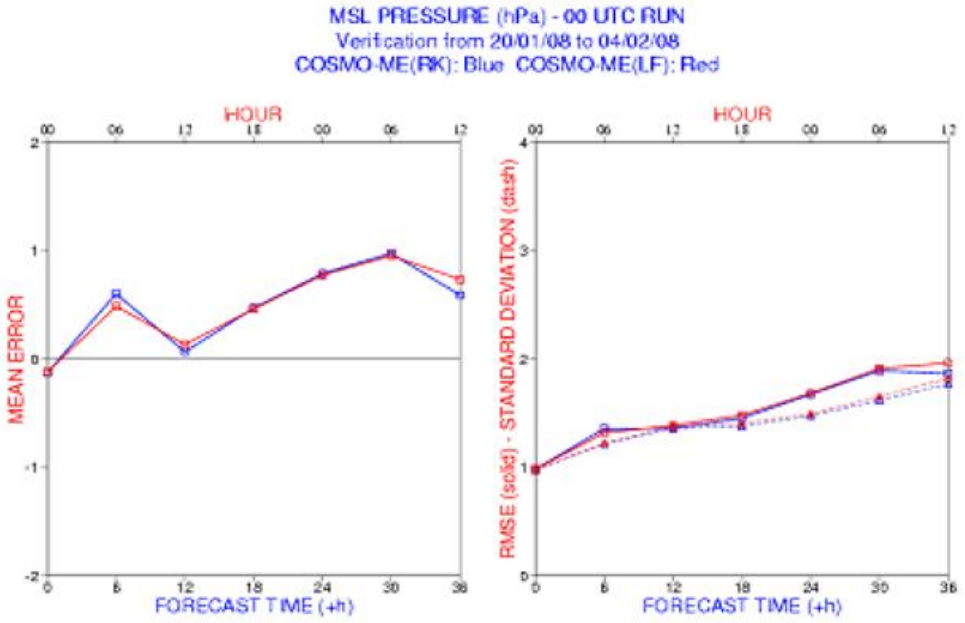

Figure 3: Comparison between RK and Leapfrog, 7 km resolution.

2.1.1 Heat source term in p equation

The pressure bias problem was also found in experiments using a coarser resolution (14 km) and enlarging the domain size (7 km). This could be an indication of some inconsistencies in the formulation of COSMO T/p budget equations. As suggested by Gassmann and Herzog (2006), a possible source of pressure bias could be neglecting the diabatic term in pressure equation. Preliminary real case experiments (winter period) without this approximation showed that the impact on the pressure bias is not general in 7 km runs (a slight deterioration around 12 UTC. Fig. 6), but it is apparent in 14 km runs (Fig. 7). Objective verification results (7 km) for a summer period were not so promising as those for the winter period (Fig. 8). No reduction of the amplitude of the pressure bias variation was found, but only a temporal shift in MSLP bias behaviour was present. More work would be needed. The pressure bias problem is typical for the COSMO model (not only of RK core !) and it seems to be mainly related to the model equation formulation. The use of a prognostic p-equation does not guarantee an exact mass conservation (accuracy depending on numerical algorithm), which is equivalent to introduce artificial sources or sinks in the continuity equation. Problems arise in applications such as data assimilation systems, where the pressure accuracy is important. A more conservative dynamical core is needed for the COSMO model.

2.1.2 New reference state

Introducing a reference state reduces the computational error in the calculation of pressure gradient terms in the equation of motion for not too large deviations of pressure from reference pressure.

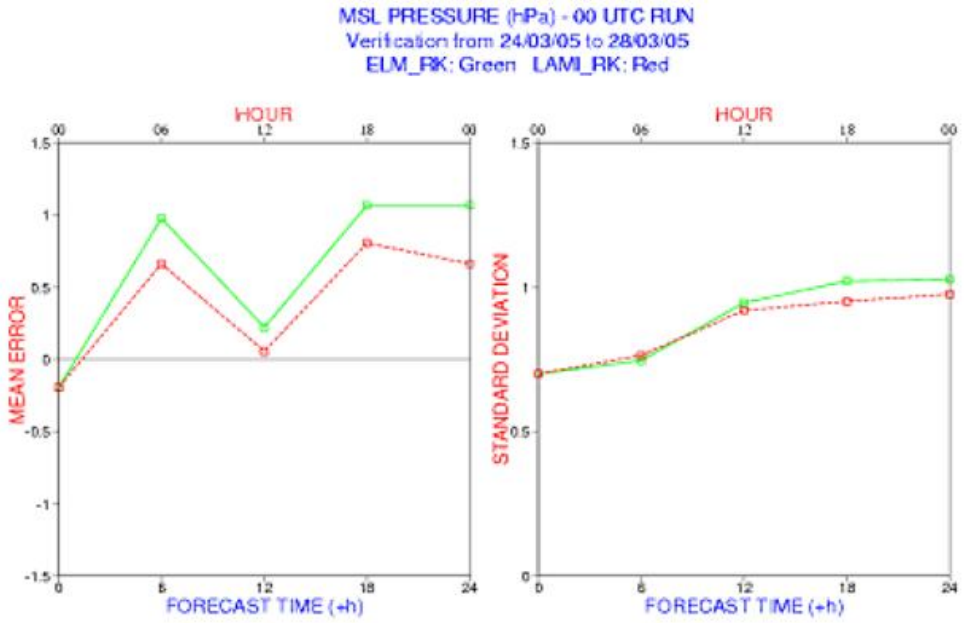

Figure 4: Influence of the domain size to the pressure bias.

At present, the reference atmosphere in the COSMO model is defined through the sea- level pressure, p_{00}, the sea-level temperature, T_{00}, and a generalized vertical temperature gradient

$$\frac{dT_0}{dlnp} = c_1. \tag{1}$$

Integration of the hydrostatic equation yields

$$T_0(z) = [T_{00}^2 - \frac{2gc_1}{R_d}(z - z_0)]^{1/2} \tag{2}$$

and

$$p_0(z) = p_{00}exp(\frac{T_0(z) - T_{00}}{c_1}) \tag{3}$$

From that follows

$$\frac{dT_0}{dz} = -\frac{gc_1}{R_d T_0} \tag{4}$$

which implies that the ordinary vertical temperature gradient becomes increasingly negative in the stratosphere. For the default values used in the COSMO model, p_{00} = 1000 hPa, T_{00} = 288.15 K and c_1 = 42 K, the reference temperature reaches 0 K at a height of 28923 m. This is clearly too restrictive for future plans to raise the model top to 10 hPa (about 30 km) or even higher. Another questionable property of the current reference atmosphere is

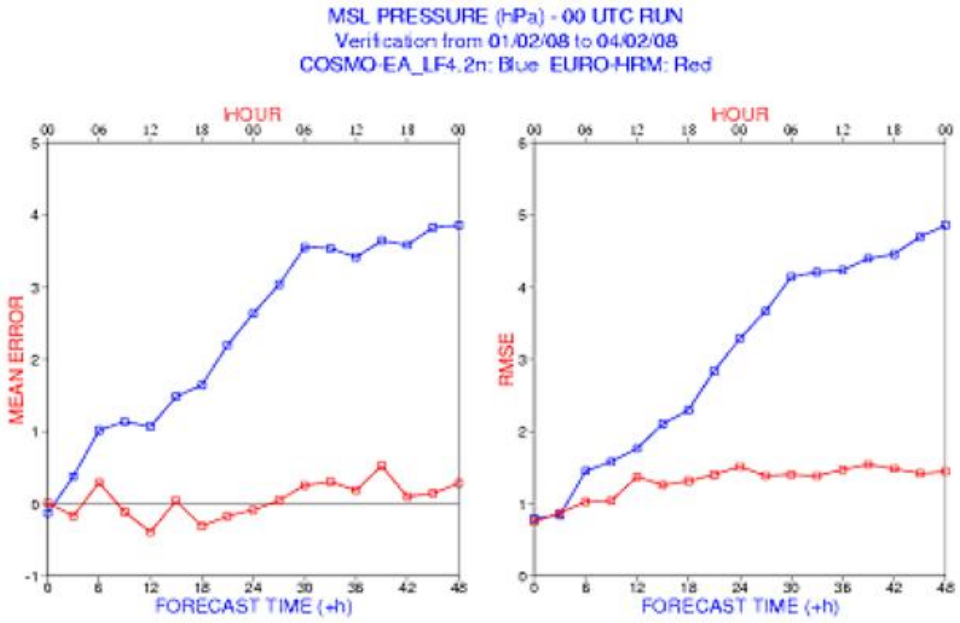

Figure 5: Comparison between COSMO-model and HRM for 14 km resolution.

that the base state pressure does not reach zero where the temperature does so. For the above-mentioned default values, $p_0 = 1.05$ hPa at the height where $T_0 = 0$ K.

To mitigate these problems, a new reference atmosphere has been implemented. Its temperature profile is defined through

$$T_0(z) = T_{00} + \Delta T exp(-z/H) \tag{5}$$

with reference values of $T_{00} = 213.15$ K, $\Delta T = 75$ K, and H = 10 km. For this temperature profile, the hydrostatic equation can be analytically integrated as well, yielding

$$p_0(z) = p_{00} exp[-\frac{gH}{R_d T_{00}} ln(\frac{exp(z/H)T_{00} + \Delta T}{T_{00} + \Delta T})] \tag{6}$$

and

$$T_0(p_0) = T_{00} + \frac{T_{00}\Delta T}{exp(-\frac{R_d T_{00}}{gH} ln\frac{p_0}{p_{00}})(T_{00} + \Delta T) - \Delta T} \tag{7}$$

With this definition, the temperature profile approaches an isothermal gradient in the stratosphere, which

- is closer to reality than an increasingly negative gradient and
- does not impose any limitation on the vertical extent of the model domain.

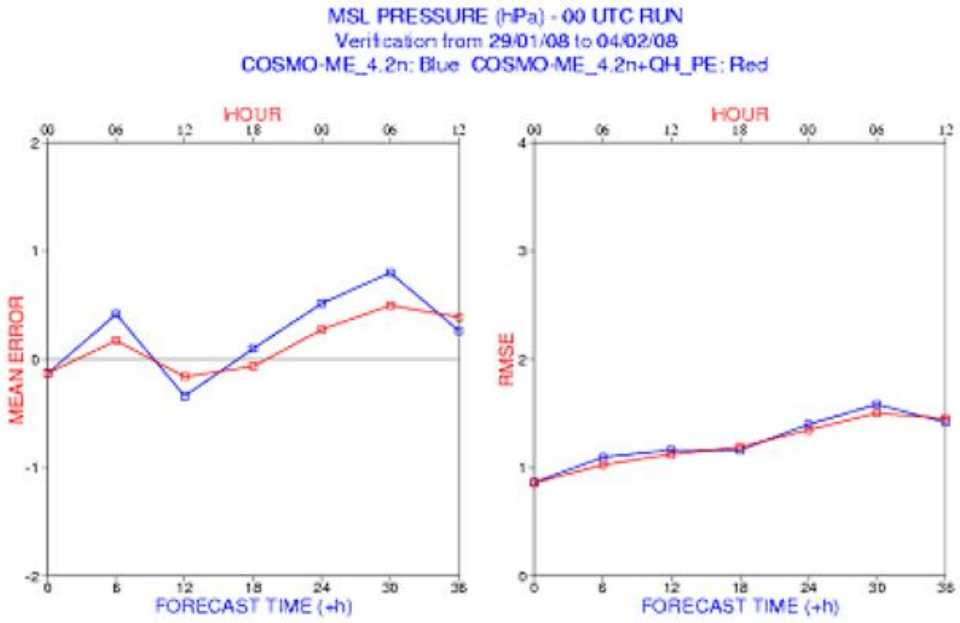

Figure 6: Influence of the diabatic terms in the pressure equations for 7 km resolution.

In the context of implementing the new reference atmosphere, an inconsistency in the computation of the reference pressure at the full model levels has been removed. Up to now, the reference pressure at full levels was set to the arithmetic mean of the reference pressure at the adjacent half levels, which is not consistent with the fact that the geometric height of the full levels is also assumed to be the arithmetic mean of the adjacent half levels. In the revised implementation, two possibilities for initializing the reference pressure are provided, both starting from an arithmetic averaging of height. One method directly uses the analytically integrated hydrostatic equation, the other one numerically integrates the hydrostatic equation from the bottom towards the model top. First experiments conducted with the new reference atmosphere and the corrected initialization of the reference pressure field indicate that both modifications could have a beneficial impact on the surface pressure forecast. Results are presented here for 72-hour forecasts on the COSMO-EU domain, starting on (i) 03 March 2008 (Fig. 9) and (ii) 30 May 2008 (Fig. 10). In all cases, initial data have been interpolated from the GME assimilation run, whereas lateral boundary conditions have been taken from the operational GME forecast. For reference, an experiment using the operational COSMO-EU setup (in particular the leapfrog core) is included. Moreover, an experiment using a non-approximated prognostic equation for perturbation pressure, as recently implemented by L. Torrisi, is shown. The surface pressure field has been validated against interpolated analyzes from GME assimilation runs every 12 hours.

The results reveal several interesting features:

- All experiments, except for the simulation with the non-approximated pressure equation in the March case, show a mostly negative slope in the pressure bias curves, with the bias turning from positive values at early forecast times into negative ones later on.

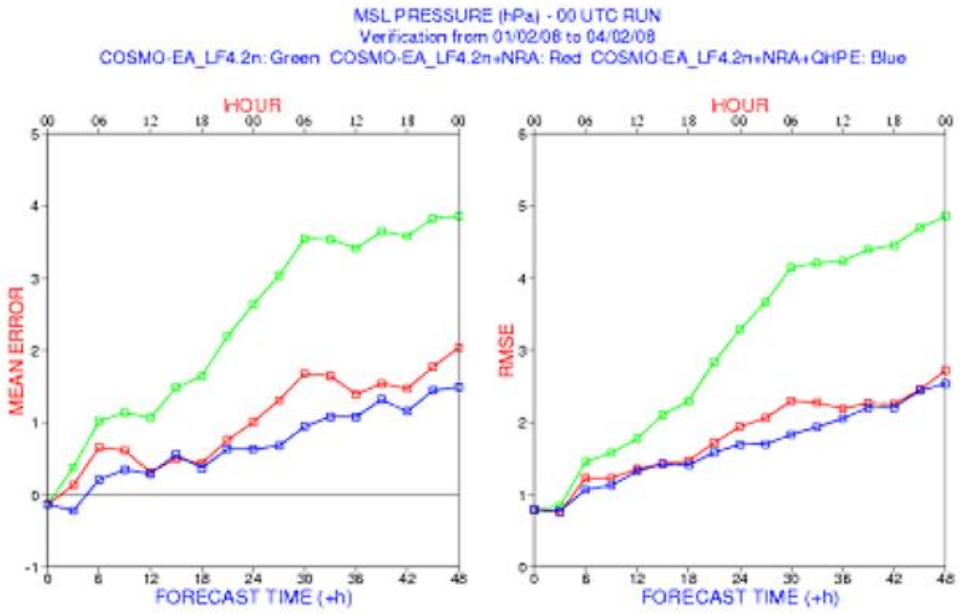

Figure 7: Influence of the diabatic terms in the pressure equations for 14 km resolution.

- Using the analytically integrated hydrostatic equation ("corr 2" in Fig. 9 and Fig. 10) induces a systematically more positive (or less negative) pressure bias than using the numerically integrated equation. This discrepancy is markedly larger for the old reference atmosphere than for the new one, particularly for the March case. Of all experiments using the Runge-Kutta core, the time-averaged bias is smallest when combining the new reference atmosphere with the analytically integrated hydrostatic equation.

- The rms error tends to be somewhat lower with the new reference atmosphere than with the old one. In the cases considered here, the Runge-Kutta core combined with the new reference atmosphere performs similarly well as the old Leapfrog core, whereas somewhat larger rms errors are obtained with the old reference atmosphere.

In summary, the most promising results have been obtained when combining the new reference atmosphere with initializing the reference pressure field from the analytically integrated hydrostatic equation. Thus, longer-term experiments should preferably be carried out with this setting. Objective verification results for only few runs using a 7 km grid spacing for the COSMO-ME showed a slight improvement around 06 UTC (Fig. 11). A dramatic improvement was found for 14 km runs (Fig. 12).

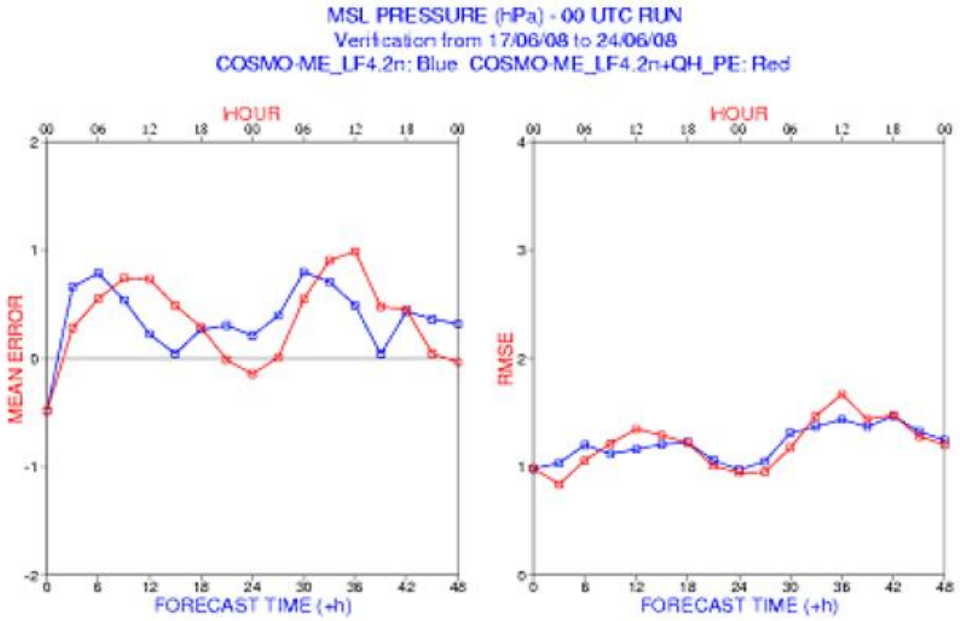

Figure 8: Influence of the diabatic terms in the pressure equations for 7 km resolution; summer period.

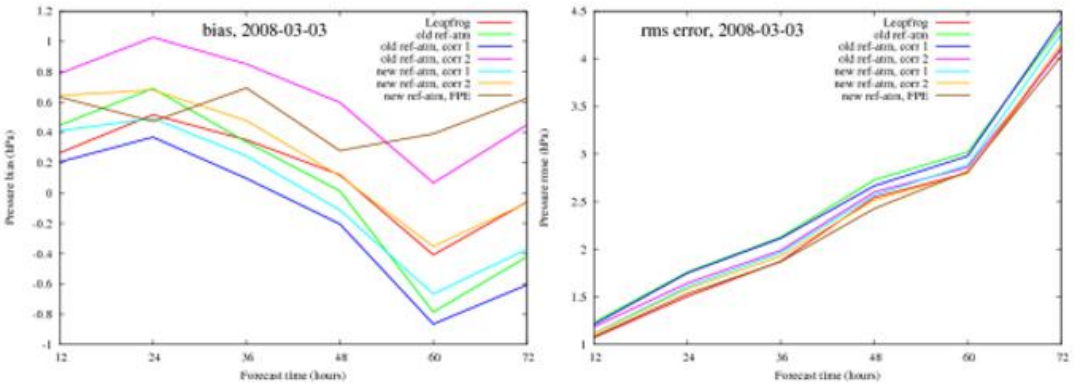

Figure 9: Bias and rms error of the surface pressure field for the experiments started at 00 UTC on 03 March 2008. The experiment denoted as "leapfrog" has been conducted with the operational COSMO-EU setup, all other experiments use the new Runge-Kutta core. The two methods available for calculating the base state pressure are denoted as "corr 1" for the discretized integration of the hydrostatic equation and as "corr 2" for the calculation based on the analytic formula. "FPE" stands for "full pressure equation", using the non-approximated prognostic equation for the perturbation pressure field.

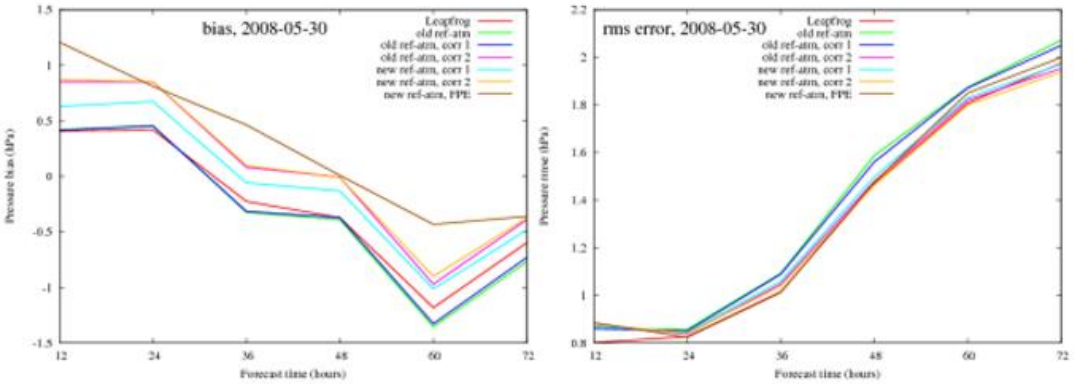

Figure 10: Same as Fig. 9, but for experiments initialized at 00 UTC on 30 May 2008.

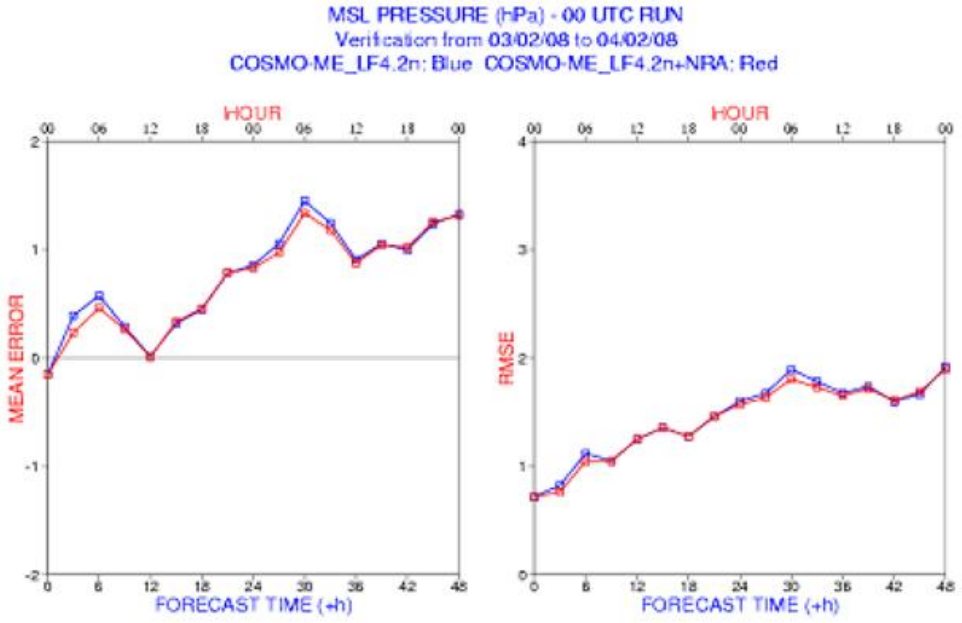

Figure 11: Slightly positive influence of the new reference atmosphere in 7 km runs.

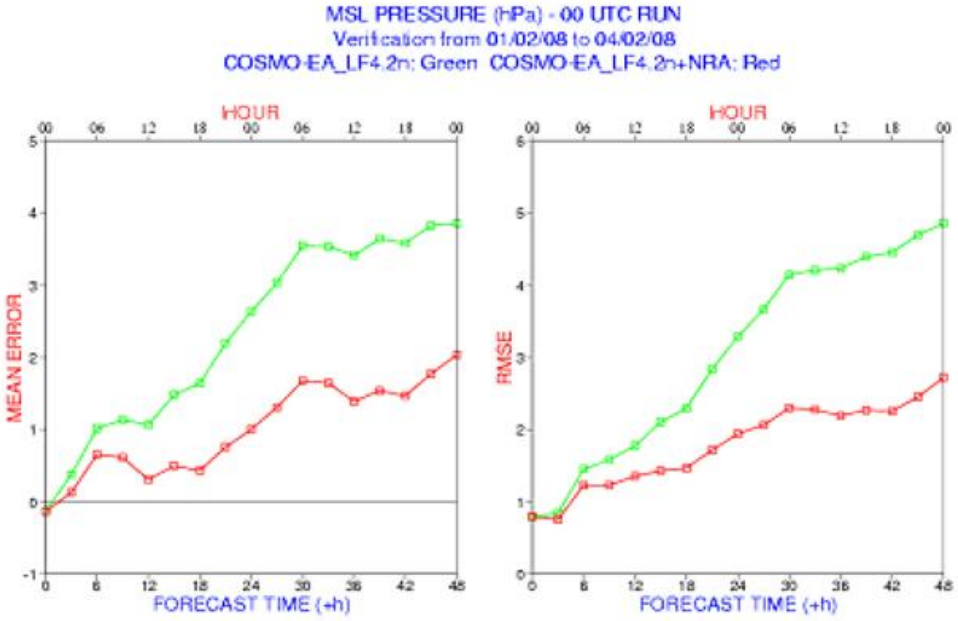

Figure 12: Bigger positive influence of the new reference atmosphere in 14 km runs.

2.2 Task 2: Continue RK case studies

The case studies done at MeteoSwiss were very closely linked with the set-up of the new model cascade which went operational on February 2008. This cascade consists of the new COSMO-7 model which is computed with a grid mesh of 6.6 km (0.06 degree resolution) and the imbedded COSMO-2 model covering the whole Alpine region which has a grid mesh of 2.2 km (0.02 degree resolution). The description of the different configuration of these 2 models can be found under:

http://www.cosmo – model.org/content/tasks/operational/default.htm

One feature is that they are both computed with the same 60 level distribution and use the Runge-Kutta dynamics. Originally it was planned to use a very fine vertical resolution (L60.1) of the planetary boundary layer, i.e. 29 levels below 2 km but operationally the level distribution of the driving model from ECMWF (IFS with 91 levels) was preferred (L60.2). This level distribution uses the bottom 43 levels directly from IFS and adapts the last levels so that the top of the model is at 23.6 km height. The bottom distribution has only 17 levels below 2 km and the level thicknesses are more or less constant (below 500 m) from the height of 5 km up to the tropopause. The problem with the very fine levels was finally solved by the work of Oliver Fuhrer with the stability analysis of the explicit vertical diffusion of TKE (see COSMO General meeting in Kracow, 2008).

2.2.1 First difficulties and their solutions

From a week's visit of Jochen Förstner (DWD) and Günther Zängl (at that time from München University) in March 2006 some interesting results were put together by the participants and are available in a separate Word report in German

ftp://ftp.cscs.ch/in/put/abc/morsier/Arbeitstreffen_Zusammenfassung.doc

Here are the main outputs:

- extra orographic smoothing, development of the lower bottom boundary conditions, and the p',T'-dynamics (see Task 6);
- the explicit lateral boundary condition helped to solve some of the unstable cases MeteoSwiss encountered but others needed extra horizontal diffusion at the lateral boundaries and just below the Rayleigh damping zone;
- use of the driving model orography at the boundaries with a smooth linear transition over 20 grid points to the high resolution orography in the inner domain (llbc_smooth in INT2LM);
- nice semi-idealized simulation of the thermal circulation in the Inn-valley.

During the whole project period many test cases were evaluated. Starting with 10 weather episodes from high precipitation MAP cases in 1999 to convective, storm and stratus cases and then to verification periods for COSMO 2.2 over the months of July to October 1995, 1997 and 1999 (COSMO-2 for WINDBANK). The encountered instabilities led to the following choices for the configuration of both COSMO 2.2 km and 6.6 km:

(see: *ftp://ftp.cscs.ch/in/put/abc/morsier/*200703*_gdm_RK_Langen.ppt*)

- the use of the SL advection of humidity variables instead of the Eulerian Bott 2nd order polynomials. These schemes are positive definite but the SL scheme uses multiplicative filling instead of clipping to achieve this property;
- the use of the standard 3rd order in time RK version instead of the more precise Total Variation Diminishing (TVD) variant which is also 3rd order in time but has less smoothing properties;
- the fixing of a bug in LM2LM in the shift of the boundary layer structure of the temperature (and horizontal winds). This helped to get the model started when downwards extrapolation into deep alpine valleys produced warm air bubbles.

2.2.2 General testing and some verification results

The choices made after the above first difficulties are still operational and the following list shows the systematic verification operated before the introduction of the 2 new models in February 2008:

(i) 6.6 km vs. 7 km

For the winter period a very slight improvement of the wind strength could be seen in the SYNOP verification over the whole domain. There were also some differences in the precipitation at the proximity of the boundaries and this also impacted on the cloud cover. But these effects were not significant.

(ii) Storm 18-20 Jan. 2007 (Kyrill)

This storm event was used to check the stability of the different numerical settings. Curiously the main differences were not seen in the wind speed but in the 2m temperature, on the total cloud cover and the precipitation. This is shown in Fig. 13.

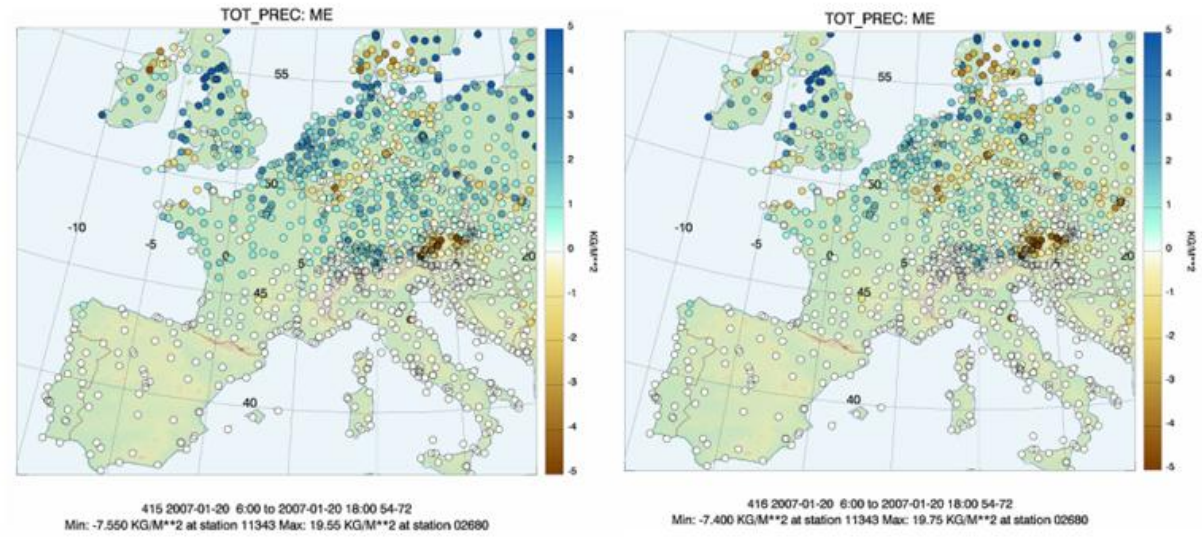

Figure 13: Kyrill precipitation in configuration COSMO 6.6L60.1 (left) and COSMO 6.6L60.2 (right).

(iii) 2.2 km, 7 km, 45 and 60 levels

These experiments were all conducted with their corresponding assimilation cycles to have the best initial and boundary conditions and to prevent differences to come from a common experiment setup. The results are illustrated with the upper-air verification in Fig. 14. There is a problem with the boundary layer of the fine 60 level version (L60.1 of version 424) and these results led to the choice of new vertical levels based on the IFS model (L60.2 of version 427) because the explicit vertical diffusion of the TKE with the very fine vertical model resolution was not stable (see Oliver Fuhrer's presentation at the General Meeting in Kracow in September 2008).

(iv) 2.2 km RK vs. 6.6 km RK vs. 7 km LF

(s3: JuneJulyAugust, s4: SeptOctNov, s1: DecJanFeb)

- S3: The differences in performance are generally small, but in a few cases, there are quite large differences. Notably the standard deviation of the surface pressure error is much decreased in COSMO-2 relatively to COSMO-7. This is probably a direct effect of the better representation of the topography in COSMO-2 and shows the limit of vertically interpolating surface pressure to the station height with a constant gradient. The smaller bias in the 2m-temperature shows that the gradient used in the vertical interpolation to the station high is not optimal. In contrast to surface pressure, using a constant gradient is not a problem, as the standard deviation confirms. Both of these effects show up in the Alpine domain because all stations are used for verification, regardless of the height difference between station and model surface. The precipitation deficit with strong precipitation in COSMO-7 is ameliorated in COSMO-2. The bias and the frequency bias of strong precipitation (> 10 mm/12h) are both much closer to their optimal value 0 and 1, respectively. For 4 different months the following Fig. 15 shows the much better performances of the Runge-Kutta scheme against the operational Leap-Frog for the same horizontal resolution of 7 km;
- S4: The pre-operational COSMO-6.6 with Runge-Kutta integration scheme generally performed about the same or slightly better than the operational COSMO-7 with Leap Frog in October 2007 and Runge-Kutta in November 2007. The exception is cloud coverage, where COSMO-6.6 has a clearly increased positive bias. Large differences are found in the precipitation, which is significantly reduced in COSMO-6.6. The positive bias in COSMO-7 is negative in COSMO-6.6 and slightly larger in absolute value. This is however mainly an effect of the few very much overestimated stations along the model boundary. The positive frequency bias for the smallest threshold (0.1 mm/12h) has decreased. For the largest threshold (10 mm/12h) however, the slight underestimation of the frequency of occurrence in COSMO-7 is amplified to a considerable underestimation in COSMO-6.6. Consequently, the probability of detection drops for this threshold by more than 5%.

(v) 6.6 km vs. 7 km RK

The pre-operational COSMO with 6.6 km resolution generally performs about the same or slightly better than the operational COSMO with 7 km grid spacing. The exception is dew point temperature, where COSMO-6.6 has an increased positive bias, but the standard deviation is still slightly smaller. A special case is the wind speed. It is notoriously underestimated at mountain tops by all COSMO versions due to the non-representativity of mountain tops for grid cell averages. The reduction in wind speed increases this negative bias, but it also decreases the positive bias at many stations in the Swiss Middleland, which is the more important aspect.

The previously found large differences in the precipitation between COSMO-7 and COSMO-6.6 have disappeared due to the fact that both versions now run with the Runge-Kutta integration scheme. Only for the large precipitation (> 10 mm/12h), COSMO-6.6 has a smaller frequency bias.

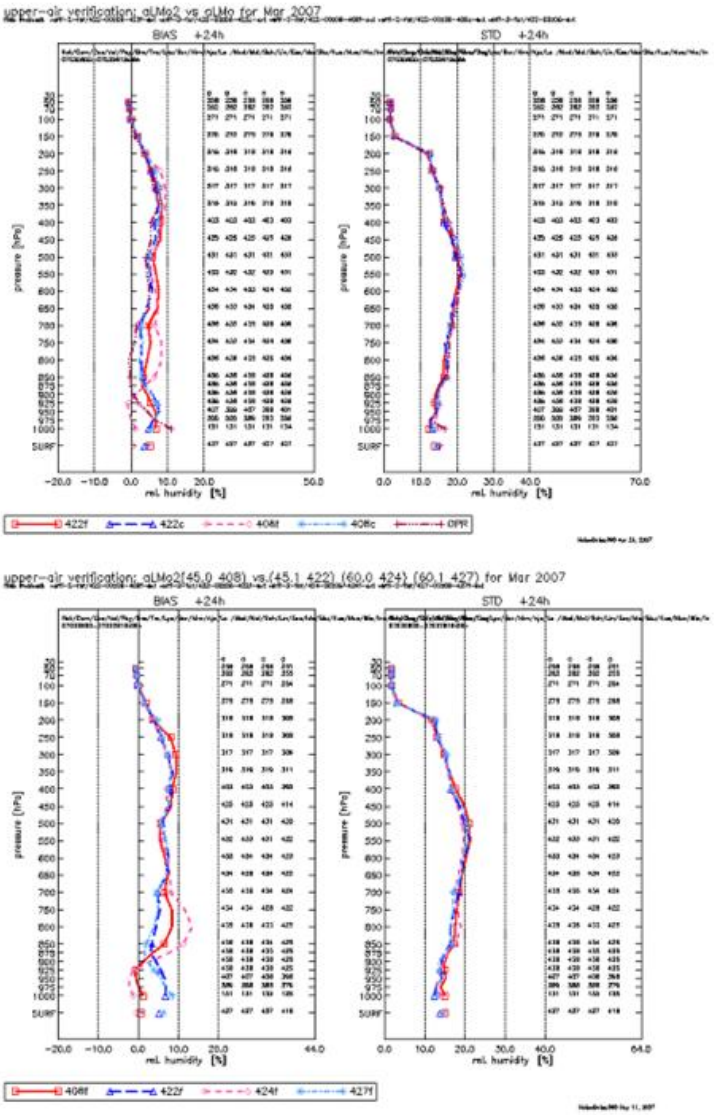

Figure 14: Upper-air (TEMP soundings) relative humidity verification (bias left and standard deviation right) of 24h forecasts in March 2007 for 5 different model versions: OPR: Leap Frog L45; 408: Runge-Kutta 7 km L45, 2 km L60.1; 422: Runge-Kutta L45; 424: Runge-Kutta L60.1; 427: Runge-Kutta L60.2. The letter "c" at the end of the experiment tags stands for coarse (7 km) and "f" for fine (2.2 km).

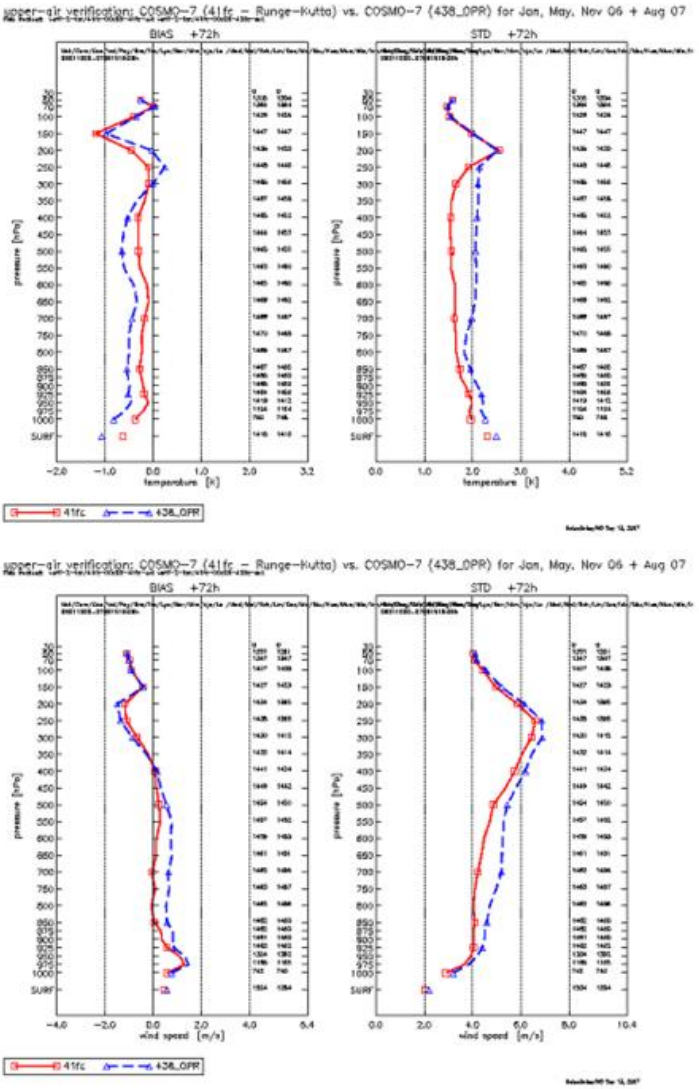

Figure 15: Upper-air (TEMP soundings) temperature (top) and wind speed (bottom) verification of 72h forecasts in Winter, Spring, Autumn 2006 and Summer 2007. The red curves are for the Runge-Kutta version and the blue curves are for Leap Frog.

2.3 Task 3: A Tool for Testing Conservation Properties in the COSMO-Model

2.3.1 Introduction

The fundamental equations of fluid mechanics, especially those used in Meteorology, can be formulated as conservation equations (or at least as balance equations) for mass, momentum and energy, as an example. Therefore a possible conservation of these variables (or others, like potential vorticity) should be obtained in a numerical model. Unfortunately this cannot be achieved in general but is guaranteed at most for a few variables in models which are formulated and also discretized in flux form. In all other cases it would be desirable to determine the strength of conservation violation. To this purpose, a tool was developed to determine budgets of arbitrary scalar variables for the COSMO-Model over an arbitrarily given cuboid volume inside of the model domain (see Fig. 16).

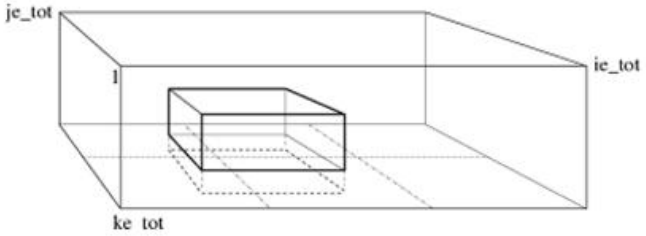

Figure 16: Integration area 'cuboid' lying in the model domain (in the transformed coordinate system). Here, a 3 * 2 domain decomposition is shown.

A general balance equation for a scalar ϕ (a generalized density) with an appropriate flux $\mathbf{f}_\phi$ reads in integral form (i.e. over a steady volume V):

$$\frac{d\Phi}{dt} + F_\Phi = Q_\Phi \tag{8}$$

total amount:

$$\Phi = \int_V \phi dv \tag{9}$$

total flux:

$$F_\Phi = \int_{\partial V} \mathbf{f}_\phi \cdot d\mathbf{A} \tag{10}$$

all sinks/sources:

$$Q_\Phi = \int_V q_\phi dv \tag{11}$$

In the case of ϕ being an integral conservative variable the right hand side of the first equation vanishes and the residuum $Res = d\Phi/dt + F_\phi$ describes the violation of conservation. Consequently, for the determination of these budgets, one has to be able to calculate volume integrals and surface integrals over fluxes in the model. The user of the 'conservation testing tool' first has to define the points in the model area which define the integration box volume (see Fig. 16). The coordinates of the corners of the cuboid imin_integ, imax_integ, jmin_integ, jmax_integ, kmin_integ, kmax_integ are read from the NAMELIST-parameter group DIACTL. In doing this the user is completely independent of any domain decomposition of the model parallelization. Secondly, one has to deliver a scalar field ϕ at the grid

position of the scalars (i, j, k) to calculate the volume integral over it. Thirdly, one has to deliver the vector field $\mathbf{f}_\phi$ whose components are defined at the grid positions of u, v, and w respectively to calculate the flux integral over the surface of the box. The details of the numerical implementation of these integrals and the subroutine calls to use the tool are described in Baldauf (2008b), section 2 and 5, respectively.

2.3.2 'Shift-test'

To test the abilities of the integration tool, a simple 'shift-test' is performed: an initial distribution is given and is simply shifted (or one could say: is transported by a perfect advection scheme) with a constant velocity through the model domain. On a discrete grid there occur some inaccuracies in the balance of this process which will lead to two artifacts. Firstly, a 'volume calculation artefact', which can arise for a transport with a non-integer Courant-number simply by a sampling error (this artefact is partly due to this artificial shift test, it cannot occur in a finite-volume schemes). Secondly, and more important, a 'flux calculation artefact' occurs due to errors in the estimation of the flux field $\mathbf{f}_\phi$ from the neighboring grid point values of ϕ. An unexpected result was that a simple upwind first order calculation is partly better than a second order centered difference or even higher order flux calculation (with or without higher order RK-time integration). However, recent studies by R. Petrik (MPI Hamburg) show that a Lax-Wendroff flux calculation seems to be the best choice. The addition of both artifacts can disturb the balance of conservation. In the tested example a relative error of the residuum of about 10^{-4} occurs. Nevertheless, the simple shift test did not show a significant programming error in the tool.

2.3.3 Weisman-Klemp test case

A first application of the integration tool was carried out with the idealized warm bubble test case (Weisman and Klemp, 1982). An ellipsoidal warm bubble serves as an initial disturbance with an increase of temperature of max $\Delta T = 2$ K. The atmosphere is in steady state at the beginning. The physics parameterizations are completely switched off, only the saturation adjustment (condensation and evaporation) is active. Therefore only water vapor q_v and cloud water q_c can occur. Further on there occur only advective fluxes $\mathbf{v}\rho_x$, but no turbulent or sedimentation fluxes. In Fig. 17 the balance of the moisture mass is shown. During the rising of the bubble (approximately the first 400 timesteps) moist air is sucked especially from the lower portions of the atmosphere. When the buoyancy is reduced, the bubble expands sidewards and blows out the moist air (timesteps 400-600). During this process the positive tendency of the mass change is not very well balanced by the negative tendency of the flux divergence (and vice versa); the residuum is rather big (Fig. 18). And therefore the relative error is about 0.7%. Therefore the question arises if this is a real error in the model or an artefact by the integration tool. Because the (conserving) Bott-advection scheme delivers very similar results, the problem seems not to be due to the Semi-Lagrange advection scheme, which was used here. The error in the total mass calculation of about 0.04% seems to be too small to explain this moisture mass change, too. Further effects of the 'flux integral artefact' could be excluded by an increase of the box volume by a factor of 2 in both x- and y-direction which does not change the residuum. This indicates, that the violation of the conservation is not induced by the inflow through the boundaries, but there seems to be a violation of conservation by the description of the physical process by the model.

A further experiment, where the the saturation adjustment was switched off showed a dras-

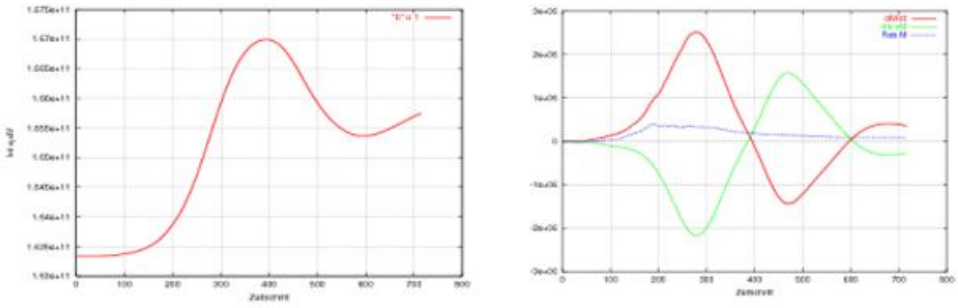

Figure 17: Weisman-Klemp-test case, density of moisture $\rho_x = \rho_v + \rho_c$, total mass of moisture (left); right: balance terms $\Delta\Phi/\Delta t$ (red), F_ϕ (green) and the residuum (blue).

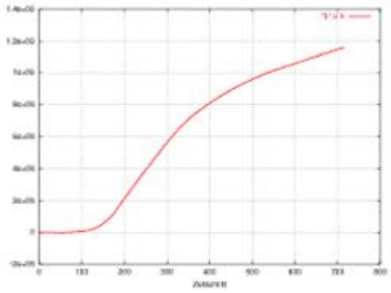

Figure 18: as Fig. 17 for the temporal integral of the residuum ΔM.

tically reduced residuum. This indicates, that the cause for the violation of conservation of moisture mass stems from the saturation adjustment. Indeed, the saturation adjustment in the COSMO-model conserves the specific mass (and specific energy) but not mass (and energy) themselves. This test serves as a first example to show in which way such a conservation testing tool can find hidden inconsistencies of the model. Although such a tool itself has some inherent, sometimes misleading properties as was discussed shortly for the 'shift-test', it can be used successfully at least in idealized simulations and can give valuable hints for the violation of conservation properties.

2.4 Task 4: Advection of moisture quantities in conservation form

This task is described in more detail and with further references in Förstner, Baldauf, and Seifert (2006). In the beginning of the development of COSMO-DE stable integration of the prognostic equations for the moisture quantities (q_x) was realized by doing two sequential Eulerian advection steps with half the time step of the dynamics to ensure Courant numbers less than one. Furthermore, to deal with the transport equations in advection form, after calculating the flux divergence the additional divergence term was subtracted, thereby destroying again the positive definiteness of the flux form advection scheme ("Flux Form - DIV"). Skamarock (2006) summarizes and presents ideas which combine several desirable properties of transport schemes used up to day. He concentrates on Eulerian schemes in flux-form and addresses splitting errors, mass conservation, Courant number restriction and positive definiteness. Following these ideas different schemes were implemented in the COSMO-DE in a Courant number independent (CRI) way. To switch to a "Conservation Form" of the equations, the specific moisture quantities are first multiplied with the air density. Then the resulting densities are transported and finally transformed back into the specific values. To do this a value for the air density, which was updated using the same advection scheme as for the moisture, is used. Since the advection is split into separate 1D steps for the different directions, a Strang-splitting approach is used to reduce the splitting error. To circumvent the Courant number restriction, the Courant number at each cell face is broken up into an integer and a remaining fractional part. While flux calculation is quite simple for the integer part only, the fractional part is dealt with a more sophisticated flux form transport scheme which is normally restricted to Courant numbers less than one. As a scheme with rather low numerical diffusion, a CRI version of Bott's (1989) positive definite advection was implemented into the COSMO-DE. The Bott scheme is realized in two variants with either second or fourth order polynomials for the calculation of the integrated (fractional) fluxes. When we compare the CPU time for a real case simulation, where advection is calculated for all six prognostic moisture variables q_v; q_c; q_i; q_r; q_s and q_g, while the fourth order version is slightly more expensive, the second order one is comparable to the semi-Lagrangian transport in this respect. All in all with the CRI version of the Bott scheme we get a high-order positive definite scheme at a reasonable computational cost. To verify the correct implementation and for comparison of the different schemes idealized advection tests were carried out with the COSMO-DE. As a first and also very common test, the solid body rotation of a tracer cone was simulated (Fig. 19). In the case shown, the angular velocity was rather high, leading to Courant numbers well above one. The schemes perform equally well, at least in two aspects: first the Courant number independence is fulfilled, since in each case we get a stable integration; second the circular shape of the cone is more or less retained, i.e. errors due to the directional splitting method used for the Bott scheme are negligible.

A tracer experiment where an almost uniform tracer distribution was transported in the flow field of a real case study clearly showed that it is not a good idea to use the "Flux Form - DIV" variant mentioned above and the "Conservation Form" of the equations is clearly to be preferred. Further details can be found in the newsletter article. The 2nd order Bott scheme is currently used for the advection of the moisture variables in the COSMO-DE. Additionally the Bott advection was tested in the COSMO-EU in a quasi operational setup. These tests were run over periods of several months. While most of the time these runs performed well and without serious deficiencies, a crash of the model could be traced back to the moisture advection. In this case the splitting error due to the splitting of the horizontal and vertical directions in combination with a very steep slope of the terrain led to this failure. Similar results were obtained at MeteoSwiss where the scheme failed in several cases due to the steep slopes in the Alpine region. It is possible to reduce the splitting error by a more complete

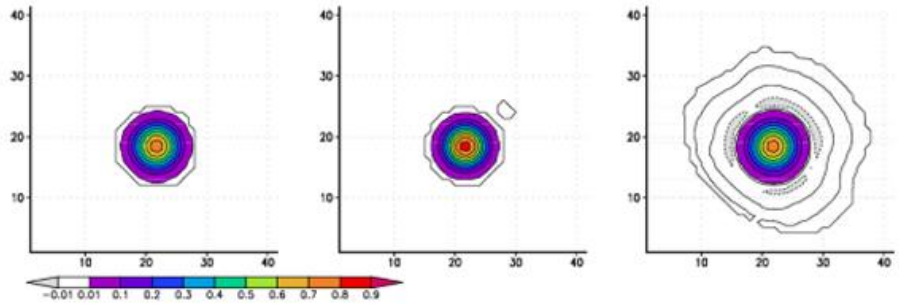

Figure 19: Solid body rotation of a tracer cone with an initial maximum of 1.0. Results after 80 time steps equivalent to one revolution. The Courant Number in the domain is close to a value of 3 near the lateral boundaries and approximately a value of 2.2 at the centre of the cone. Left: Bott (2nd order); Middle: Bott (4th order); Right: semi-Lagrange (tri-cubic).

but also more expensive (by a factor of 5/3 for the advection) form of the Strang splitting. In contrast, the semi-Lagrange advection is a multi-dimensional scheme, which needs no directional splitting and therefore proofed to be more robust in these situations. But it has the disadvantage to be a non-positive definite scheme, for which a simple clipping violates the conservation. This can be cured in a rough manner by a global acting multiplicative filling algorithm. In verifications done at CNMCA, the semi-Lagrangian scheme also gave slightly better scores for 7 km runs.

2.5 Task 5: Investigation of convergence

The aim of Task 5 is to study and analyze convergence properties of the Runge-Kutta dynamical core at high resolutions. Such properties can be inspected by considering different horizontal resolutions and a very good resolved vertical coordinate. Tests where done with:

- 2-dimensional linear mountain flows, both hydrostatic (Na/U $\gg 1$) and non-hydrostatic (Na/U ~ 1),
- 2-dimensional non-linear mountain flows (NH/U ~ 1),
- 3-dimensional mountain flows

For all mountain sizes 4 or 5 different horizontal resolutions were tested, in order to evaluate the spatial convergence of the scheme. For all cases the Brunt-Väisälä frequency N has been set equal to 0.01 Hz and the basic flow velocity U is 10 m/s. The mountain ridge has a Gaussian shape, $h(x) = Hexp[(-x^2/a^2)log2]$, where H is the mountain maximum height and a (the mountain width) is the horizontal distance from the mountain top where the height is H/2. The following results are all performed with the p'T'-dynamics. The Rayleigh damping layer starts at 11 km.

Several error measures (error norms) for the variables vertical velocity, kinetic energy, wave drag, U-momentum component were inspected:

- L0 = max $\mid F - F_{finestmesh} \mid$
- L1 = $1/N \sum \mid F - F_{finestmesh} \mid$
- L2 = $[1/N \sum (F - F_{finestmesh})^2]^{1/2}$

The reference solution in each case is a high resolution simulation on the finest mesh. The summation is performed over a subdomain containing the mountain.

The mountain wave drag will be computed by integrating the surface pressure in the x-direction.

$$D = \sum p'(x,0) dh/dx \Delta x \tag{12}$$

The vertical flow of the U- momentum component will be computed at each grid level by summing up all the cells in a grid level

$$D(z) = -\sum \rho_0(z) u'(x,z) w'(x,z) \Delta x \tag{13}$$

The values obtained will be compared, if possible, with the analytical solution (available in the linear hydrostatic case). To extract the effect of the improved horizontal discretization schemes, a very good resolved vertical coordinate Δz = 100 m was used which at least for the hydrostatic test cases should always lead to well converged solutions. There occurred some problems with the inflow and outflow boundaries, where the vertical velocity had positive values partially in the same order as the signal from the mountain (see Fig. 20, left). This error is too small to be noticeable in real-case applications; however, it becomes evident in idealized simulations with constant flow and a very low mountain (or no mountain at all). These artifacts could be reduced by initializing with the reference state, i.e. to set p'=0 and T'=0. An alternative solution for this problem was found by G. Zängl: the perturbations occur because the present initialization of the perturbation pressure field (executed in

src_artifdata for idealized simulations, otherwise in int2LM) is not exactly consistent with the discretized buoyancy term in the vertical momentum equation. To fix the problem, a new initialization procedure has been developed by solving the discretized vertical wind equation (for dw/dt = 0) for p'; ideally, this would ensure strict absence of buoyancy at the lateral model boundaries. The improvement by this measure can be seen in Fig. 20 (right).

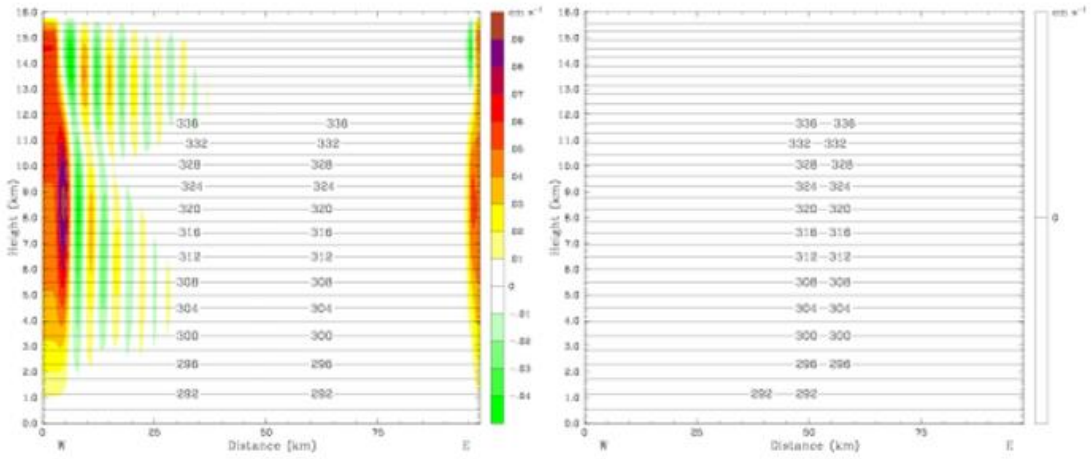

Figure 20: Comparison of the old p' initialization (left) which delivers error amplitudes of about w $\sim$ 1 mm/s and the new one (right) with error amplitudes of w $\sim 10^{-4}$ mm/s. Simulation with flat surface, u = 10m/s, and fixed relaxation b.c.'s, t = 12 h. Fields: Θ (contour interval 2 K), w (colors).

2.5.1 Hydrostatic linear mountain flow simulations

In case of a hydrostatic 2-dimensional mountain flow (mountain width a=10 km, mountain height H=10 m and U/Na=0.1), simulations have been performed with constant horizontal resolution Δx equal to 4000 m, 2000 m, 1000 m and 500 m, along either x- and y- directions ($\Delta x = \Delta y$). The extension in y-direction always covers 7 cells. The mountain ridge is located in the middle of the domain. As mentioned Δz=100 m with 195 vertical levels was set. The total simulation time is 60 h. For all the resolutions the same timestep dt=2.5 sec was used with a domain size of 500x19.5 km^2. The chosen horizontal resolutions are 4 km, 2 km, 1 km, 500 m (250 m). A comparison of L0, L1, L2 error norms for vertical velocity and kinetic energy for the two versions of the 3rd stage Runge-Kutta (TVD and 'standard') is shown in Fig. 21. The differences between the two schemes are quite small (note that for the TVD scheme the plot shows also the 250 m resolution), and only a small advantage of the 'standard' RK3 (Wicker and Skamarock, 2002) compared to the TVD-RK3 can be detected. The convergence is less than 2nd order for the resolutions simulated here, but the plots for the kinetic energy show that a nearly 2nd order convergence is approached for higher resolutions.

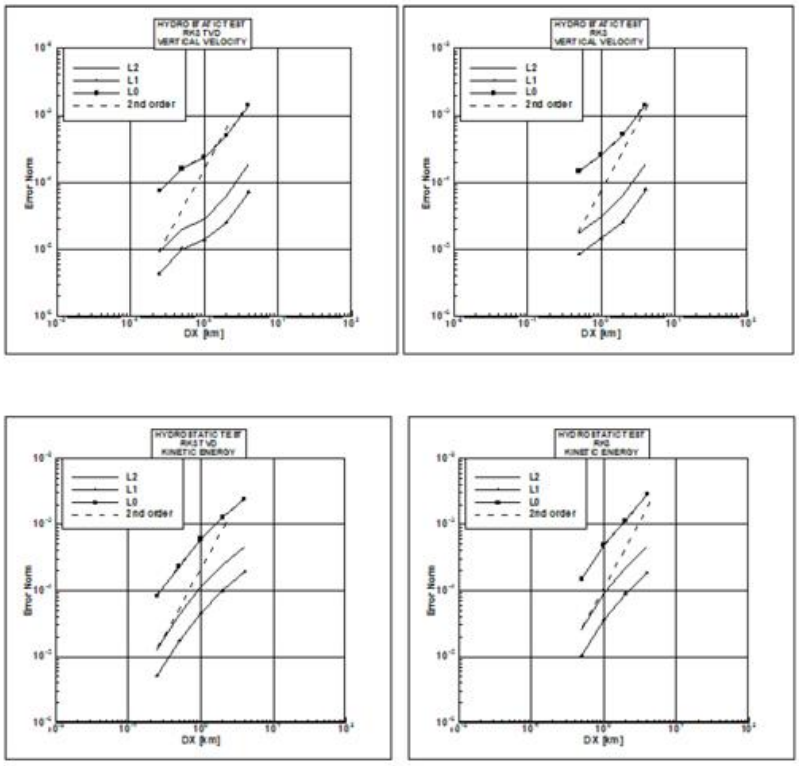

Figure 21: error norms L0, L1, L2 for vertical velocity and kinetic energy for the TVD Runge-Kutta and the standard Runge-Kutta scheme in the hydrostatic linear case. Dashed lines indicate 2nd order convergence.

2.5.2 Hydrostatic non-linear mountain flow simulations

Now the mountain has a height of H = 500 m with the same width than before (a=10 km). The simulation time had to be chosen a little bit longer to attain stationary results (Time = 100 h). Again the same time step dt = 2.5 sec has been chosen. The domain size was 500x19.5 km^2 and the horizontal resolution is 4 km, 2 km, 1 km, 500 m, (250 m). The height of the mountain was chosen in a manner that any non-stationary effect should occur. As the theory foresees, the wave breaking over a gaussian ridge takes place for NH/U>0.85 (which means H>850 m). Whereas the kinetic energy behaves completely similar for the two RK-schemes, the vertical velocity converges better in the TVD-variant.

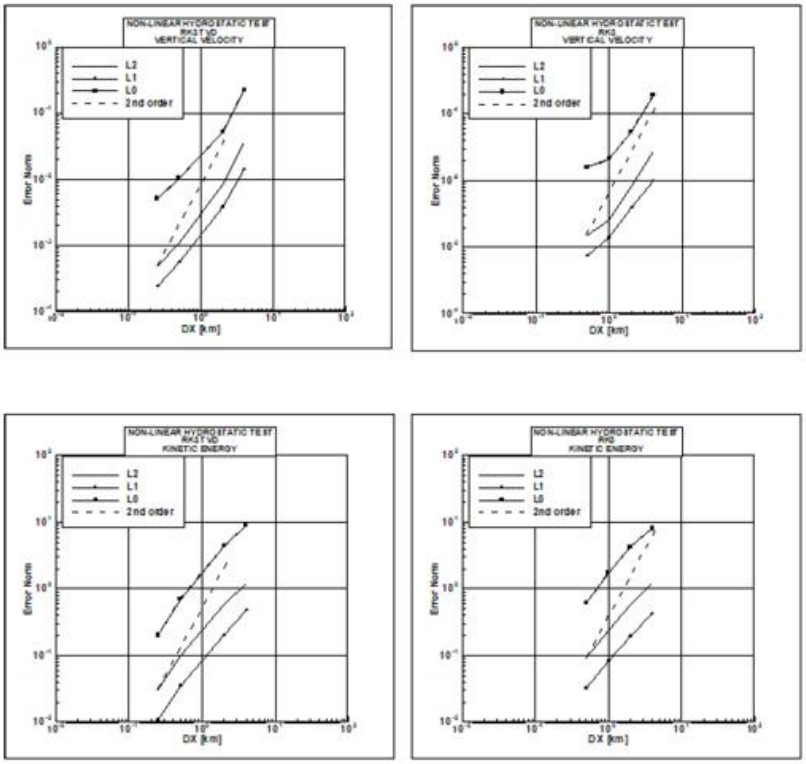

Figure 22: error norms L0, L1, L2 for vertical velocity and kinetic energy for the TVD Runge-Kutta and the standard Runge-Kutta scheme in the hydrostatic non-linear case. Dashed lines indicate 2nd order convergence.

2.5.3 Non-hydrostatic linear mountain flow simulations

In case of non-hydrostatic mountain flow (mountain width a=500 m, mountain height H=10 m which leads to U/Na=2.0), simulations with a constant horizontal resolution equal to 2000 m, 1000 m, 500 m, 250 m and 125 m ($\Delta x = \Delta y$) have been performed. Also in this case Δz has been set to 100 m and 195 vertical levels have been used. The total simulation time is 100 h, dt = 2.5 sec, and the domain size is 250x19.5 km^2; the horizontal resolutions are 1 km, 500 m, 250 m, 125 m. In this case no differences can be seen for the two RK-variants (Fig. 23 and Fig. 24).

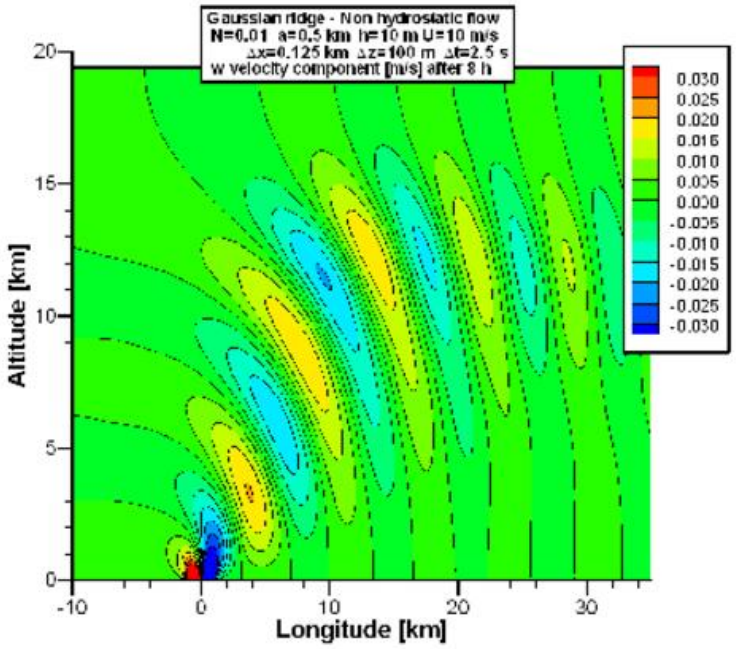

Figure 23: Non-hydrostatic flow example: vertical velocity.

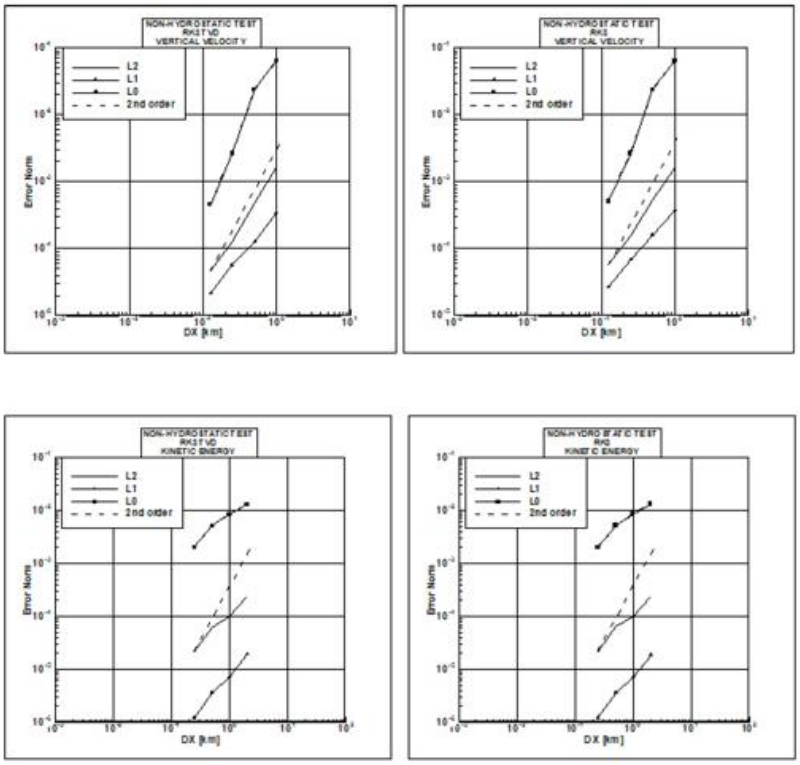

Figure 24: error norms L0, L1, L2 for vertical velocity and kinetic energy for the TVD Runge-Kutta and the standard Runge-Kutta scheme in the non-hydrostatic linear case. Dashed lines indicate 2nd order convergence.

2.5.4 3D mountain flow tests

In Gassmann (2002), chapter 5, the flow solutions obtained with different time integration schemes (Leap Frog and Runge Kutta) and resolutions for an Agnesi mountain were simulated and showed a rather different behaviour for different resolutions. The idea is to show that a similar behavior is only due to the different spatial scheme (i.e. 3rd order and 5th order upwind), and to the grid size.

In the present test case the mountain has again a gaussian shape, h=750 m, and a=10 km. It was not possible to get a steady solution for a 1500 m high mountain as in Gassmann (2002). The grid spacing ranges from 16 km to 4 km (smaller sizes up to 0.5 km were tested, but the solution does not change significantly) and the horizontal domains are 352 km x 352 km for the 16 km grid, 256 km x 256 km for the 8 km grid, 256 km x 128 km for the 4 km and smaller meshes (not shown here). Again 195 vertical levels with constant spacing of 100 m have been used. Reference dry atmosphere has been defined with constant Brunt-Väisälä frequency N=0.01 s^{-1}, ground Temperature 15 Celsius and ground pressure 10^5 Pa. Basic flow velocity U=10 m/s. Test runs were carried out for 20 hours, that is enough for disturbances traveling at 10 m/s to be advected away from the flow domain.

All the test cases have been computed with 3rd order Runge Kutta TVD time integration scheme (RK3), setting the iadv_order input parameter to 5 (that is indicated as UP5 in the pictures) and 3 (UP3 in the pictures).

In Fig. 25 something similar to Gassmann (2002), fig. 5.1 is shown, i.e. the vertical velocity component for different resolutions at the symmetry plane of the flow domain. The pictures cut away most of the Rayleigh damping layer, that starts from an altitude of 11 km and is 85 levels thick. In Fig. 26 the horizontal velocity component at the ground level is shown. The differences between the UP5 and UP3 schemes are visible. Note that in the coarsest resolution among the tests in Gassmann (2002) the grid size was about 3 times the mountain width (7 km / 2.6 km), that might explain the larger differences there.

The following conclusions from the convergence tests can be drawn:

- for 2D flows:
  - slightly less than 2nd order spatial convergence was reached. Obviously the convergence rate is dominated by the 'weakest' discretization, the fast waves scheme;
  - TVD and non-TVD 3 stages Runge Kutta show similar behaviour with slight advantages of the standard scheme in linear cases and slight advantages of TVD in non-linear cases;
  - the time step has minor effect (if any) on spatial convergence;
  - 2D flow tests are rather sensitive to a proper parameter setting for the upper and lateral boundary conditions (damping layers); fortunately these sensitivities are much less for 3D flows;
  - it was difficult to compare with analytical solutions (Baldauf, 2008c), due to boundary conditions (see below).
- for 3D flows:
  - the optimal damping parameter dt*nrdtau increases to $\sim$ 1000 s;
  - with poor resolutions different schemes can give different solutions. This is an indication that the resolutions are far from convergence. Here the higher order upwind schemes can improve the results (see Fig. 25 and Fig. 26);

– during this task, a program to calculate linear solutions for flow over mountains with very few approximations was developed. The theory behind it and implementation details are described in Baldauf (2008c). Fig. 27 shows the quite good similarity between this linear analytic solution and the COSMO-model simulation over a bell-shaped mountain with a high frequency modulation.

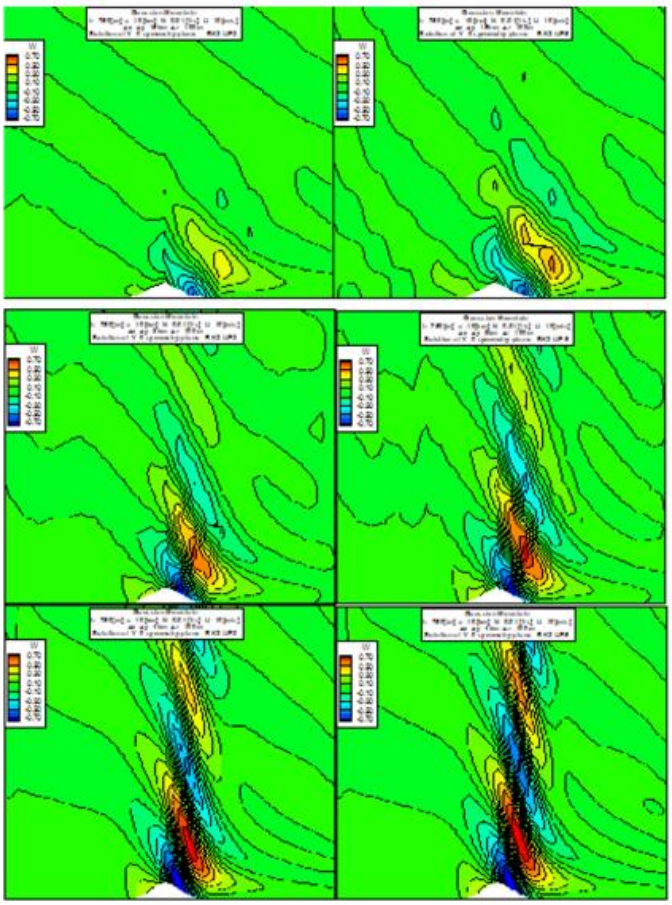

Figure 25: Velocity vertical component at the symmetry plane. On the left: solutions obtained with 3rd order upwind. On the right: solutions with 5th order upwind. From top to bottom horizontal grid spacing: 16 km, 8 km, 4 km. The horizontal size of the picture ranges from -96 km to 96 km, the vertical size from 0 to about 12.65 km.

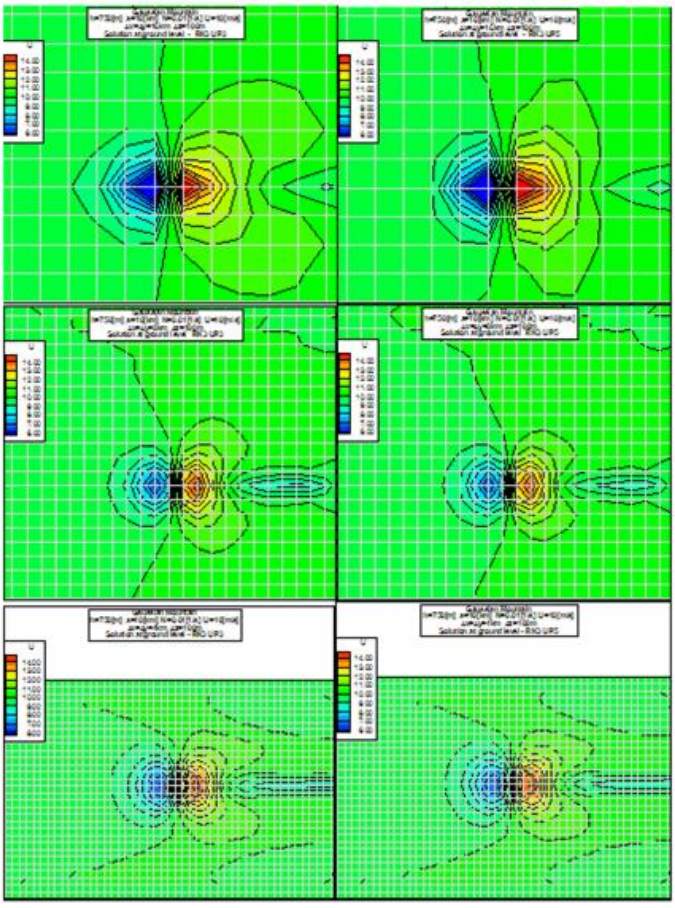

Figure 26: Velocity longitudinal component at the ground plane. On the left: solutions obtained with 3rd order upwind. On the right: solutions with 5th order upwind. From top to bottom horizontal grid spacing: 16 km, 8 km, 4 km. A gray circle (radius 10 km) indicates the mountain position.

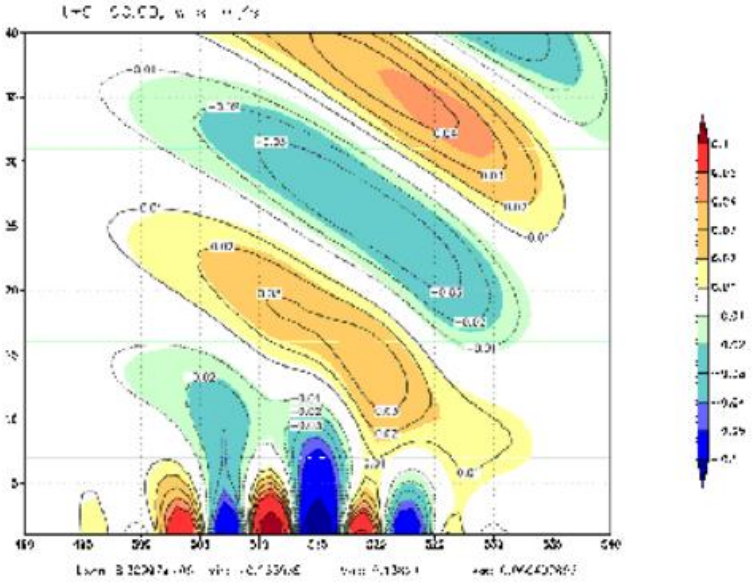

Figure 27: Comparison of the vertical velocity between COSMO-Simulation (colors) and the analytic solution (contours).

2.6 Task 6: Deep valleys + Task 7: Different filter options for orography

Task 7 is closely linked to task 6 since the filtering of orography is one measure to circumvent the problems in deep valleys. Namely the formation of unrealistic cold (or sometimes also hot) spots in the Alpine region. An example is given in Fig. 28 where on the left side a temperature plot of the Alpine region is given. In this case (3 Feb. 2005) the temperature in the first model layer reached an erroneous minimum of ≈200 K. The introduction of the "Dynamic Bottom Boundary Condition" (DYN_BBC) (Gassmann, 2004) was the key measure to circumvent the cold pool problem. This can be seen in the temperature difference plot in the right part of Fig. 28. The temperature in the run with the new bottom boundary condition is more than 70 K higher in the problematic region, i. e. no cold pool builds up. It can also be seen, that the changed BBC leads to significant changes only in the orographically structured regions. The basic equations for the DYN_BBC can be found below. For the layer right above the ground, the normal centered-difference approximation of the vertical pressure gradient term in the horizontal momentum equations ($\partial p^*/\partial\zeta$) is deteriorated. In the new formulation the momentum equations are set into the condition given in eq. 17.

$$\frac{\partial u}{\partial t} = -\frac{1}{\rho a cos\varphi}\left(\frac{\partial p^*}{\partial \lambda} + \frac{J_\lambda}{\sqrt{G}}\frac{\partial p^*}{\partial \zeta}\right) + f_u \tag{14}$$

$$\frac{\partial v}{\partial t} = -\frac{1}{\rho a}\left(\frac{\partial p^*}{\partial \varphi} + \frac{J_\varphi}{\sqrt{G}}\frac{\partial p^*}{\partial \zeta}\right) + f_v \tag{15}$$

$$\frac{\partial w}{\partial t} = \frac{1}{\rho\sqrt{G}}\frac{\partial p^*}{\partial \zeta} + g\frac{\rho_0}{\rho}\left(\frac{T - T_0}{T} - \frac{T_0 p^*}{T p_0}\right) + f_w \tag{16}$$

$$\frac{\partial \dot{\zeta}}{\partial t} = \frac{1}{\sqrt{G}}\left(\frac{1}{\rho a cos\varphi}\frac{\partial z}{\partial \lambda}\frac{\partial u}{\partial t} + \frac{1}{a}\frac{\partial z}{\partial \varphi}\frac{\partial v}{\partial t} - \frac{\partial w}{\partial t}\right) = 0 \tag{17}$$

In this way a dynamical expression for the vertical pressure gradient terms is found. The introduction of new filter options for the orography also helped to deal with the problems arising in deep valleys. A set of discrete local (i.e. applicable directly in the physical space) filters of different filter widths is used to filter the orography data. Their local nature makes it easy to combine the treatment with a local condition for the individual grid points. For the COSMO-DE first the orography is filtered globally to remove scales approximately smaller than 4Δ. In a second step a stronger filter (5Δ) is used for all points with a step of the orography still bigger than 625 m.

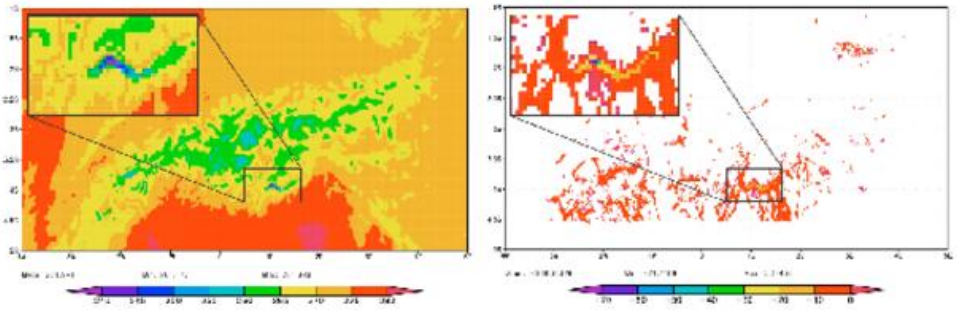

Figure 28: Left: Temperature in the lowest model layer in the Alpine region (init: 00 UTC, date: 2005020317) for a run using the old BBC. Right: Temperature difference of two runs using the old ("NO_DYN_BBC") and the new dynamic ("DYN_BBC") bottom boundary condition, i.e. "NO_DYN_BBC" - "DYN_BBC". Differences smaller 1 K are masked out.

2.7 Task 8: Higher order discretization in the vertical

For a model with increasing resolution, the vertical advection process gets increasing significance. This is the case in particular for convection resolving models with high vertical velocities and therefore a big amount of vertical transport. Due to the fact that the grid levels have a small distance in the lower part of the model, the vertical Courant numbers can reach values bigger than 1. This fact prevents the use of an explicit scheme. Indeed in the WRF model an explicit scheme is used also in the vertical. Tests with COSMO-DE (2.8 km horizontal resolution) show that a significant fraction of grid points in the model domain have vertical Courant numbers bigger than 1. To use an explicit scheme some sort of friction or simply a limitation of vertical velocities is needed. But this measure seems not adequate in a model which should not damp the resolved convection. The current model version contains an implicit scheme using centered differences 2nd order. It is absolutely stable but is not very accurate. Therefore an implicit scheme of 3rd order was implemented. It shows a better behaviour than the 2nd order scheme as can be seen in Fig. 29. But using this scheme in every Runge-Kutta step (as it is done with the 2nd order scheme) causes an increase in the overall computation time of about 30% and therefore is not ready for operational use. This amount can be hardly reduced by optimizing the scheme itself because each of the two steps, calculation of the coefficients of the 5 band diagonal equation system, and solving the linear equation system with a direct 5 band diagonal solver, takes approximately the same time.

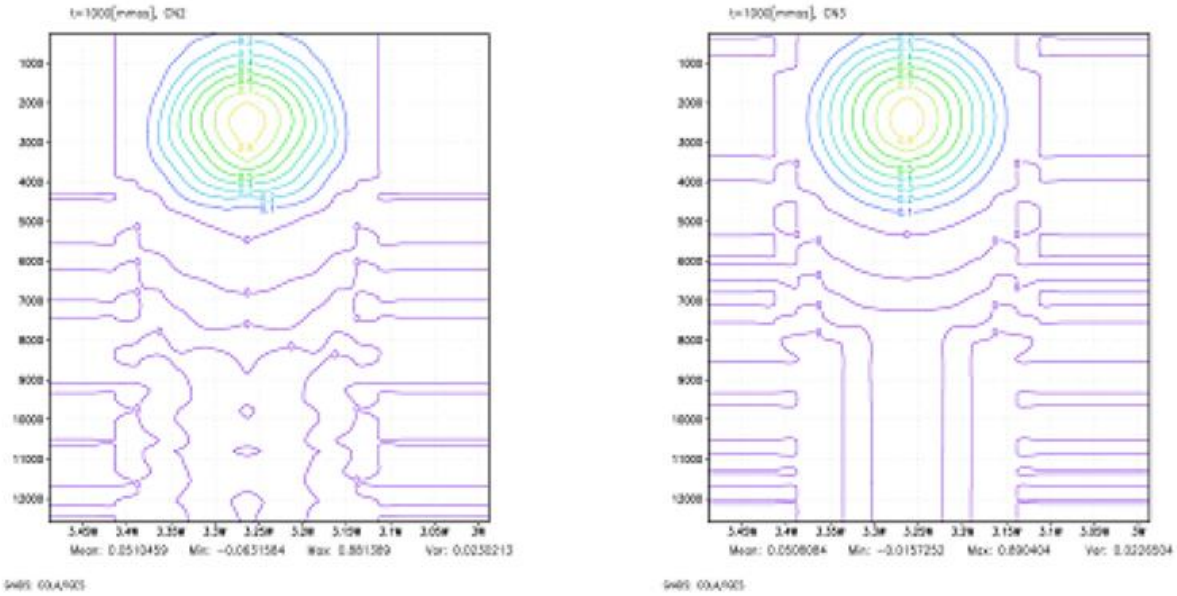

Figure 29: Implicit vertical advection; test with a constant velocity and starting with a cone distribution, 2nd order (left), 3rd order (right).

Not yet inspected is an alternative approach: the calculation of the vertical advection outside of the Runge-Kutta scheme. There are two reasons for that: first, the implicit advection needs no stabilization through the Runge-Kutta scheme, second, an implicit scheme is not very well suited for use in a Runge-Kutta substep. Questions of stability (in combination with the fast waves solver) and accuracy (splitting error) have to be inspected.

2.7.1 Addendum

Some months after finishing the Priority Project, the work on this task could be continued. The use of the implicit scheme outside of the RK-scheme leads to promising results. Pure 2D-advection tests show a strongly improved behaviour compared to the currently used scheme. The coupling with fast waves is stable and shows no significant splitting error as could be shown with linearized 2D shallow water equations. Beyond this, idealized and real test cases with the COSMO-model show a realistic behaviour of the new implicit scheme.

2.8 Task 9: Physics coupling scheme

A special procedure to couple microphysics and dynamics is described in the WRF documentation (Skamarock et al. 2005). A similar numerical treatment of latent heat is now implemented in the Runge-Kutta core of the COSMO-DE. In both models the microphysics parameterizations are calculated in one Eulerian time step after the Runge-Kutta integration of the dynamical core and the Marchuk-splitting method is used here to finally update the fields in a balanced way and complete the time step. The diabatic heating term in the prognostic equation for temperature includes the physical tendencies due to radiation, convection, turbulent mixing and latent heat conversion in the microphysics (e.g. the saturation adjustment). While the former tendencies are integrated within the acoustic steps, the last temperature tendency has not been part of this integration. The new variant uses the tendency due to latent heat conversion of the previous time step as an estimate which enters the integration of the fast waves in the same way than the other physical tendencies. After the Runge-Kutta update, this tendency estimate is subtracted again and the time step is completed as before. Tests with this new variant of coupling showed deficiencies especially in combination with the moist turbulence scheme. Especially vertical cross sections revealed 2Δz-structures of the TKE and cloud water fields. To circumvent these problems the temperature tendencies in the saturation adjustment step directly after the Runge-Kutta integration do not enter the summation of the latent heat tendencies. This could only be a preliminary solution. The reason for the mentioned problems should be studied further. Also other possibilities for the physics-dynamics coupling should be investigated.

2.9 Task 10: Testing of alternative fast wave scheme

In Gassmann (2005) a new split-explicit time integration scheme was proposed. This scheme is alternative to the Wicker-Skamarock type (1998, 2002) of splitting, which is closely related to the Runge-Kutta (RK) method. According to Gassmann this splitting method seems to have a stable and smaller splitting error compared to other existing split explicit schemes based on RK. The Gassmann scheme seems to be also more sensitive to the inconsistencies in the fast-waves terms than the RK version of Wicker and Skamarock. According to Gassmann along with this splitting method it is necessary to use the non-isotropic divergence damping and to include the vertical p*/T advection terms related to the vertical velocity w to have a consistent fast-mode solver. This implies the splitting up of vertical p*/T advection into two parts related to the two components of the contravariant vertical velocity ζ:

$$\dot{\zeta} = \dot{\xi} - \frac{1}{\sqrt{G}} w| \tag{18}$$

where

$$\dot{\xi} = \frac{1}{\sqrt{G}}(\frac{u}{acos\varphi}\frac{\partial z}{\partial \lambda} + \frac{v\partial z}{a\partial \varphi})| \tag{19}$$

the first one responsible for the actual vertical advection placed in the fast-waves solver and the second one accounting for a vertical advection component apparently present because of terrain-following coordinates involved in the slow-mode equations. A direct application of the free-slip condition is no longer possible in the p*/T slow vertical advection terms of the pressure and temperature equations. At the lower boundary the advective part of the model determines the w field:

$$w_{lowbound} = (\frac{u}{acos\varphi}\frac{\partial z}{\partial \lambda} + \frac{v\partial z}{a\partial \varphi})_{lowbound} \tag{20}$$

According to Gassmann (2006) the lower BC in this form is a slow term and it should be evaluated once per large time step and thus been held constant during the short time integration. Actually, in the slow part the full ξ=0 at the lower boundary is used (instead of ζ) in the vertical p*/T advection to avoid the evaluation of a vertical p*/T gradient which was not available in the numerical grid. A COSMO model version including the new time splitting scheme and fast-waves solver along with its documentation (Gassmann, 2006) was provided by Almut Gassmann (at that time Uni Bonn). All the tests performed with this version of code were not successful. The COSMO model crashed after a few hours of integration. Preliminary tests using the Gassmann splitting method implemented using the fast-waves solver of the RK core (without the vertical p*/T advection splitting and with the isotropic divergence damping) was successful (unofficial code) showing similar results to the default Wicker-Skamarock type RK scheme (MSLP scores are showed in Fig. 30). The above described formulation of the lower boundary condition used for the vertical p*/T advection splitting could probably be responsible for these crashes, but the issue how to formulate an appropriate lower boundary condition in this case has not been addressed.

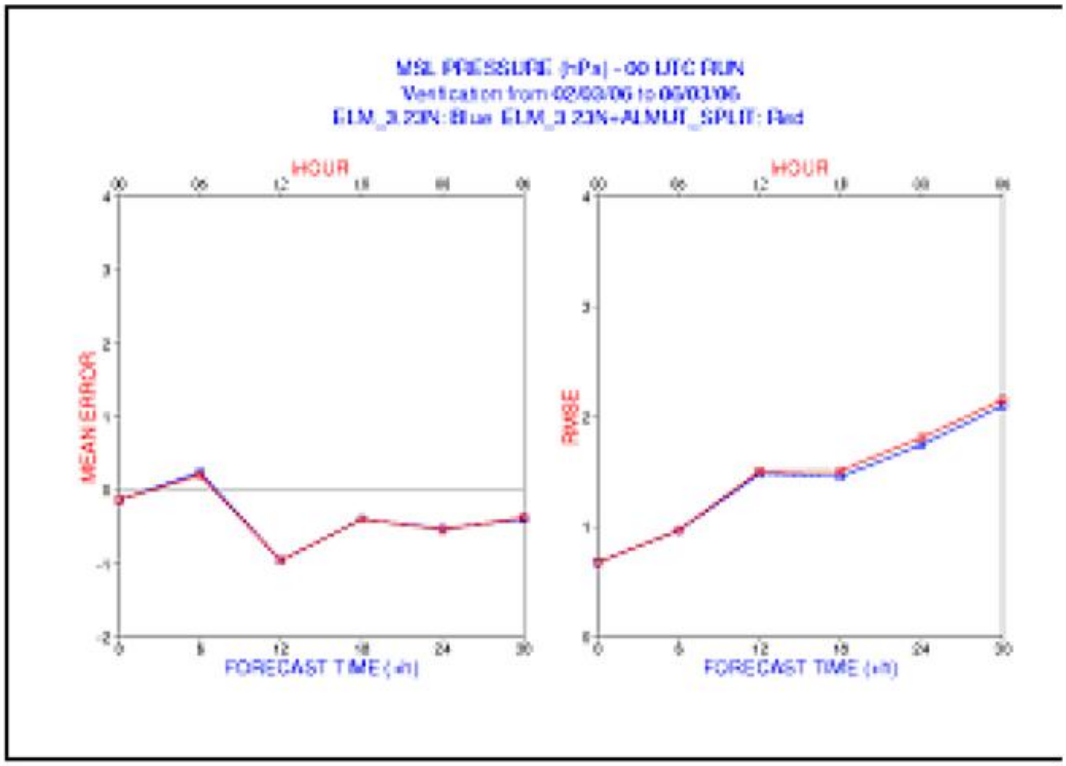

Figure 30: Comparison of pressure at MSL between the 'standard-RK' scheme and the 'Gassmann-RK'-scheme.

2.10 Task 13: Divergence damping in a true 3D-version

Cases occurred, where the up to now used 'quasi-2D' divergence filtering lead to unstable results. But a complete abandoning of the divergence filtering (as proposed by A. Gassmann for her dynamical core) also leads to several instabilities. This was also shown by stability analyzes of the RK-core by M. Baldauf. P. Prohl (DWD) could demonstrate that the Bryan-Fritsch-test case of a rising warm bubble is unstable with 'quasi-2D' divergence damping but becomes stable only with a full 3D (=isotropic) version (realized with a preliminary explicit formulation). For operational use an implicit version of 3D divergence damping is necessary. This task was defined relatively late and could not be treated during the project.

2.11 Task 14: Digital Filter Initialization (DFI)

DFI is an initialization scheme based on time filtering proposed by Lynch and McDonald (1990). The high frequencies are removed by applying a digital filter to a short time series of the prognostic model variables obtained by an integration from the initial data. The twice digital filter initialization (Lynch and Huang, 1994), implemented in COSMO model, consists of two model integrations subjected to a filter of span T: an adiabatic backward integration from 0 to -T and a diabatic forward integration from -T/2 to T/2 (see COSMO scientific documentation, part 1 for further details). The backward integration is realized by simply changing the time step Δt to $-\Delta t$. DFI did not work appropriately both in Leap-Frog (LF) and Runge-Kutta (RK) dynamical core. DFI using LF dynamics works correctly in COSMO model V3.23 with a 7 km grid spacing, after having fixed an error in the treatment of the boundary condition (dfi_initialization.f90). Some technical changes (mostly in the numerical functions of advection) were needed to run DFI using the RK core (dfi_initialization.f90, src_runge_kutta.f90, src_advection_rk.f90, fast_waves_rk.f90, numeric_utilities_rk.f90). All the odd order advection operators were changed to run in the backward model integration. The problem was that the odd order advection operators contain a dissipative term that needs a special treatment in the backward integration of the DFI. For example the 5th order horizontal advection operator is the sum of the 6th order advection operator and a dissipative term.

$$L_i^h(\phi)^{(5th)} = L_i^h(\phi)^{(6th)} + \frac{|u_i|}{60\Delta x}[-\phi_{i-3} + 6(\phi_{i-2} + \phi_{i+2}) - 15(\phi_{i-1} + \phi_{i+1}) + 20\phi_i - \phi_{i+3}] \quad (21)$$

The last term includes an absolute value of velocity and needs to be treated as the horizontal diffusion operator in the backward model run (sign of the diffusion coefficients reversed). The dissipative term of the odd order advection operators is multiplied to -1, when the integration time step is less than 0 (modifications in the next release of COSMO model). Additionally an optimization of the horizontal advection routines could be carried out by abandoning the concept of an operator acting on every grid point and using instead field operations, which can be much better optimized.

DFI using RK dynamics works well with a 7 km grid spacing after these changes. An example of the domain averaged surface pressure tendency and grid scale rain flux behaviours, as a function of the time step, are showed respectively in Fig. 31 and Fig. 32 for RK runs with (solid line) and without (dashed line) DFI. Some problems were found using RK core with a 2.8 km grid spacing. DFI worked only in some cases using the explicit version of the vertical advection.

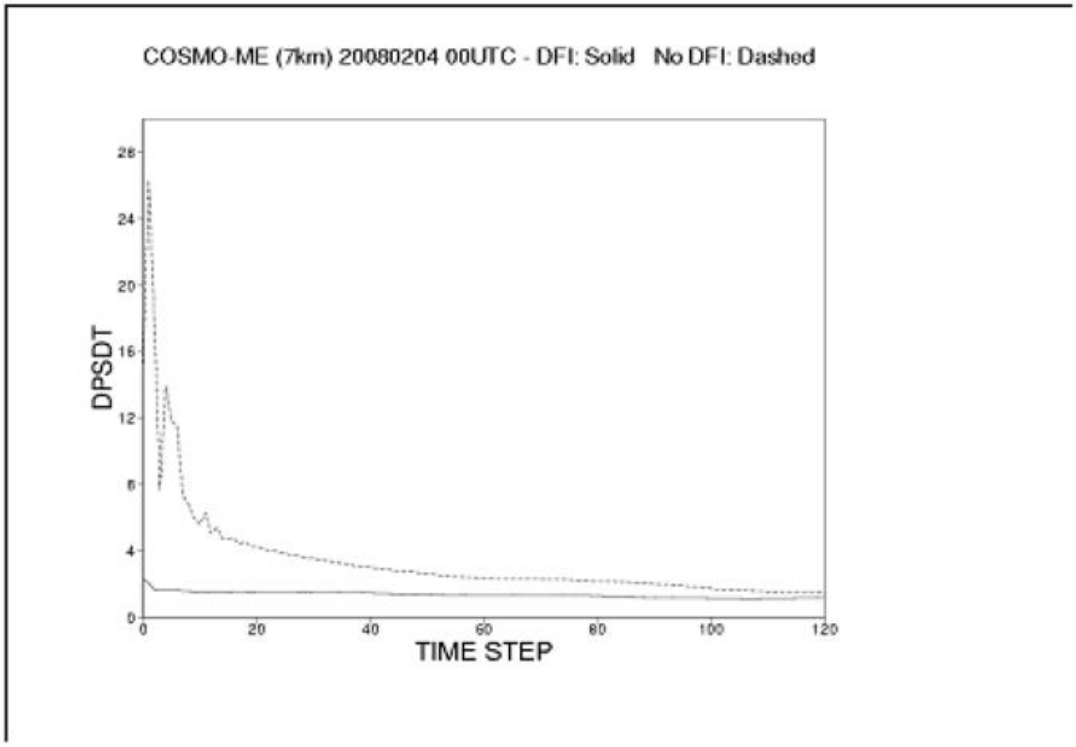

Figure 31: Domain averaged surface pressure tendency for a simulation with and without DFI.

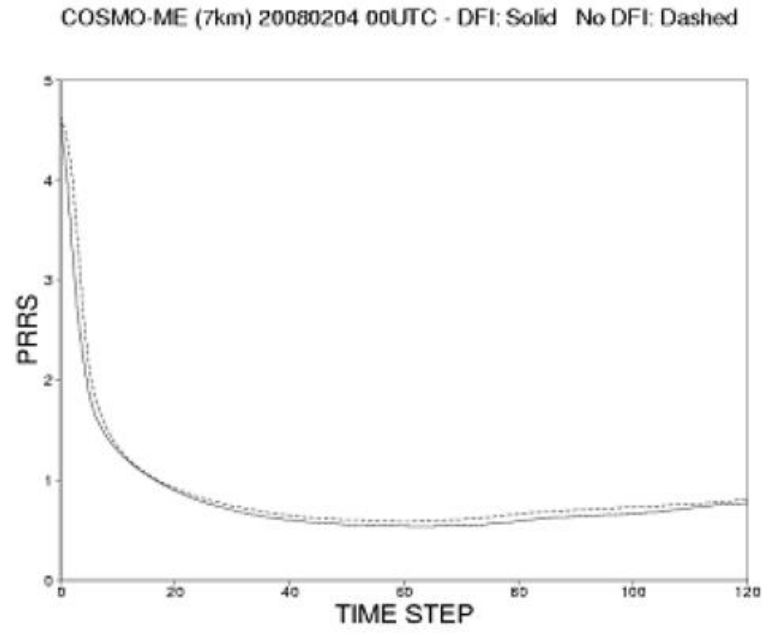

Figure 32: Grid scale rain flux for a simulation with and without DFI.

2.12 Open points

The Runge-Kutta scheme used here is adapted mainly from the WRF-model. The question that arises is if this basic scheme can be improved. A study about the stability of several combinations of Runge-Kutta schemes and horizontal advection schemes leads to only 3 useable combinations: namely RK3+upwind 3rd or 5th order and RK4 + centered difference 4th order (Baldauf, 2008a). This question was not yet inspected with the full COSMO model. Despite the fact that the pressure bias problem could be improved at least by the combination of several measures, the need of an at least mass conserving dynamical core is obvious. The problem of steep orography was solved by a slightly stronger filtering of the orography. Of course it would be more satisfying to solve this problem at the level of the discretization. Again, there is some hope to tackle this with a more conservative dynamical core (compare very interesting results with the EULAG model).

2.14 Lessons learned

In this project people or rather small working groups from at least 4 different locations contributed to this project. Of course, it is not easy to communicate the relevant information among such different groups. During the project, the management instruments changed rather quickly (different forms of Excel-sheets, different web-based tools). During a project a more consistent reporting philosophy is certainly helpful. And, of course, only the most important reporting should be required.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW) and Romania (NMA). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

Project report

1 Summary

The project had the goal to explore various ways to verify very high resolution models taking into account the fact that this kind of model are not to be looked at one gridpoint, at least not for precipitation, on which the project finally focussed on. We explored methods which allow building statistics out of the distribution of values surrounding a gridpoint. These methods are commonly called fuzzy verification. Applying the various methods onto idealized precipitation patterns, upscaling and the fraction skill score were kept for their adequate properties. This is shown in Section 3. Verifications have then been carried out on different regions and seasons with the Swiss COSMO-2 (2.2 km) and the German COSMO-DE (2.8 km). It turns out that the useful scales of these models are situated between 30 and 50 km. This value can even be higher depending on the considered precipitation threshold. The verification scores of very high resolution models are however better than the corresponding high resolution models COSMO-7 and COSMO-EU which have a grid spacing of ≈ 7 km. Sections 3 and 4 show details on these facts. Optimal verification methods should lead to corresponding products. Upscaling is quite commonly used by building averages of precipitation around gridpoints or over hydrological catchments. A product linked to the fraction skill score is provided by the neighborhood method in which probabilities are built out of the distribution of precipitation included in a spatial and temporal neighborhood of an observation point. Optimization of the method and examples are shown in Section 5. It is also interesting to compare the distribution functions of both the observed and the modelled precipitation contained in boxes of 100 km x 100 km. Global models are clearly unable to reproduce the tails of the distributions while high resolution models behave better although not perfectly. This leaves possibilities to use higher moments of the distribution function like for instance some quantiles, or to calibrate the distribution as done with EPS. This work is exposed in Section 6.

2 General introduction

The project had the goal to investigate advanced postprocessing methods, including hydrological applications, but it soon appeared that the most challenging postprocessing was the one consisting of extracting pertinent information from the very variable fields provided by very high resolution models (1-3 km), in particular for precipitation. This report will thus target on the scale dependency of the precipitation verification. In very high resolution models (1-3 km), the precipitation fields show usually a lot of variability. Although not positioned at the right position at the right time, the structures are often more realistic than those given by high resolution models (5-10 km). Typical images are shown in Fig. 1.

Clearly, the forecasts that can be generated by these two forecasts will differ, the probability of exceeding some small threshold being smaller in the 2 km case. Even if one can argue that the 2 km forecast is more useful than the 7 km forecast, the classical verification scores will be smaller for the very high resolution model when looking at the grid scale (this is often referred to as the double penalty effect). Therefore, methods have been developed for extracting the information out of boxes of growing sizes. These so called fuzzy verification methods are described in various papers (non exhaustive list): Contiguous Rain Area (Ebert and McBride, 2000), Neighborhood method (Theis et al. 2005), Fraction skill score (Roberts 2005), Intensity scale technique (Casati et al. 2004, Mittermaier 2006). Other references can

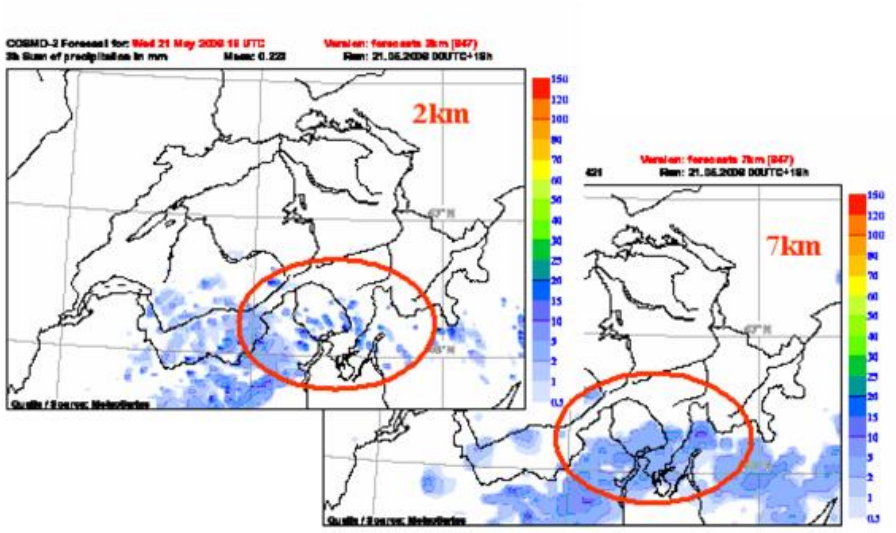

Figure 1: Example of precipitation field.

be found in Section 9. The generic behavior of such verifications has been sketched by N. Roberts (Fig. 2).

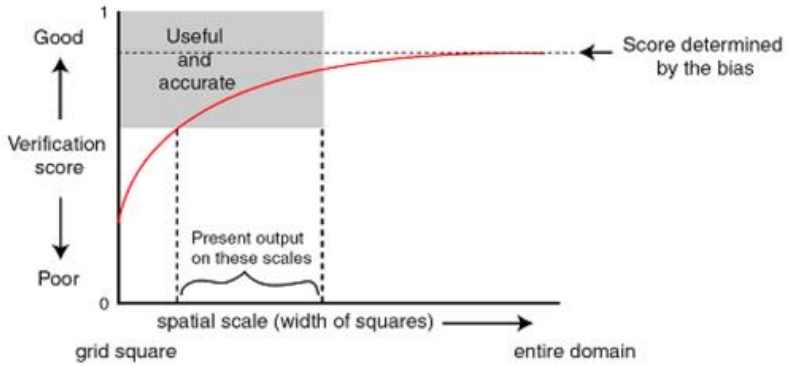

Figure 2: Generic behavior of verification.

The goal of the present project was to find out the highlighted "useful and accurate" scale. Of course, the other interesting question is to know if at this scale the very high resolution models show better scores than high resolution models. The scale dependency has been looked at from four different points of view which are reproduced in the following chapters:

- Fuzzy verification: theoretical aspects and application during the MAP D-PHASE DOP, by T. Bähler, F. Ament, T. Weusthoff

3 Fuzzy verification: theoretical aspects and application during the MAP D-PHASE DOP (T. Weusthoff, T. Bähler, F. Ament, MeteoSwiss)

3.1 Introduction

High resolution numerical weather forecast models are often punished when evaluated by traditional scores, which are based on a point wise comparison of observation and forecast. Although the structure of the observation may seem well forecasted by a high resolution model, a standard score may reveal a bad score due to e.g. spatial discrepancies. The coarser resolution model which cannot resolve the small-scale structure may in such a case get better scores although the subjective impression tells us different. However, so-called fuzzy verification methods try to avoid that problem by evaluating the forecast within a window around the region of interest. The forecast is hereby evaluated on increasing spatial scales by moving window domains of various sizes over the verification domain. The result is then presented as a function of spatial scale and threshold (see Fig. 3).

A variety of methods proposed by different authors can be allocated to "fuzzy verification", like those listed in Tab. 1. They are compiled by E.E. Ebert in form of a fuzzy verification toolbox - the IDL code can be downloaded from her webpage:
http://www.bom.gov.au/bmrc/wefor/staff/eee/beth_ebert.htm.

The different verification methods are in a first instance evaluated by means of idealized test cases. This way, three methods are identified to be well suited for the purpose of high resolution precipitation forecast. Those methods, namely the Fraction Skill Score, Upscaling and Intensity Scale, are then employed for the verification of precipitation forecasts of the Swiss COSMO models during the D-PHASE operations period.

Table 1: List of methods from the fuzzy verification toolbox (Ebert, 2008) which were evaluated by means of the test bed approach.

Acronym	**Method**	**Score**	**Decision model for useful forecast**
UP	Upscaling (Zepeda-Arce et al., 2000; Weygandt et al. 2004)	ETS	Resembles observation when averaged to coarser scales.
YN, MC	Anywhere in Window, 50% Coverage (Damrath, 2004)	ETS	Predicts event over minimum fraction of region.
FZ	Fuzzy logic (Damrath, 2004)	ETS	More correct than incorrect.
JP	Joint probability (Ebert, 2002)	ETS	More correct than incorrect.
ME	Multi-event contingency table (Atger, 2001)	HK	Predicts at least one event close to observed event.
IS	Intensity scale (Casati et al., 2004)	SS	Lower error than random arrangement of observations.
FB	Fractions skill score (Roberts and Lean, 2007)	FSS	Similar frequency of forecast and observed events.
PG	Pragmatic approach (Theis et al., 2005)	BS	Resembles forecast based on perfect knowledge of observations.
PP	Practically perfect hindcast (Brooks et al., 1998)	ETS ratio	Can distinguish events and non-events.
CS	Conditional square root of RPS (Germann and Zawadzki, 2004)	CSRR	High probability of matching observed value.
RM	Area-related RMSE (Rezacova et al., 2007)	RMSE	Similar intensity distribution as observed.

3.2 Test bed

3.2.1 Set-Up

The fuzzy verification package of E.E. Ebert contains a large number of methods and scores which are applicable for different purposes. In order to determine which of the available verification methods are suitable for verification of high resolution precipitation forecasts, the methods were tested in an idealized case study. A test bed was set up as follows (Fig. 3): a synthetically generated field that reflects a precipitation field containing simplified convective rain cells is modified by a perturbation generator which induces several known and assessable errors on that field. For each perturbation the resulting field was verified against the initial synthetic field by means of the fuzzy verification toolbox. In addition to that, the initial field was verified against itself, which represents a perfect forecast and should result in perfect scores. The observed response to the perturbations is then compared to the expected behavior. The sensitivity of the different methods and their cross-redundancy was determined. Working with a synthetic field - instead of radar data - provides the advantage of a simplified field with easier appreciation of the induced errors. However, the whole procedure was repeated with real radar data as will be presented in an upcoming publication. The results for the idealized cases are presented in the next section.

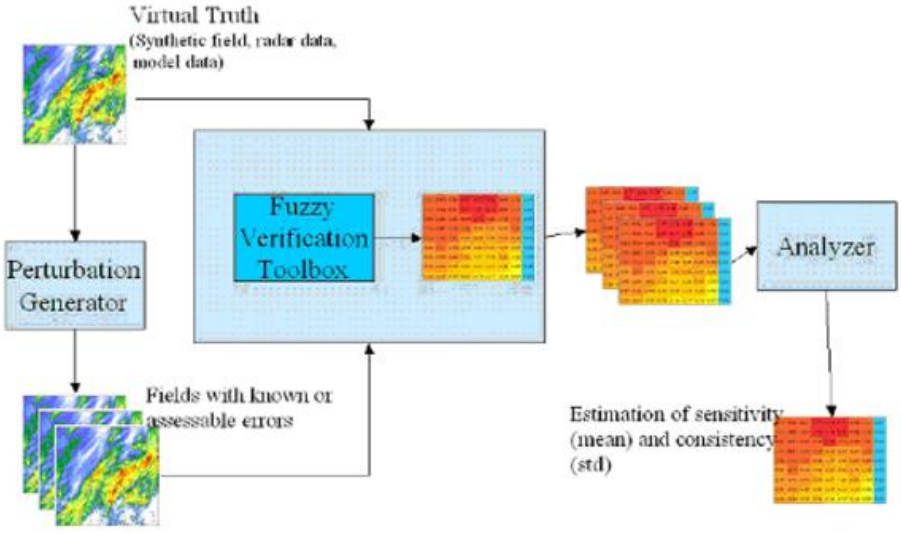

Figure 3: Test bed setup for the evaluation of fuzzy verification methods.

3.2.2 Perturbations and expected response

The synthetic field was perturbed by different perturbations for which a specific response was expected and additionally verified against itself ("perfect forecast"). Five types of perturbations are applied:

- XSHIFT - horizontal translation (10 gridpoints)
- BROWNIAN - no small scale

- LS_NOISE - wrong large scale forcing
- SMOOTH - high horizontal diffusion
- DRIZZLE - overestimation of low intensity precipitation

The appearance of the perturbations to the idealized precipitation fields is displayed in Fig. 4, while the expected response to each perturbation is shown in Fig. 5. Here, red boxes indicate scales where any sensitivity to the respective perturbation is expected, while blue boxes denote the scales for which no response is assumed.

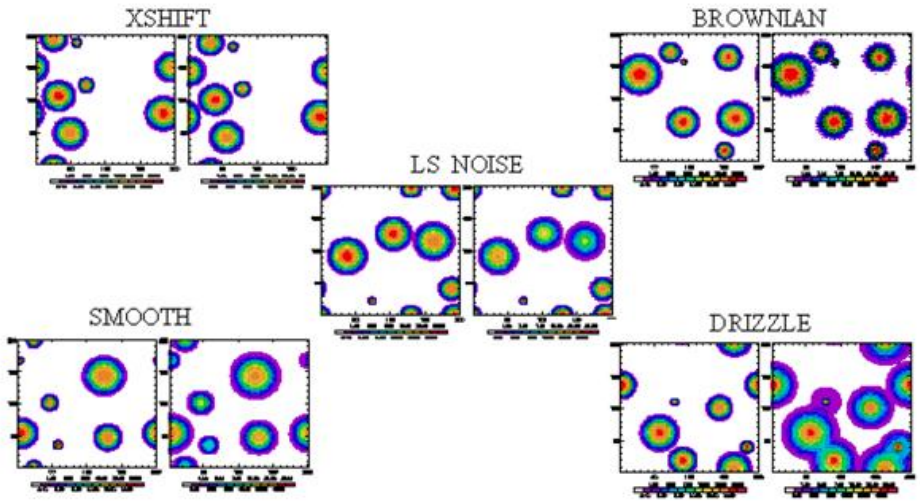

Figure 4: Perturbations on the synthetically precipitation field.

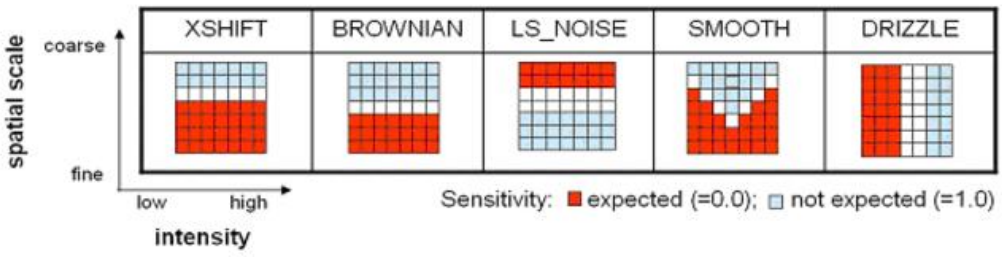

Figure 5: Expected response to the perturbations. Red boxes indicate that a response is expected on these scales why blue boxes indicate scales where no sensitivity to the perturbation is expected. When applying XSHIFT, for example, the verification results are expected to be sensitive for small scales and all thresholds.

3.2.3 Results of Sensitivity Studies

The sensitivity of the results is expressed by means of the difference between the expected behavior and the actual response to the perturbations. As measure for this difference, the contrast is calculated. It is defined as the mean value of the fuzzy boxes where no response was expected minus the mean value over all boxes where a response was expected:

contrast = mean(not_expected) - mean(expected)

The more the actual response equals the expected one, the higher the value of the contrast. The results of the idealized cases in terms of contrast are given in Fig. 6. Some methods were found to miss a perfect forecast, i.e. when the initial field was verified against itself, the scores did not give the perfect value, which is usually 1. Those "leaking scores" were not further considered (FZ, JP, ME, PG, CS). For the five perturbations, the scores revealed very different responses. Some are fairly good for all perturbations (e.g. UP and PP), while others are especially good for a special kind of perturbation but fail to detect others (e.g. YN and JP).

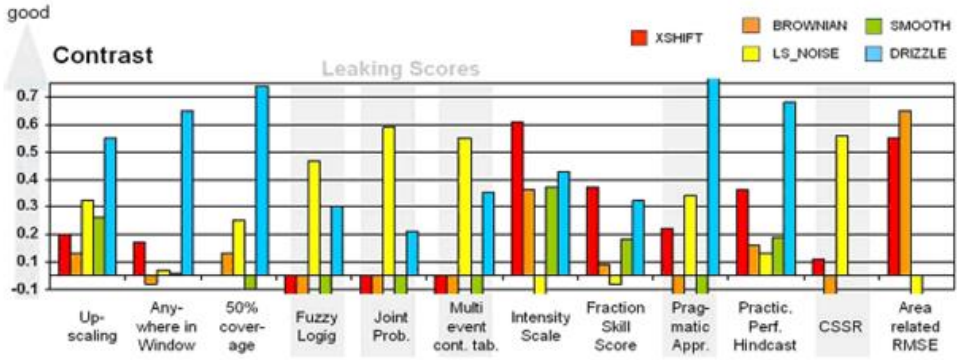

Figure 6: Results of the test bed experiment for the five perturbations on the idealized precipitation field.

Finally, the redundancy of the different methods was determined by calculating the correlation of the scores resulting from the test bed experiments. The scores for all window sizes and thresholds are therefore averaged over all perturbations and the correlation between the different scores is determined (Fig. 7). Three main groups of redundant methods have been identified this way: the first contains the methods UP, YN, MC, FB and PP, another group includes FZ, JP and a third one FB, PP. In addition it should be mentioned that the reliability is good for all scores - they show low standard deviations. Best performance in this respect was found for RM, which has, however, no intensity component and requires a lot of computational time. The Fraction Skill Score (FB) and Practically Perfect Hindcast (PP) generally show very good results. As both scores were found to be redundant, the more popular Fraction Skill Score was chosen as an appropriate method for the verification of quantitative precipitation of high resolution numerical models. To account for large scale error patterns, the Upscaling technique (UP) is added as a second method. Finally, Intensity Scale (IS) seems to be a promising technique, which is very fast and able to detect a specific scale of a spatial error.

3.2.4 Conclusions

Out of the huge set of methods which are available in the Fuzzy verification tool box, three methods and corresponding skill scores were identified to be suitable for a verification of high resolution quantitative precipitation forecast. The "Upscaling" method (UP) considers the mean value within each window to define an event (Zepeda-Arce et al. 2000; Weygandt et al. 2004), while for the "Fractions Skill Score" (FB) fractions of observed and forecast gridpoints exceeding a certain threshold are determined and a score is calculated based on these fractions (Roberts and Lean 2007). "Intensity Scale" (IS) uses a slightly different

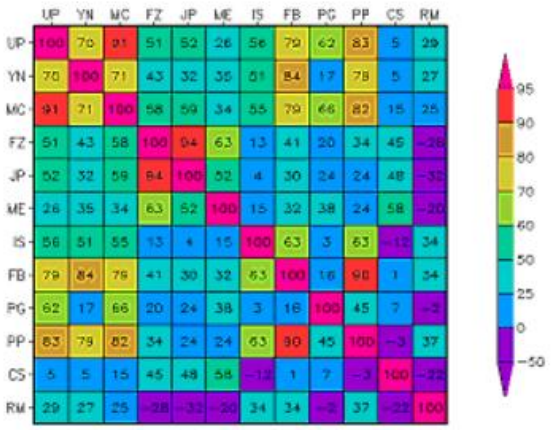

Figure 7: Correlation of the tested scores (see Tab. 1) derived from the averaged scores for each method.

approach: observation and forecast are transformed into binary images (rain larger then threshold or not) and a wavelet analysis is performed on the binary error image (Casati et al. 2004). For more information on the methods, the reader is referred to the given references.

3.3 Application during the D-PHASE operations period (DOP)

3.3.1 D-PHASE - Settings

The Forecast Demonstration Project (FDP) of the WWRP (World Weather Research Programme of WMO) D-PHASE (Demonstration of Probabilistic Hydrological and Atmospheric Simulation of flood Events in the Alpine region) was initiated to demonstrate the ability of forecasting heavy precipitation and related flooding events in the Alpine region. The D-PHASE operations period (DOP) covers the months from June to November 2007. During this time, several numerical and probabilistic models were run and alerts were issued based on those models. In this section, results of the verification of the quantitative precipitation forecast from two of those models, namely the Swiss COSMO models (COSMO-2 (2.2 km) and COSMO-7 (6.6 km)) are presented. The reference observation is the Swiss radar composite (NASS product). The verification is done on different spatial scales by varying the window sizes and for various thresholds defining an event. For the present analysis, window sizes of 1, 3, 5, 9 and 15 gridpoints were chosen for the coarser model and 1, 3, 9, 15, 27 and 45 for the high resolution model. The window sizes $whigh = 3*wcoarse$ of the high resolution model are comparable to window sizes $wcoarse$ of the coarse resolution model. The considered thresholds depend on the accumulation times that were evaluated. For 3 h accumulations, the following thresholds were chosen: 0.1, 0.2, 0.5, 1, 2, 5, 10, 20 mm/3h. For 24h accumulations, respective larger thresholds were chosen.

The scores are determined for 3h and 24h rain accumulations and are then aggregated on different time scales. Hereby, for the 3h accumulations always the latest model run is taken for both models beginning with a leadtime of 3h. This means that for COSMO-2 the leadtimes +3 to +6 are evaluated and for COSMO-7 (6.6 km) the leadtimes +3 to +15. It will be shown that the leadtime has no considerable influence on the difference in the skill of the two models. However, if all runs of the lower resolution model are available they should be

used for a "fair comparison". The 24h accumulations are only evaluated for the 00UTC runs of both models without any cutoff, i.e. for leadtimes +0 to +24.

3.3.2 Results

The results concerning the verification of quantitative precipitation forecasts during the D-PHASE Operations Period (DOP, June to November 2007) are presented for the two Swiss COSMO models. In Fig. 8, the scores calculated for 3h accumulations using the two methods UP and FB are given - the actual values for the score as well as the differences in the score's value of the two models for the respective scale. Generally, the skill increase with increasing window size and decreasing threshold for both methods and both models. For the Fraction Skill Score, which is displayed in the bottom row of the plot, useful scales are plotted in bold numbers. Those are the scales at which an acceptable level of skill is reached, which is given by $FSS_{uniform}$ lying halfway between random forecast skill and perfect forecast skill (Roberts and Lean 2007). The difference plot (COSMO-2 - COSMO-7) reveals that COSMO-2 has better skill on all scales. Especially small spatial scales (6.6 km to 50 km) and thresholds between 0.4 and 5 mm/3h can be pointed out here. According to the Fraction Skill Score, useful scales are especially those with low thresholds and large window sizes. The COSMO-2 precipitation forecast is hereby also useful on grid scale for very low precipitation thresholds, while COSMO-7 reaches a useful scale only for window sizes larger or equal 3 gridpoints.

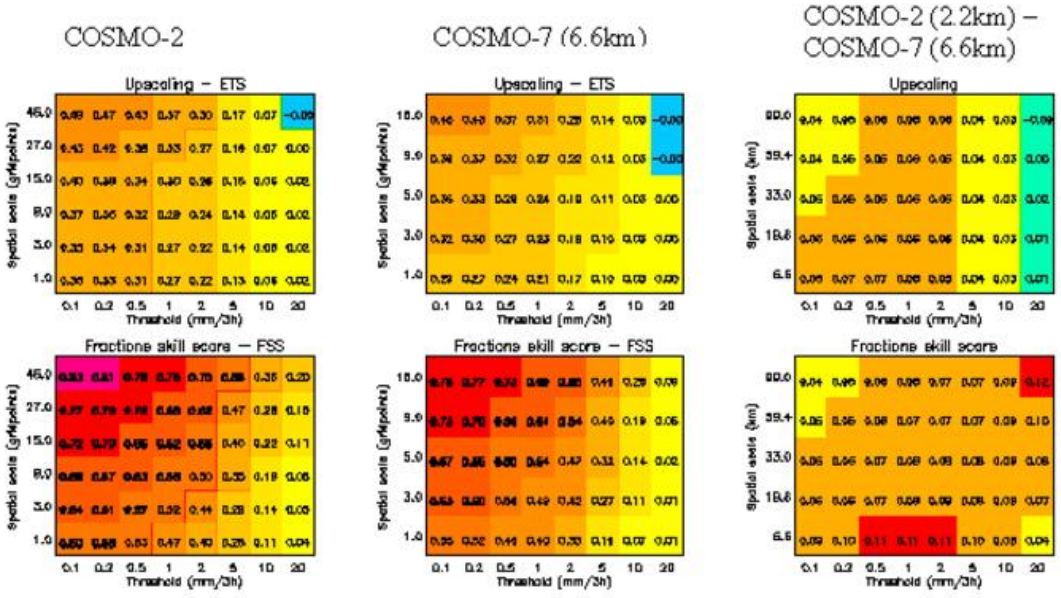

Figure 8: Verification results for the two methods UP (top row) and FB (bottom) and the period from June to November 2007 (3h accumulations). Displayed are the skill scores for the COSMO-2 (left), COSMO-7 (middle) and the differences between those two (right). For the latter, the spatial scale of the COSMO-7 in terms of gridpoints has to be multiplied by 3 to get the comparable spatial scale of COSMO-2.

The second example (Fig. 9) shows the results for 24h accumulations with only the 00UTC model runs used for verification. The skill is higher for both models on all scales and the useful scales are more numerous and almost identical for both models in terms of gridpoints. The difference plot looks slightly different from that for the 3h accumulations. The differences

in the skill of the two models are smaller and for a very small number of scales the coarser resolution model has slightly better skill. However, for the larger number of evaluated scales the skill of COSMO-2 is slightly better. This is especially true for the scales where the most pronounced differences were found for 3h accumulations.

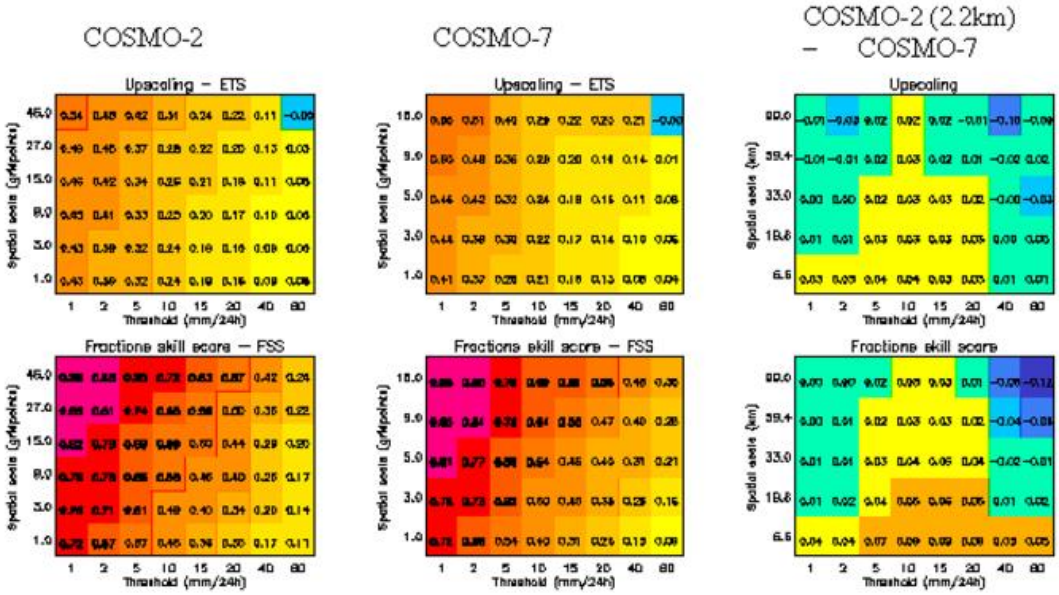

Figure 9: Verification results for the two methods UP (top row) and FB (bottom) and the period from June to November 2007 (24h accumulations). Displayed are the skill scores for the COSMO-2 (left), COSMO-7 (middle) and the differences between those two (right). For the latter, the spatial scale of the COSMO-7 in terms of gridpoints has to be multiplied by 3 to get the comparable spatial scale of COSMO-2.

In Fig. 10, the results of the verification by means of the "Intensity scale" method (IS) are shown. The advantage of this method is that each scale is evaluated separately, while for the other methods presented only the respective smaller scales are filtered. The results for the two models show no consistent behavior for the different scales. However, both accumulation times evaluated for each model reveal comparable skill. COSMO-2 has best skill for small windows (low thresholds) and for large window sizes. For a window size of 16 gridpoints, i.e. a spatial area of approx. 35 km x 35 km the score shows a relatively minimum. COSMO-7 behaves different: the skill is largest for high thresholds and large windows and a relative maximum in skill can be found for a spatial scale of 16 gridpoints, i.e. an area of approx. 105 km x 105 km. The test bed experiment revealed that the "Intensity scale" method is able to detect the specific scale of a spatial error. Imposing a perturbation in form of an horizontal shift, the response of the score was a minimum in skill for that specific scale. The results presented here are averaged over a period of 6 month. However, such a minimum in skill could be detected for the COSMO-2. To decide if this result is an artificial effect or originates from a shift in the precipitation forecast, more detailed investigations are needed.

3.3.3 Conclusions and Outlook

With fuzzy verification methods, forecasts are evaluated on different spatial scales and for varying thresholds. This procedure gives the chance to determine the scales on which a forecast model reveals the desired skill for a specific purpose. Furthermore, a better comparison

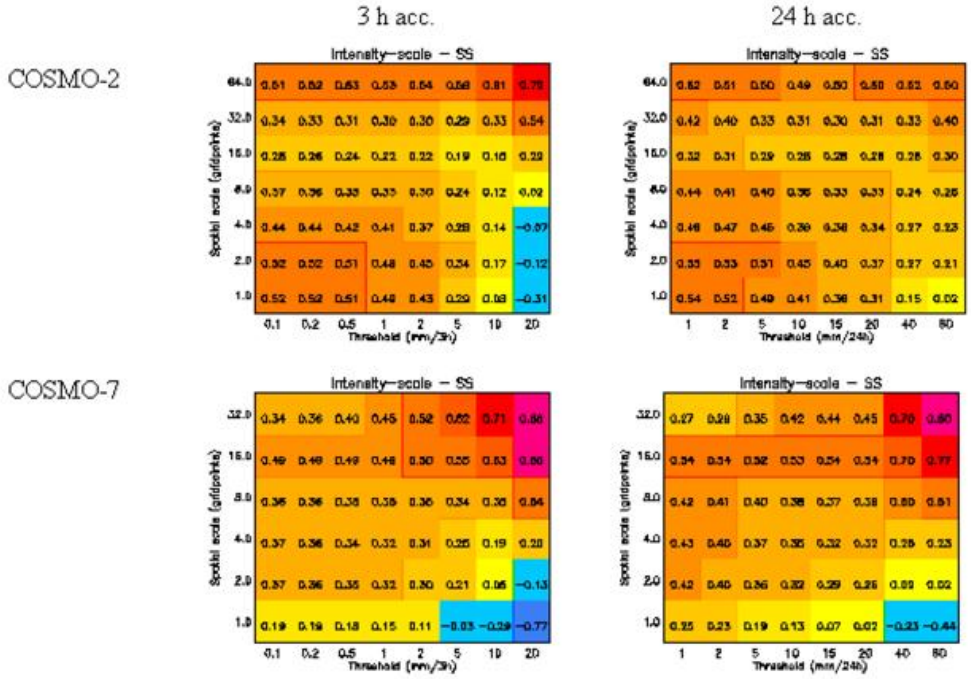

Figure 10: Verification results for the "Intensity scale" method (IS) for the period from June to November 2007 - 3h accumulations (left) and 24h accumulations (right). Displayed are the skill scores for the COSMO-2 (top) and COSMO-7 (bottom).

between models of different spatial resolution is possible. Three methods were chosen by means of a test bed experiment to be suitable for the purpose of precipitation verification and those methods were applied to the quantitative precipitation forecasts of the two Swiss COSMO models during the D-PHASE operations period. The three methods have different characteristics and thus give different results. The upscaling method dumps out high intensities by averaging over the respective window and spreads low intensities on the other hand. The resulting scores give an impression of the accuracy of the mean precipitation values. Fraction Skill Score in contrast considers the fraction of precipitation rates at grid-scale with values above a certain threshold and allows also a direct evaluation of high rain rates. However, due to the low sample of high rain rates, those scales are not classified as useful scales. The results of the two methods (UP and FB) reveal that the high resolution COSMO-2 (2.2 km) has better skill on all scales for 3h accumulations and on most scales for 24h accumulations. Useful scales, according to the Fraction Skill Score, are especially detected for low thresholds and large windows. The third method (IS) allows an evaluation for individual scales and reveals a more complex picture, which is harder to interpret. More detailed investigation is necessary to understand the results of this score. One of its main features is the ability to detect a horizontal shift of the forecast precipitation field. However, the three methods constitute an appropriate basis for the evaluation of quantitative precipitation forecasts of numerical models with different spatial resolutions. The results presented here are averaged over a rather long period of time (6 months). More information on the strength and problems of the individual models can be gained from conditional verification, e.g. stratified by weather types.

4 Verification of DWD-models against high resolution precipitation and SYNOP measurements (U. Damrath, DWD)

4.1 Introduction

Precipitation forecasts with high resolution models often show a high variability of forecasted patterns which have in some cases a characteristic size of only a few grid points. For those cases with observations with nearly the same characteristic size usually it cannot be expected that forecasted values and observed ones match correctly. Therefore, it is necessary to use verification methods that take into account that also right "signals" of forecasted events are judged beyond point by point verification which are further needful for weather elements with no high variability.

4.2 Methods

Traditional verification is carried out at DWD for nearly all weather elements which are observed near the ground and far from the ground. RMSE and BIAS are calculated for temperature, dew point depression, pressure wind (speed, direction and vector wind, no BIAS). Categorical scores are computed for cloud covers at different heights, gusts and precipitation in different classes. In order to check also the capability of the models to signal an event in a region of interest so called "fuzzy" techniques are used. These techniques are fully described by Ebert, 2008, Roberts and Lean 2008, and Casati, 2004. A lot of scores are defined within those frameworks and we have put our attention to the ETS from the upscaling method, the fractions skill score and a modification of the energy squared score. Using the energy squared score observed and forecasted fields are splitted in so called wavelets that contain the differences of values of a scale under consideration from the scale above. The modification relates to the original MSE Skill Score:

$$1 - \frac{2MSE(Y,X)}{En^2(X) + En^2(Y)} \tag{1}$$

to

$$1 - \frac{MSE(Y,X)}{En^2(X) + En^2(Y)} \tag{2}$$

MSE is the mean square difference between observed and predicted precipitation for a given wavelet, En^2 is the sum of the squared values for the given wavelet. The main difference between the wavelet method and the other methods is that with the wavelet method each scale can be separated but with the other methods an overview of all scales below the scale under consideration is given.

4.3 Data

For fuzzy verification forecasts of GME, COSMO-EU and COSMO-DE are compared on the same grid. That means that the forecasts of GME and COSMO-EU are transformed to the COSMO-DE grid. Observations are the values from the radar composite of DWD measurements which are also available on the grid of COSMO-DE. Traditional verification uses SYNOP observations and the forecasted value for the nearest grid point for COSMO-EU and an averaged value over 9 x 9 grid points for COSMO-DE in order to avoid scale dependent effects. Evaluations were made for all forecasts starting in an interval of 3 hours.

4.4 Results

Figs. 11 to 15 show exemplary the behavior of FSS, the ETS for August 2008 and these scores together with the modified energy squared score for January 2009. Also an example for traditional verification is presented (Figs. 16 and 17). These results are representative for most of the other months.

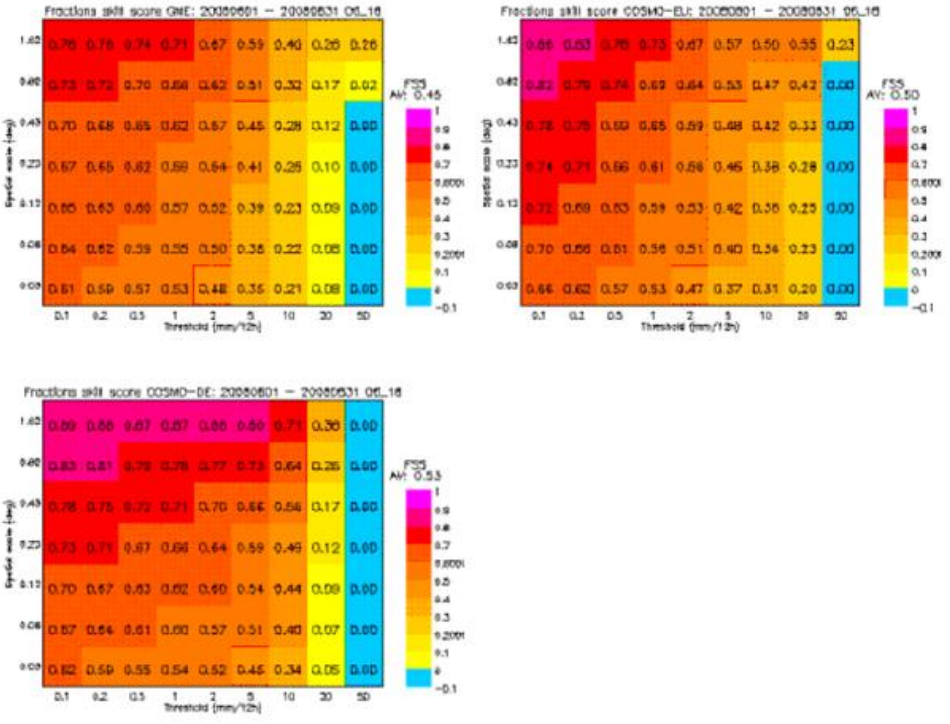

Figure 11: Fractions skill score for forecasts of GME, COSMO-EU and COSMO-DE for August 2008, forecast time 06-18 hours.

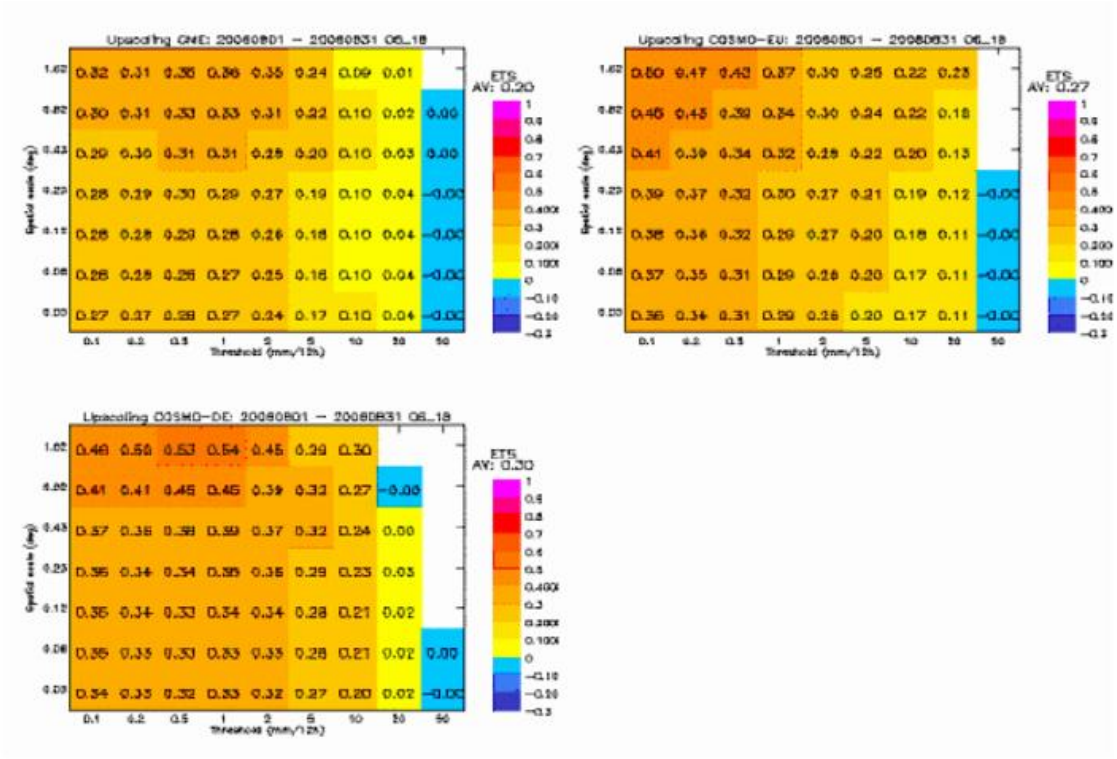

Figure 12: ETS from upscaling for forecasts of GME, COSMO-EU and COSMO-DE for August 2008, forecast time 06-18 hours.

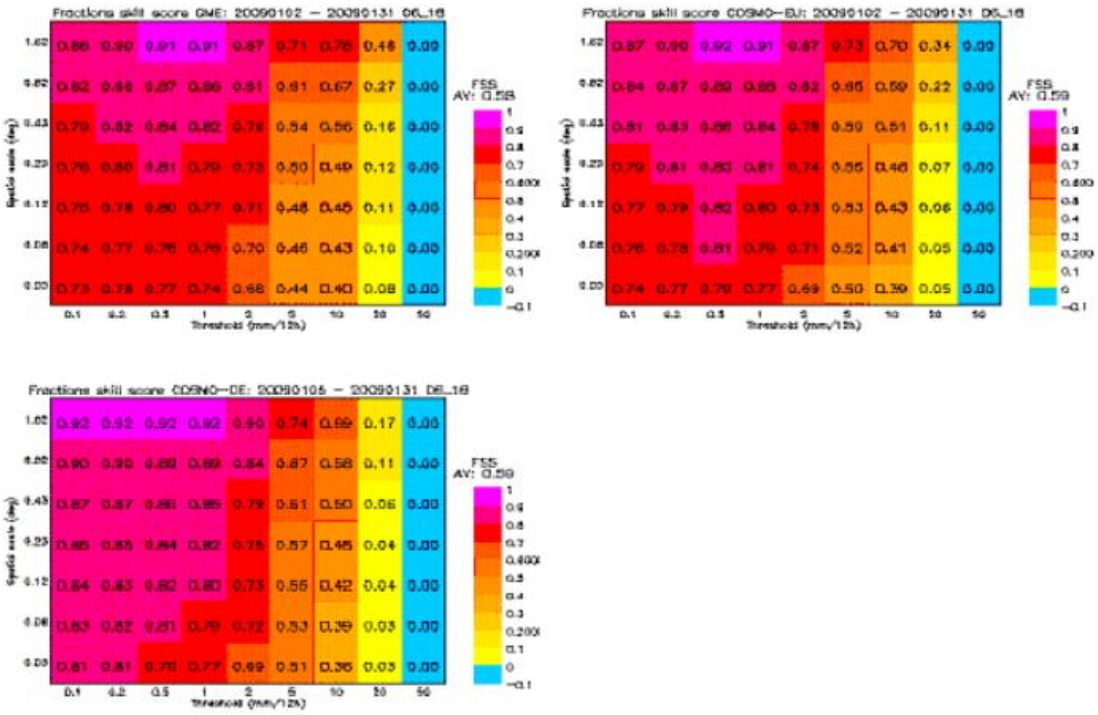

Figure 13: Fractions skill score for forecasts of GME, COSMO-EU and COSMO-DE for January 2009, forecast time 06-18 hours.

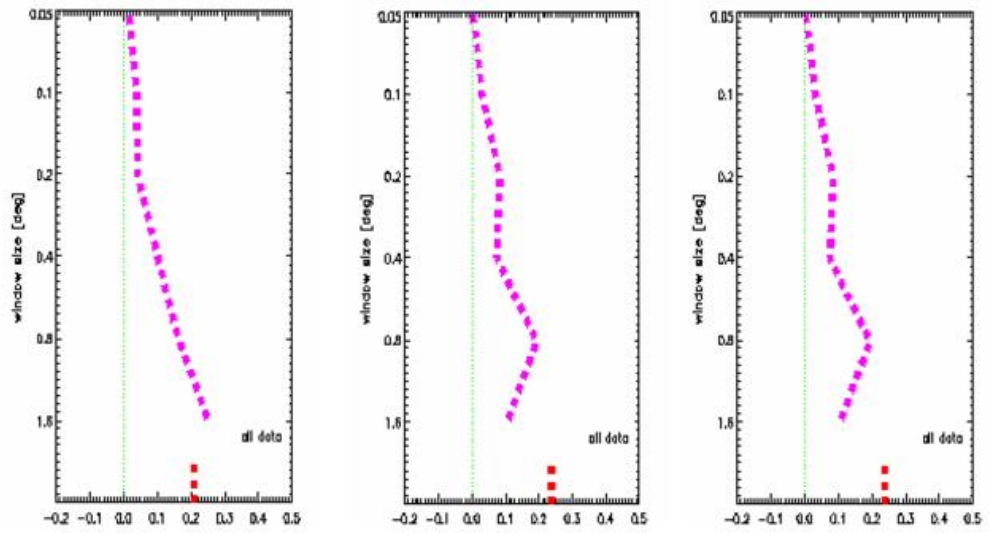

Figure 15: Modified energy squared score for forecasts of GME (left), COSMO-EU (center) and COSMO-DE (right) for January 2009, forecast time 06-18 hours; horizontal: skill score; vertical: window size; red mark: skill for all scale.

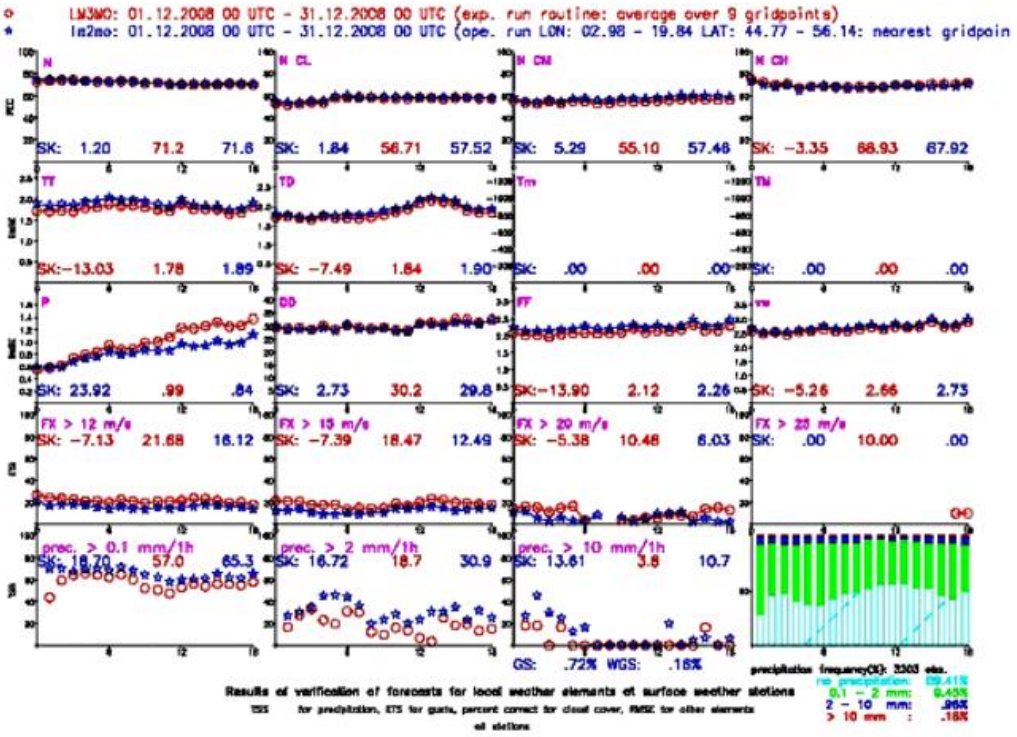

Figure 16: Example of traditional verification for surface weather elements for December 2008 (Start of forecasts 00UTC, scores measuring the quality of forecasts).

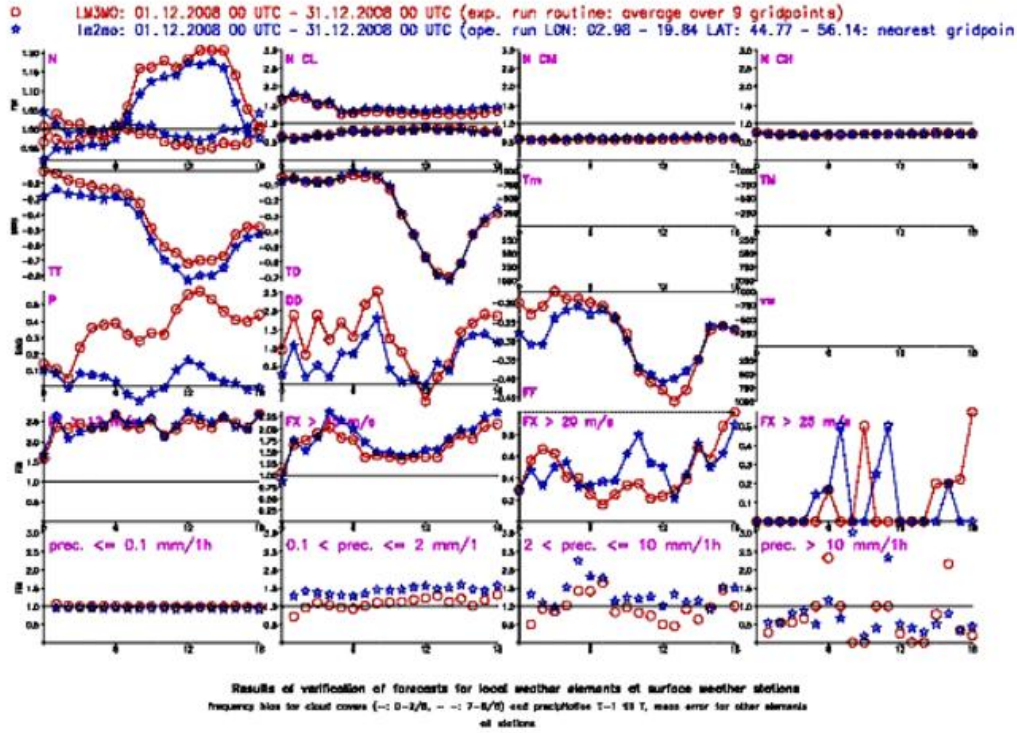

Figure 17: Example of traditional verification for surface weather elements for December 2008 (start of forecasts 00UTC, scores measuring the bias of forecasts).

This is a list of abbreviations which appear in Fig. 16:

- N: total cloud cover
- N CL: cloud cover of low clouds
- N CM: cloud cover of medium height clouds
- N CH: cloud cover of high clouds
- TT: 2m-temperature
- TD: 2m-dew point depression
- Tm: 2m-minimum temperature
- TM- 2m-maximum temperature
- P: pressure reduced to mean sea level
- DD: 10m-wind direction
- FF: 10m-wind speed
- vw: 10m-vector wind
- FX: gust over the given threshold
- Prec: precipitation for the given thresholds
- SK: skill of COSMO-EU agains COSMO-DE
- GS and WGS: global skill and weighted(different weights for each element) global skill over all elements
- red numbers: averages of the score for COSMO-DE
- blue numbers: averages of the score for COSMO-EU

4.5 Summary

Fuzzy verification methods show the following results which could be expected, but are assessed now:

- The quality of precipitation forecast is best for low precipitation values and large areas.
- For extreme precipitation values the dependency on the scale is as for low precipitation amounts. Higher quality occurs for larger areas. That means, indeed, that right "signals" often can be detected - especially by the models with finer resolution.
- Unfortunately, the number of those cases is relatively low and, therefore the statistical value of the scores is limited.
- The comparison between the models - and that follows from all the scores under consideration - indicate that the quality of forecasts increases in general with the degree of horizontal resolution.

- The question, whether the forecasts of a model has an economical benefit cannot be answered using these scores. It depends on the specific cost loss relationship. But if one can accept that a fractions skill score of above 0.5 or a ETS from upscaling is higher than 0.3 than one can find some areas in the graphics which indicate the horizontal scale and the amounts of precipitation that could be accepted as "good" forecasts.
- The example with the modified energy score shows that below a scale of 0.2° forecasts of GME have no skill. COSMO-models have a small skill below this range. For precipitation scales below 0.1 generally no skill can be expected.

Concerning the traditional verification it can be stated:

- Cloud covers are modeled with nearly the same quality for both models.
- COSMO-DE forecasts of temperature and dew point depression show small but systematic advantages against COSMO-EU.
- Although RMSE for pressure is for larger forecast times in COSMO-DE higher than in COSMO-EU (this is mainly related to the BIAS) wind forecasts of COSMO-DE are more trustable than those of COSMO-EU. This is also valid for gusts.
- QPF verification against SYNOP observations shows in general a frequency bias which is closer to 1 for COSMO-DE than for COSMO-EU. The small overestimation of COSMO-EU forecasts compared to COSMO-DE leads to a bit higher TSS for COSMO-EU. The evaluation of other scores that are not so strongly dependent on the frequency bias is under consideration.

5 Post-processing of COSMO-7 and COSMO-2 Precipitation with the Neighborhood Method (P. Kaufmann, MeteoSwiss)

5.1 Introduction

With increasing resolution, the numerical weather prediction models advance towards scales that are less and less deterministically predictable. This is especially true for precipitation with its high temporal and spatial variability. The time of onset and the location of a single convective cell for example cannot be predicted exactly due to the random nature of convection. This uncertainty in time and space needs to be accounted for when using high-resolution model output fields. The neighborhood method (Theis et al., 2005) accounts for the probability related to the spatial and temporal uncertainty on the scale of a few model grid cells. It solves the above-mentioned predictability problem by sampling a spatio-temporal neighborhood around each grid cell to derive a probabilistic forecast for that cell. Doing this, the neighborhood method provides a way to derive a probabilistic forecast from a deterministic model. In the present study, precipitation forecasts of the two Swiss models, the COSMO-7 with a grid spacing of 7 km (6.6 km after Feb. 2008), and the COSMO-2 with 2.2 km, are used as input.

5.2 Optimizing the neighborhood

5.2.1 Method

The neighborhood size has an important impact on the magnitude of the predicted probabilities. Theis (2005) found that she could not optimize the neighborhood size based on objective verification alone. With this unpromising perspective, I based the optimization for the Swiss COSMO models on case studies of precipitation cases. The optimization of the neighborhood uses a graphical comparison of the forecast probabilities with actual precipitation measurements of 2006 - 2008. An objective evaluation of the neighborhood determined in this way remains highly desirable and will be done this year (2009).

5.2.2 Spatial radius of neighborhood

Theis et al. (2005) tested three different sizes for the neighborhood: a small, a medium and a large neighborhood with a spatial radius of 3, 6 and 10 grid points, respectively. In this study, four sizes of 1, 3, 5, and 10 grid point radius are compared for COSMO-7 (Fig. 18). While the smallest radius retains most of the structural details, it also produces probabilities that are either very high or very low with much fewer points in between than are meaningful for a probabilistic forecast. The largest radius on the other hand only produces low probabilities, blurring the structural information very strongly. The ideal neighborhood radius is a trade-off between these extremes, lying for COSMO-7 somewhere in the range of 3 to 5 (Kaufmann, 2008) and for COSMO-2 between 8 to 15 grid points radius.

5.2.3 Shape of the neighborhood

Over homogeneous, flat terrain, a circular shape in space is the natural choice. In complex terrain or along surface property discontinuities however, it seems advantageous to account for the anisotropy. Theis et al. (2005) tested different anisotropic spatial shapes. The impact

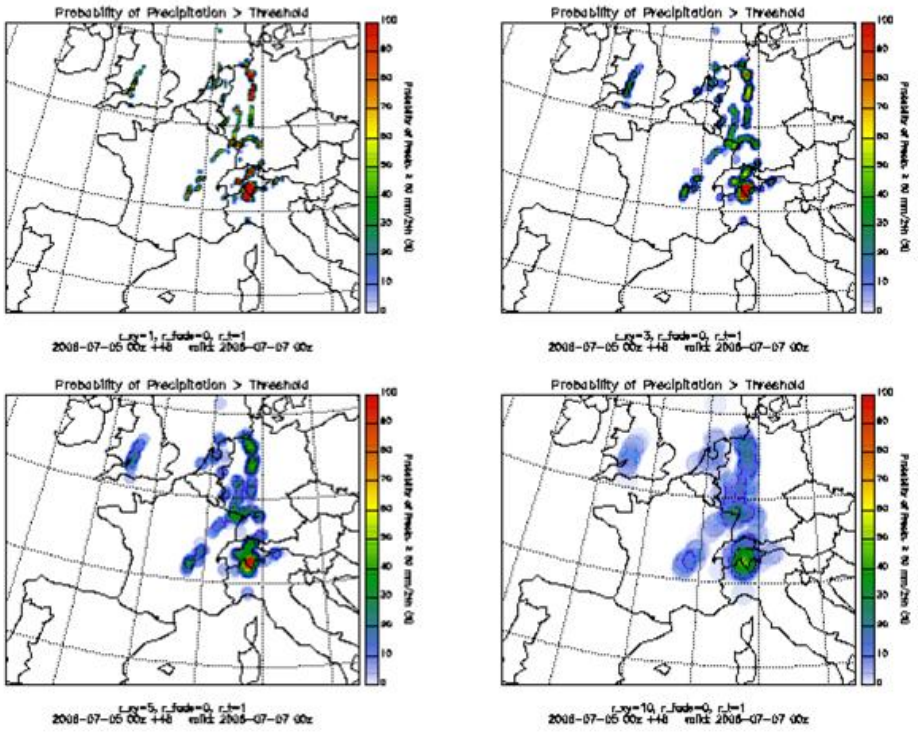

Figure 18: Probabilities of precipitation derived from COSMO-7 with a spatial neighborhood radius of 1, 3, 5, and 10 grid points, in this order.

proved to be quite small and at times even detrimental. Therefore, a circular neighborhood was chosen here, without further experimenting with the spatial shape.

The ellipsoidal shape of the neighborhood used by Theis et al. (2005) means that the spatial radius depends on the temporal distance to the central point. This implies a space-time dependency. It has at the same time the practical effect of smoothing the edges of the regions with high probabilities, because grid points near the central point contribute to the neighborhood at more time levels than those further away. If it is assumed that the time and space dimensions are independent, the spatial radius is constant in time, leading to a cylindrical neighborhood. This assumption is true if the ambient wind is nearly zero, and becomes increasingly inaccurate with increasing advection. The cylindrical neighborhood has the practical disadvantage of showing unreasonably sharp boundaries along the edges of precipitation. Smoothing of the edges has to be added to ameliorate this. A smoothing with linearly fading weights is introduced in the next section.

5.2.4 Linearly fading weights

The cylindrical neighborhood shape, in combination with localized strong precipitation peaks, leads to a dotted plot of probabilities, with a circular dot surrounding each major precipitation peak (Fig. 18). Such an unwanted feature could be smoothed out in an additional step, but it is more meaningful to do this as part of the neighborhood processing. This is achieved by adding an additional zone around the equally weighted neighborhood, with decreasing weights. For simplicity, the weights are chosen to decrease linearly. The meteorological reasoning behind such a zone is that given a convective rain forecast at the

central point, it is equally likely to appear within a certain radius, but the likelihood decreases beyond this radius and finally reaches zero at some larger distance. Fig. 19 shows the weight depending on the spatial distance of a grid cell to the neighborhood center for three neighborhood sizes.

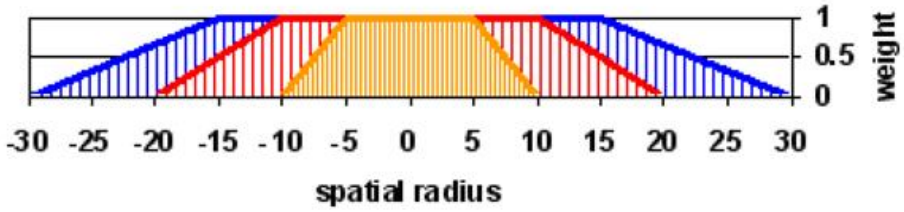

Figure 19: Weights of grid cells depending on the distance from the central cell, for tree different sizes of the neighborhood. Blue: Zone of equal weight and fading zone with 15 grid points radius each; red 10; orange: 5.

The result of adding such a fading zone is shown in Fig. 20. Here, the probability fields of the lower panels of Fig. 18 are repeated, but this time calculated with an additional linear fading zone of the same radius as the neighborhood itself. The areas are much smoother than in Fig. 18, and the peak values are somewhat decreased. This is because the total radius including the fading zone is now doubled.

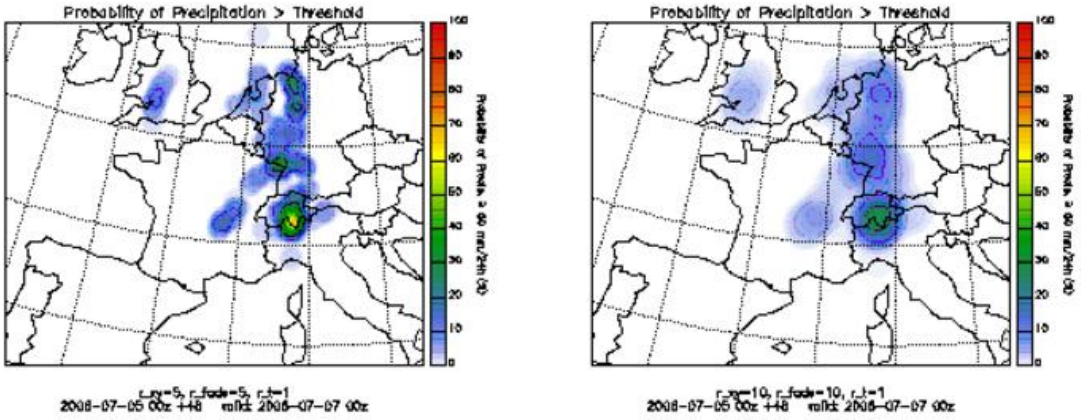

Figure 20: Same as lower two panels of Fig. 18 but with an additional fading zone of the same radius as the neighborhood, (left) 5 and (right) 10 grid points, added.

The cylindrical neighborhood shape with a fading zone is approximately equivalent with an ellipsoidal neighborhood with a larger temporal but smaller spatial radius (Fig. 21). With the same temporal radius, the linear fading provides smoother edges than the discrete weights of the ellipsoidal shape, while the values within the edges are retained. The smoother areas with non-zero probabilities are more realistic than the patchy areas of the ellipsoidal shapes.

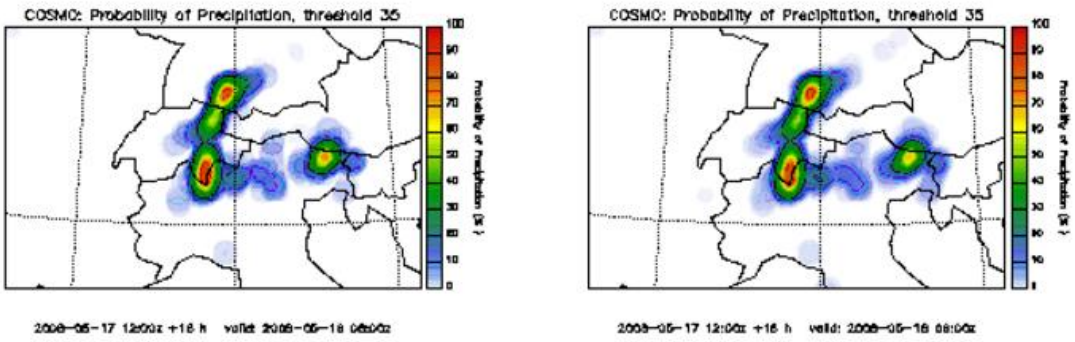

Figure 21: Approximately equivalent neighborhood shapes for COSMO-2. Left: ellipsoidal with 13 grid point radius, right: cylindrical with 8 grid point radius plus 8 grid point fading zone giving smoother transitions and edges. Shown is the 12h sum ending 18 May 2008 at 6:00 UTC.

5.2.5 Temporal radius

The temporal radius of the neighborhood represents the uncertainty in time of a rainfall prediction. For convective precipitation, it is known to span several hours. However, tests with temporal radius of 0, 1, 3, and 6 hours showed relatively little influence. The rainfall accumulation of 6 hours and even more so of 24 hours already has a smoothing effect on the time dimension, rendering the temporal extent of the neighborhood less critical. From the computational point of view, a smaller temporal radius is favorable because it is less costly.

5.3 Examples of products

5.3.1 COSMO-7, threshold 25 mm / 6h

Fig. 22 displays an example for a COSMO-7 product with a threshold of 25 mm per 6 hours. The situation shown occurred in August 2006, with a small region of strong precipitation over southern Switzerland. The probabilities for precipitation above the threshold level of 25 mm / 6h reach 50% in that region. Although probabilities and single precipitation events cannot be compared directly, large probabilities should coincide with rainfall above the threshold for a majority of cases. The probabilities generally decrease with increasing neighborhood size, thus a frequent occurrence of moderate probabilities with actual rainfall above the threshold as in Fig. 22 would indicate that the chosen neighborhood size is still slightly larger than optimal.

5.3.2 COSMO-2, threshold 25 mm / 6h

Fig. 23 shows on the left the product for COSMO-2 with a 25 mm per 6 hours threshold. On the right side, the actually occurred rainfall amount as measured at Swiss stations is shown. This is during the same episode already presented in Fig. 21, but 12 hours earlier.

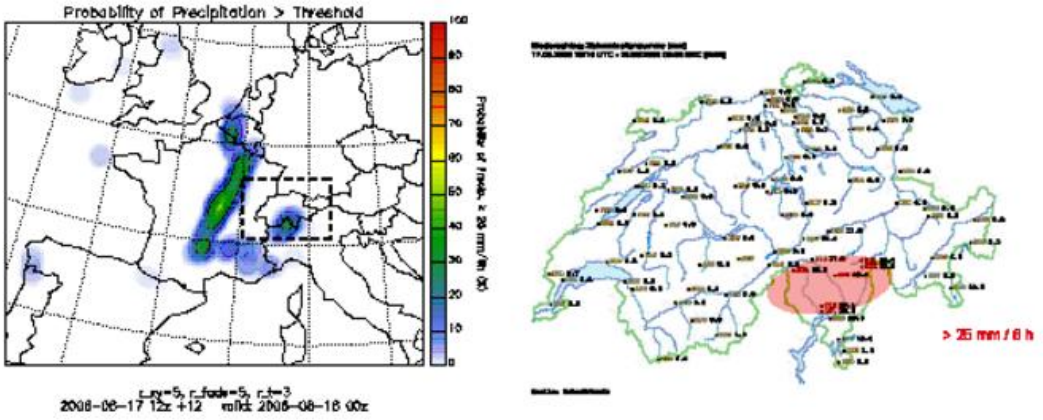

Figure 22: Probabilities predicted by the neighborhood method (left) and actual rainfall sum (right) for 2006-08-18 00:00 UTC.

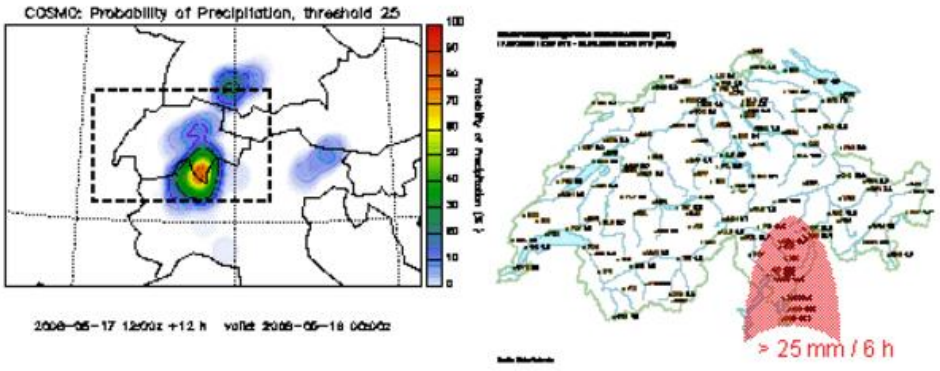

Figure 23: Probabilities predicted by the neighborhood method (left) and actual rainfall sum (right) in Switzerland (within dashed box in left figure) for 2008-05-18 06:00 UTC.

5.3.3 COSMO-7, threshold 50 mm / 24h

With a forecast range of just 24 hours, COSMO-2 cannot be used with the neighborhood method for 24h precipitation sums, unless the temporal radius is set to zero. The corresponding product for COSMO-7 (Fig. 24) shows a case with strong precipitation over northern Switzerland. The region of probabilities of 50% and more for precipitation above the threshold level of 50 mm / 24h nicely fits with the observed precipitation.

5.4 Conclusions and Outlook

The neighborhood method is used to derive a probabilistic forecast from a deterministic model. The probability is related to local-scale spatial and temporal model uncertainty. The resulting plots are compared to real cases and are optimized in this way. For COSMO-7, a spatial radius of 5 grid cells (33 km) with an additional zone of 5 grid cells with decreasing

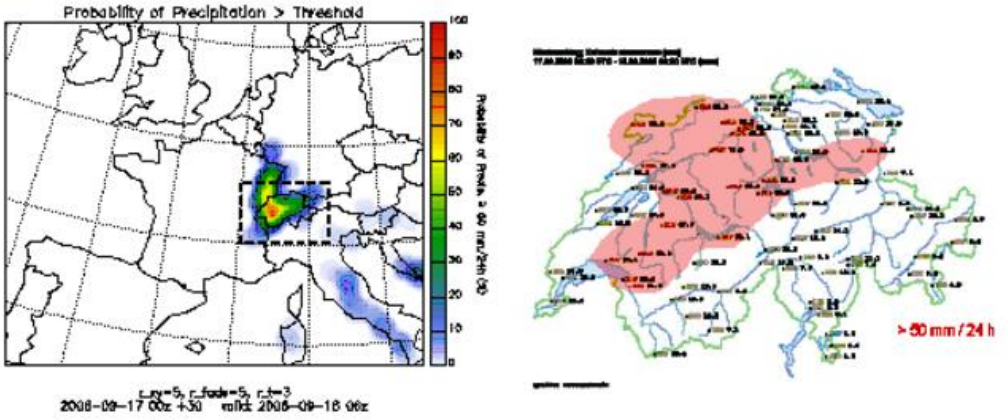

Figure 24: Probabilities predicted by the neighborhood method (left) and actual rainfall sum (right) for 2006-09-18 06:00 UTC.

weights and a temporal radius of 3 hours gives probabilities which are in accordance with the observed events and non-events. The radius of the zone with equal weight and of the zone with fading weights combine to an "effective" radius of approximately 7.5 grid cells (50 km). The temporal radius is currently chosen to be 3 hours for COSMO-7; however the extent of the neighborhood in time is of lesser importance. The respective values optimized in the same way for COSMO-2 are 10 grid cells (22 km) radius plus additional 10 grid cells for the fading zone, with a temporal radius of 1 hour. The two zones of the neighborhood add up to an "effective" radius of 15 grid cells (33 km). Compare this to the German Weather Service (DWD) which uses an ellipsoidal neighborhood with 13 grid point radius (36 km) for its 2.8 km resolution model. A throughout validation however, using objective verification, will have to follow to prove the quality of the probability forecast with the chosen neighborhood. Such a verification is planned for this year (2009). The neighborhood method is able to represent the local uncertainty concerning the prediction of the exact position and onset of precipitation. It does not account for the uncertainty related to synoptic forcing, which can be done using a model ensemble forecast. A combination of the ensemble and the neighborhood methods would combine both synoptic-scale and small-scale uncertainties.

6 Statistical properties of precipitation in boxes of various sizes (M. S. Tesini, C. Cacciamani, T. Paccagnella, ARPA-SIMC).

Model verification at ARPA-SIMC, in particular QPF, is operationally performed by using an upscaling method of both forecasted and observed fields over areas of selected size. The domain is divided in many squared areas and, for each area and for the chosen period of time, some indicators deduced by the distribution of the forecasted precipitation field (such as mean, maximum value, 90th percentile), are compared to those deduced by the distribution of the observed rainfall. Results concerning models performance depend on the considered distribution parameter; for example categorical verification scores for COSMO-I7 are better if the chosen indicator is the maximum value of precipitation in the area rather than those obtained selecting the mean value. Nevertheless all the distribution parameters are equally useful because they provide different information on the ability of the model in reproducing the precipitation field. Our interest is therefore addressed to the study of the distribution of the precipitation field, in order to analyze the capability of the models in reproducing precipitation statistical properties. Currently we focused on COSMO-I7 and ECMWF verification. The results suggest that verification methods based on the statistical description of model QPF and observations give more credit to high resolution model than the traditional standard verification, based on the comparison of model grid-point against observation (for example the choice of nearest grid point). We have applied a methodology based on the estimation of the distribution function of the observed/predicted precipitation field considering all points that fall in each area throughout the examined periods. Each area contains a lot of observation points as well as model grid-points: we assume that the occurrence of precipitation in each of these points is equiprobable. In order to consider well-founded this assumption, areas should be chosen carefully taking into account orographical and geographical features. The dimension of the selected areas is a critical point too. We followed a pragmatic approach for the choice of the dimension on the box: we should have enough forecast and observation points to perform significant statistics in each area. We chose squared areas of about 100 km x 100 km (see Fig. 25), containing about 200 COSMO-I7 grid-points or 16 IFS-ECMWF grid-points.

There are more than 1000 rain-gauges, belonging to regional/local administrations and provided by Italian Department of Civil Protection over the Italian territory, and the number of rain-gauges varies from 20 to 130 depending on the selected region. Tests on smaller area have been performed, but the results are very sensitive to the density of the observation points. We approached the problem mostly from a qualitatively point of view using a boxplot representation. A boxplot is a simple graphical summary of a dataset that can be useful to display differences between populations without making any assumptions of the underlying statistical distribution. It is possible to obtain information about the spread of the distribution and a roughly description of key measures that define it, such as the median, the quartiles, maximum and minimum values, and a range of values identified as "outliers". In this way we can, at least qualitatively, describe the type of precipitation: for instance the resulting distribution of a convective rainfall system possesses a long "tail" while the distribution of a widespread light rain event presents a distribution with a peak near a low amount of rainfall and little or no "tail". In this context, COSMO-I7 and IFS-ECMWF are used as representative of models with different horizontal resolution without focusing on their quality. In Fig. 26 the time-series of the daily forecasted/observed rainfall distribution are shown, obtained considering all the model grid-points and all the observed rain that fall daily (00-24UTC) within each area for ECMWF (blue), COSMO-I7 (red) and observations (green) during Autumn 2007. The number of stations in this area (131) is comparable with

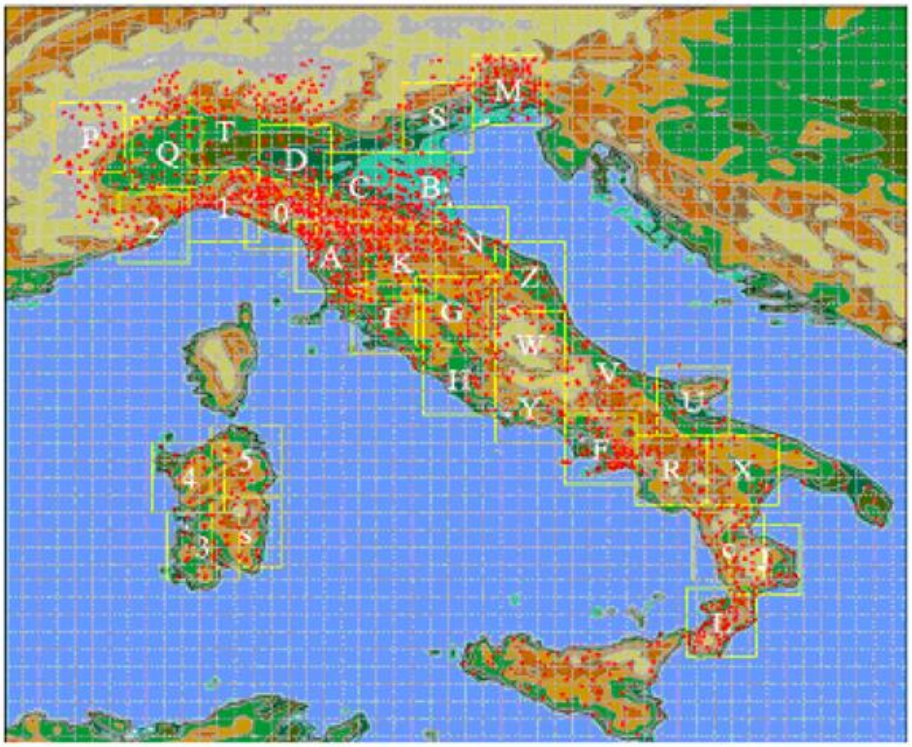

Figure 25: Box distribution.

COSMO-I7 grid-points (192), while ECMWF presents only 16 grid-points.

In general, we observe that COSMO-I7 is more realistic than ECMWF in reproducing the intra-box variability. However, COSMO-I7 presents both a large number of false alarms and high "spikes". On the other hand, ECMWF shows a greater number of missed alarms, especially if we chose high reference thresholds. According to most standard verification measures, COSMO-I7 forecast may have poor quality, but it might be very valuable to the forecaster since it provides additional information on the distribution and variability of the rain field over the considered region. The role of horizontal resolution is very important since it allows a more realistic simulation of the precipitation distribution, in particular for the "tails", that nevertheless represent the most interesting values of the rain field, especially for the emission of warning alerts to the Civil Protection. A better description of the distribution function of the observed precipitation field over each area represents a fundamental step in order to apply this methodology also to COSMO-I2, as the difference in the density of model grid-points and observations should represent a critical point. In fact, if we consider an area in which the number of model grid-points is significantly greater than the number of observations, such as the one shown in Fig. 27 where there are 34 stations, 212 COSMO-I7 grid-points and 16 ECMWF grid-points, we can see that "tail" of COSMO-I7 distribution is overestimated compared to the "tail" distribution of observations. Is it a sampling problem or does it depend on the behavior of the model in that area ? The question is still open.

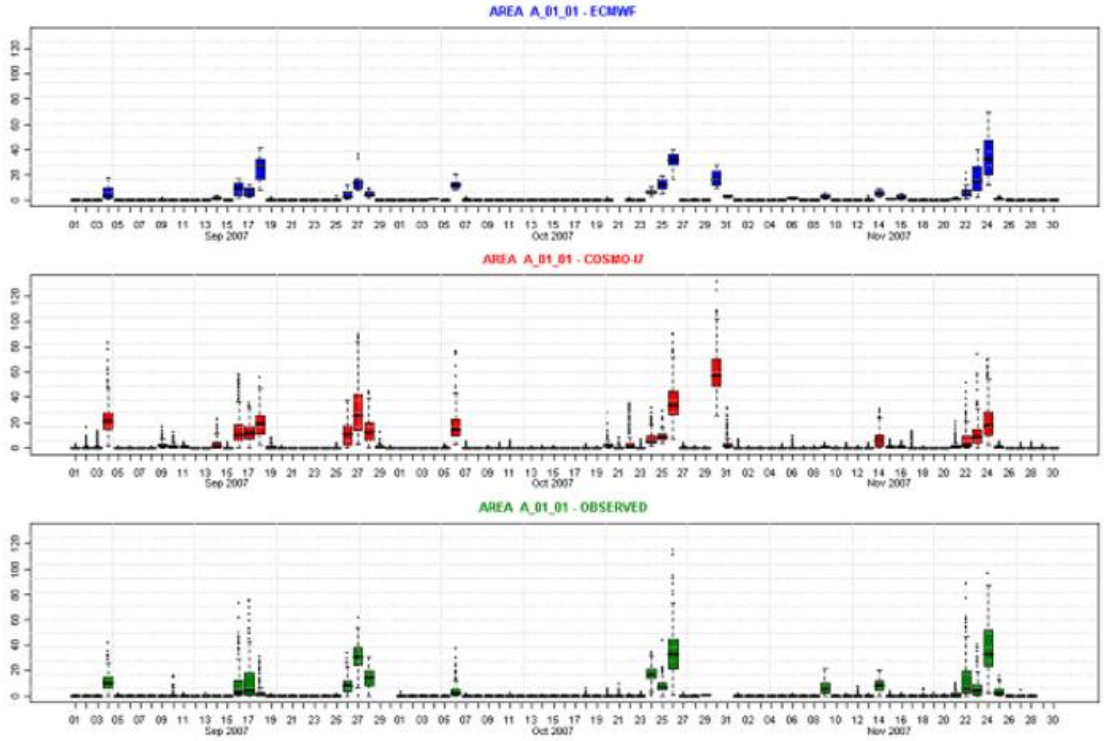

Figure 26: Time-series of the daily forecasted/observed rainfall.

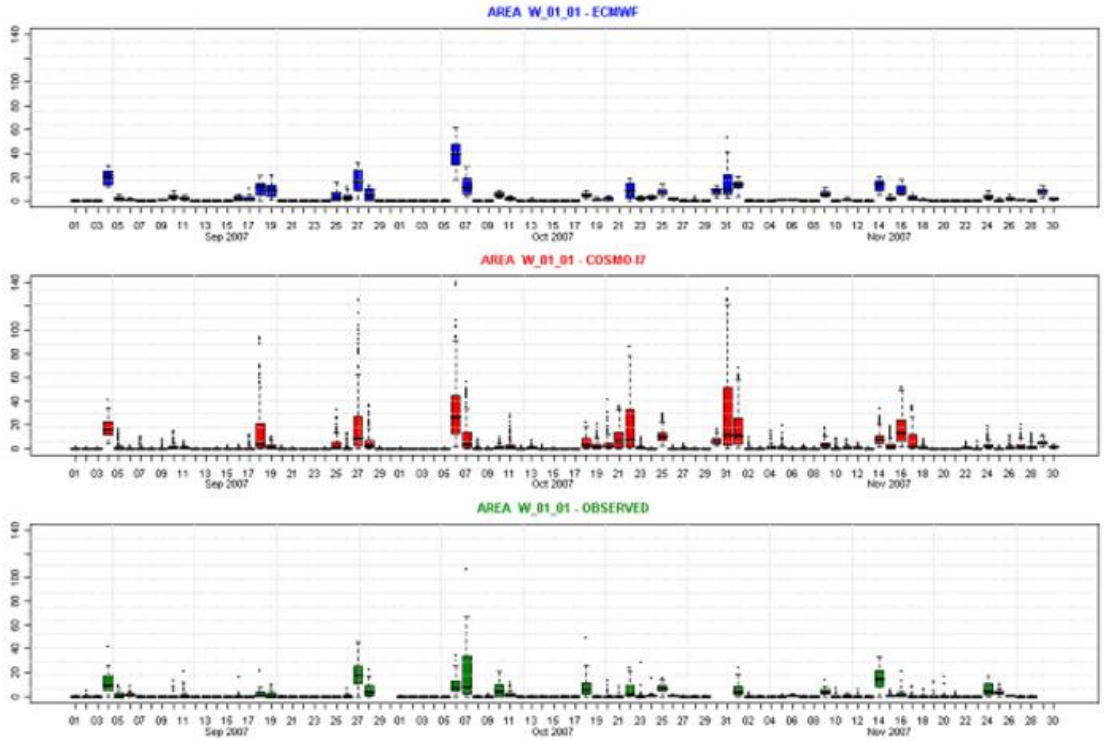

Figure 27: Example of area in which the number of model grid-points is significantly greater than the number of observations.

7 Open points

- The fact that precipitation patterns cannot be trusted at small scales is obviously dependent on the synoptic configuration. When a lot of uncertainty in the positioning is existent in purely convective situations, it is well possible that precipitation patterns are reproduced correctly in situations where orographic forcing is dominant (as long as the orography is correctly represented). Verification stratified by a weather type classification is thus recommended.
- By building statistics of precipitation values in a neighborhood of a gridpoint it is possible to build probabilistic precipitation forecasts. The same can be provided by Ensemble Prediction Systems (EPS), especially convection permitting EPS. Both methods should be compared by classical or fuzzy verification. Both systems can also be combined by applying the upscaling or the neighborhood method to the EPS.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW) and Romania (NMA). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Summary

The project focused on building an ensemble system for the short-range using the COSMO model, called COSMO-SREPS. During the first phases of the project, the ensemble was designed and implemented, then it was tested over long periods, in order to derive a robust statistical assessment of its features. In particular the system was running during the whole DOP of the MAP D-PHASE project (June to November 2007). The analysis of its performances was carried out over two COSMO regions: an alpine area and Greece. The main findings are:

- A good correlation between spread and error is observed, but the system tends to be under-dispersive. The gap between the spread and the error has been observed for a number of meteorological variables, both surface and upper-air; the gap decreases moving from surface towards upper-air variables. This evaluation is influenced by the presence of a model Bias, especially evident for 2m temperature.
- It has been recognized the need of applying more model perturbations. An extensive testing of new and more diverse parameter perturbations has been carried out within the project, but it is needed to continue this testing in the following of the project, due to the great amount of time and resources required. Furthermore, it has been decided to add also perturbations in the lower boundary of the COSMO model, to represent better the model uncertainties.
- The different types of perturbation contribute differently to the spread and to the skill of the system. In particular, driving model perturbation is the main source of spread in the ensemble as well as the main source of ensemble skill. COSMO model perturbation (parameter perturbation) plays a minor role, but contributes to the ensemble spread as well, with an amount variable according to the considered meteorological variable.
- The quality of the different driving models and of the different parameter choices are generally equivalent, since none of the different components of the system is always over-performing the others. The only exceptions are: the use of GME-driven initial and boundary conditions improve the system performances in terms of 2m temperature in summer, probably due to the coherence between soil and atmospheric fields; the use of the Kain-Fritsch scheme for the parametrization of the deep convection improves the precipitation detection at the expense of a larger number of false alarms.
- The ensemble skill in the forecast of surface weather parameters is reasonable. An objective assessment of the system quality will be carried on in the framework of the D-PHASE project, where the system performances will be compared with those of other state-of-the-art ensemble systems.

2 Project report

2.1 Introduction

The SREPS Priority Project focused on the building up of a high-resolution ensemble system for the short-range. The project main tasks were to develop and implement such an ensemble, then to run it over extensive testing periods and to evaluate the system features and performances. The ensemble is called COSMO-SREPS (COSMO Short-Range Ensemble Prediction System) and it is based on 16 integrations of the limited-area non-hydrostatic

COSMO model at about 10 km of horizontal resolution, with 40 vertical levels. This system has been built to fulfil some needs that have recently arisen in the COSMO community:

- to have a short-range mesoscale ensemble to improve the support especially in situations of high impact weather
- to have a very short-range ensemble for data assimilation purposes
- to provide boundary conditions for the COSMO-DE-EPS convection-resolving ensemble, currently under development at DWD.

Therefore, the ensemble had to be designed to describe the uncertainty affecting the short-range predictions of surface weather parameters at a high spatial resolution. Aiming at this purpose, the strategy to generate the mesoscale ensemble members proposed by this project tried to take into account as many as possible sources of uncertainties which affect the scales of interest in the weather forecast at the short time range, in order to model many of the possible causes of the relevant forecast errors. Hence, perturbations have been applied both in the driving model and in the mesoscale model. The driving model error is described by means of a multi-analysis multi-boundary approach. Initial and boundary condition perturbations are applied by driving the 10-km COSMO runs with the four 25-km COSMO members of the Multi-Analysis Multi-Boundary SREPS system of INM. These four lower resolution COSMO runs, nested on four different global models (IFS, GME, GFS, UM) which use independent analyses, are provided by INM for this purpose. A representation of the smaller scale uncertainty is accomplished by applying limited-area model perturbations as well: the values of a number of parameters included in the sub-grid process parametrization schemes are randomly changed (within their range of variability) in the different ensemble members. The main issues which have been addressed in the system evaluation are:

- if the system shows a good spread/skill relationship, representative of the capability of the ensemble in describing the forecast error
- how the different perturbations contribute to the spread and to the skill of the system
- which is the ensemble skill in the forecast of surface weather parameters.

2.2 System description and implementation

2.2.1 The COSMO-SREPS system

COSMO-SREPS takes both initial and boundary conditions from 4 integrations of the COSMO-model, performed over the Euro-Atlantic area at 25 km of horizontal resolution, and differentiated from each other according to the global model used to drive the runs. The 4 integrations at 25 km are nested on the following global forecasting systems: ECMWF (IFS), DWD (GME), NCEP (NCEP) and UKMO (UM). Since these global systems are 4 different and independent state-of-the-art forecasting chains, a good deal of differentiation in the global models driving the limited-area runs is ensured. These integrations are performed by the Spanish weather Service (INM), which provides directly the fields generated by the 4 runs of the COSMO-model at 25 km. For each of the 4 sets of initial and boundary conditions, the COSMO-model integrations at 10 km of horizontal resolution are then performed over a domain covering Central and Southern Europe (Fig. 1). Each 25-km run drives 4

10-km integrations, which differentiates from one another for different choices of the parameters representative of sub-grid physical processes. Tab. 1 reports the parameters which were selected, together with their range of variability and the values selected for the experiments, as suggested by the COSMO scientists responsible for the development of parameterizations schemes. Tab. 2 shows the set-up of each ensemble member run in terms of both driving model and physics.

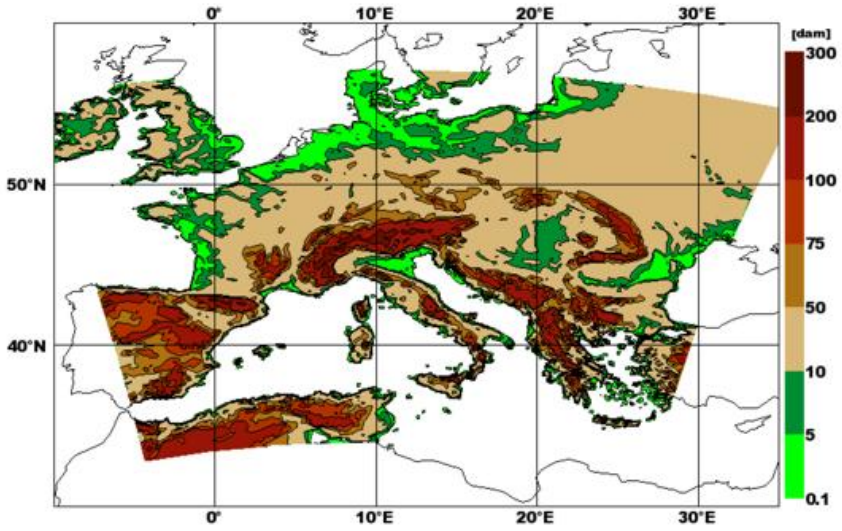

Figure 1: Integration domain of COSMO-SREPS (the model orography is shown).

Table 1: Perturbations applied to the model.

Perturbation name	Description	parameter range	default value	used value
SCHEMES				
Tiedtke	Scheme used for the parametrization of the deep convection		Tiedtke	Tiedtke
Kain-Fritsch	Scheme used for the parametrization of the deep convection		Tiedtke	Kain-Fritsch
PHYSICS				
pat_len	length scale of thermal surface patterns (influences mixing in the stable stratified atmosphere)	[0,10000] m	500	0, 10000
tur_len	maximal turbulent length scale (influences mainly stratospheric mixing)	[100,1000] m		1000

16	UKMO	tiedtke=.T.	kainfri=.F.	tur_len=-1	pat_len=10000

2.2.2 Testing period and data

The system was run over two main testing periods:

- 21 selected days of Autumn 2006, characterized by intense precipitation over either the Alpine area or Germany
- the MAP D-PHASE DOP (June to November 2007).

During Autumn 2006, 21 runs of the system were performed, on selected days characterized by intense precipitation over either the Alpine area or Germany. Fourteen runs were starting at 00 UTC, 7 runs at 12 UTC, on the basis of the availability of initial and boundary conditions. During the D-PHASE OP, 99 full runs of the COSMO-SREPS system were performed, covering not continuously the period, 50 in summer (JJA) and 49 in autumn (SON). Each full run (made up of 16 COSMO-model integrations at 10 km) started at 00UTC. The lack of continuity in the runs was mainly depending on the availability of initial and boundary conditions provided by INM. The analysis of the system was carried out over two COSMO regions:

- the Alpine area
- Greece

This is due to the availability of observations and to the COSMO scientists involved in the project. The climatology of two regions is very different, but both regions are quite complex from the geographical point of view (orography, proximity of the sea). In particular, it should be underlined that in Greece few and less intense precipitation events were observed during the D-PHASE period (this is why also the month of December has been included in the sample for Greece) and that summer 2007 was a remarkably warm one. Different data-sets have been used for the evaluation:

- high-res alpine: a dense network of stations covering northern-central Italy and Switzerland, providing precipitation data accumulated over 24h, from 06 to 06 UTC (about 1400 stations) (Fig. 2 left)
- high-res Italy: a dense network of stations covering northern-central Italy, providing precipitation data accumulated over 6h (about 900 stations) and 2m temperature data (about 600 stations)
- synop alpine: the SYNOP stations covering approximately the same area (43-48 ° N 6-14 ° E, 218 stations) (Fig. 2 right)
- synop Greece: the SYNOP stations covering Greece (about 90 stations) (Fig. 3)

Though the system performance was analyzed over both 2006 and 2007 testing periods, results are shown for the 2007 period only, due to the larger sample, which makes the analysis more statistically robust.

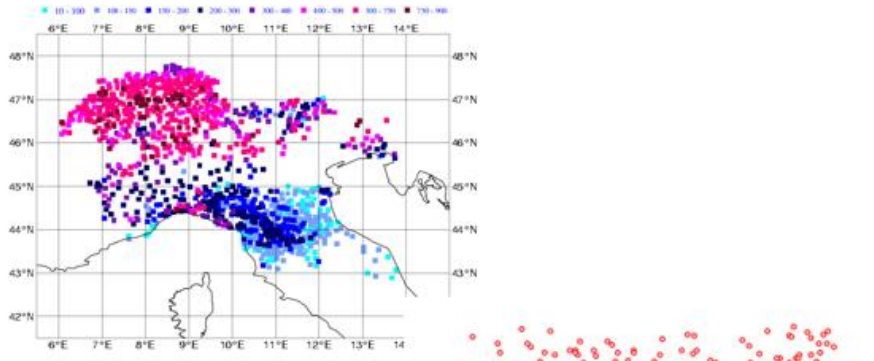

Figure 2: The high-res alpine dataset (left panel) and the synop alpine dataset (right panel). The high-res Italy dataset is made up by the Italian part only of the high-res alpine one.

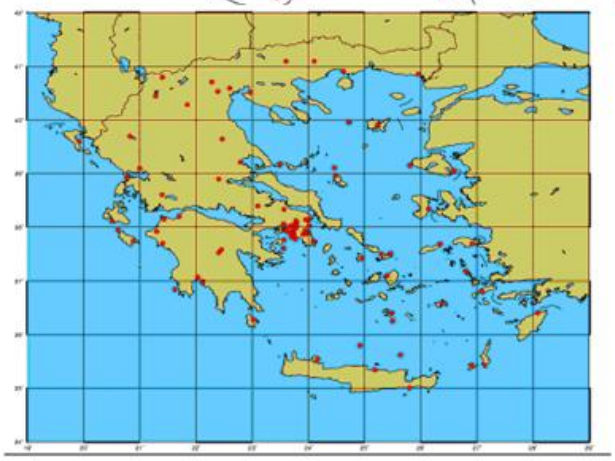

Figure 3: The synop Greece dataset.

3 Results

3.1 The spread-error relationship

The evaluation of the spread-error relationship was carried out on the Alpine area only, showing that the system still tends to be under-dispersive. The gap between the spread and the error has been observed for a number of meteorological variables, both surface and upper-air (2m temperature, mean-sea-level pressure, precipitation, temperature at 850 hPa, geopotential height at 500 hPa). Moving from surface towards upper-air variables, the gap decreases, but it is still detectable. In Fig. 4, the root-mean-square error of the ensemble mean and the root-mean-square spread of the ensemble (or ensemble standard deviation) are compared for the two seasons, in terms of 2m temperature. The error is computed by comparing forecasts interpolated on station points belonging to the synop alpine data-set with the corresponding observations, the spread is computed using these same interpolated forecast values, for homogeneity reasons.

The ensemble spread is bounded between 1 and 2 K in the summer season (Fig. 4, left panel), increasing with the forecast range and exhibiting a diurnal cycle, with values peaking at noon.

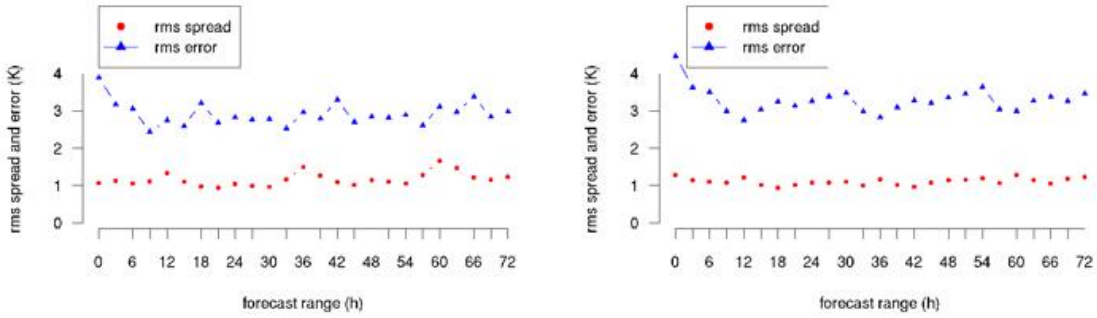

Figure 4: COSMO-SREPS spread (red) and error (blue) in terms of 2m temperature for summer (left) and autumn (right) 2007. Data are from the synop alpine dataset.

In autumn (right panel) the spread stays close to 1 K throughout the whole forecast range. In both seasons the ensemble mean error is quite larger than the spread, remaining below the 3 K value in summer, with peaks grater than 3 K at 18 UTC, while being generally above the 3 K value in autumn. The gap between the two measures is due to both the under-dispersion of the ensemble system and to the COSMO model systematic error, which should not be removed by ensemble techniques, but only by model improvement. In order to help in quantifying the contribution due to the model Bias, the same evaluation is repeated by using the COSMO-I7 analyses of 2m temperature instead of observed values in the computation of the ensemble mean error (Fig. 5). COSMO-I7 analyses are available at 00 and 12 UTC only.

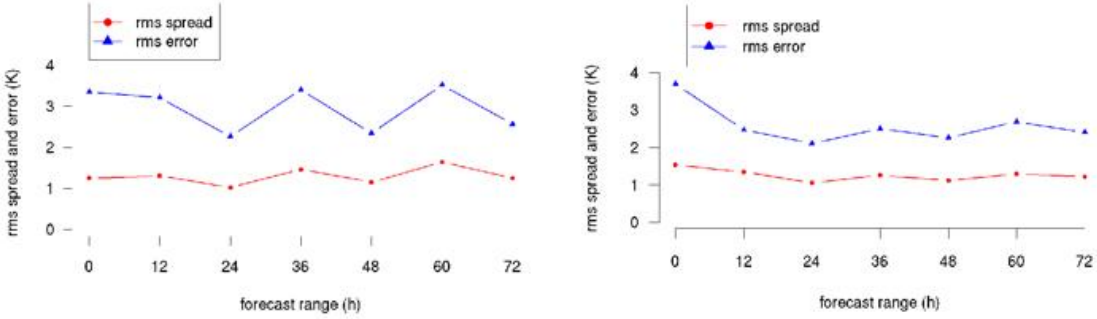

Figure 5: COSMO-SREPS spread (red) and error (blue) in terms of 2m temperature for summer (left) and autumn (right) 2007. Data are from the analysis of the COSMO model itself.

The root-mean-square spread values are the same, while the ensemble mean error is now reduced in both seasons. In summer the reduction is quite small, while is autumn the error is now bounded between 2 and 3 K, greatly improving the spread-error relationship. This indicates a dominance of the systematic error in autumn, which should be removed by model improvement and not addresses with ensemble techniques. A better representation of the spread/skill relationship of the ensemble is obtained by plotting the rms error as a function of the rms spread, after having divided the sample in classes of spread and computing for each class the average values of error and spread. This is shown in Fig. 6 for the 2m temperature

parameter, using data from the synop alpine data-set.

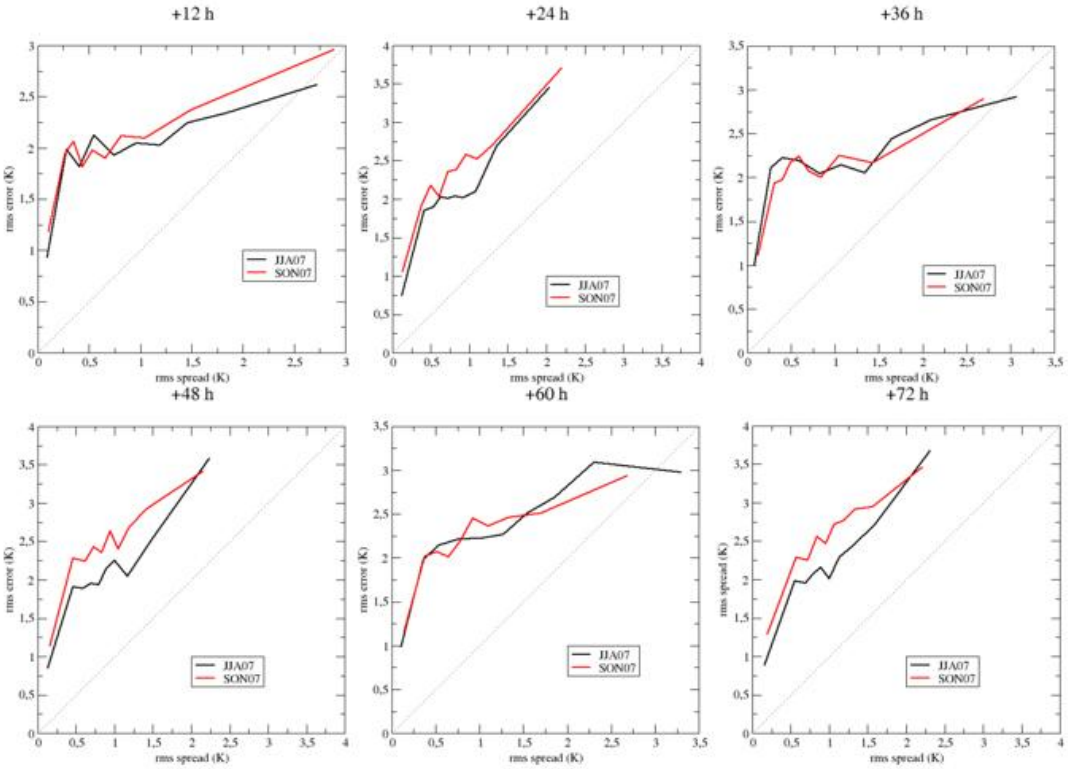

Figure 6: Spread/error relationship in terms of 2m temperature for summer (black line) and autumn (red line) 2007 for different forecast ranges (+12h, +24h, +36 h in the upper row, +48h, +60h, +72h in the lower row). Data are from the synop alpine dataset.

There is a clear correlation between error and spread, though at a given value of spread generally corresponds an higher value of error, even double. During the night (second, fourth and sixth panels, where data are from 00 UTC), the ensemble under-dispersion is less marked in the summer season. At 12 UTC (first, third and fifth panels) there two seasons exhibit a more similar behaviour, with a good relationship for high spread values. Moving from surface towards upper-air variables, the relationship exhibits only a little improvement. In Fig. 7, spread and error values in terms of temperature at 850 hPa are shown. The spread goes from 0.5 K at +12 h, increasing up to more than 1 K at the end of the period. The error grows similarly, being around the 2 K value. The spread/error relationship is shown in Fig. 8, indicating again the existence of a correlation but in presence of under-dispersion, though slightly less evident than for the surface variable.

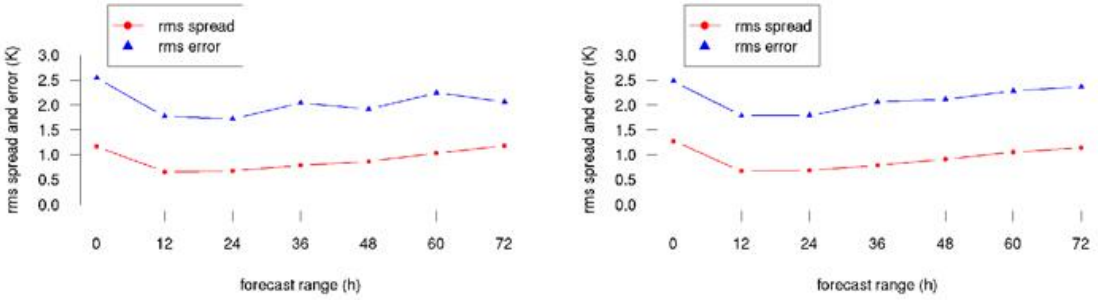

Figure 7: COSMO-SREPS spread (red) and error (blue) in terms of temperature at 850 hPa for summer (left) and autumn (right) 2007. Data are from the analysis of the COSMO model itself.

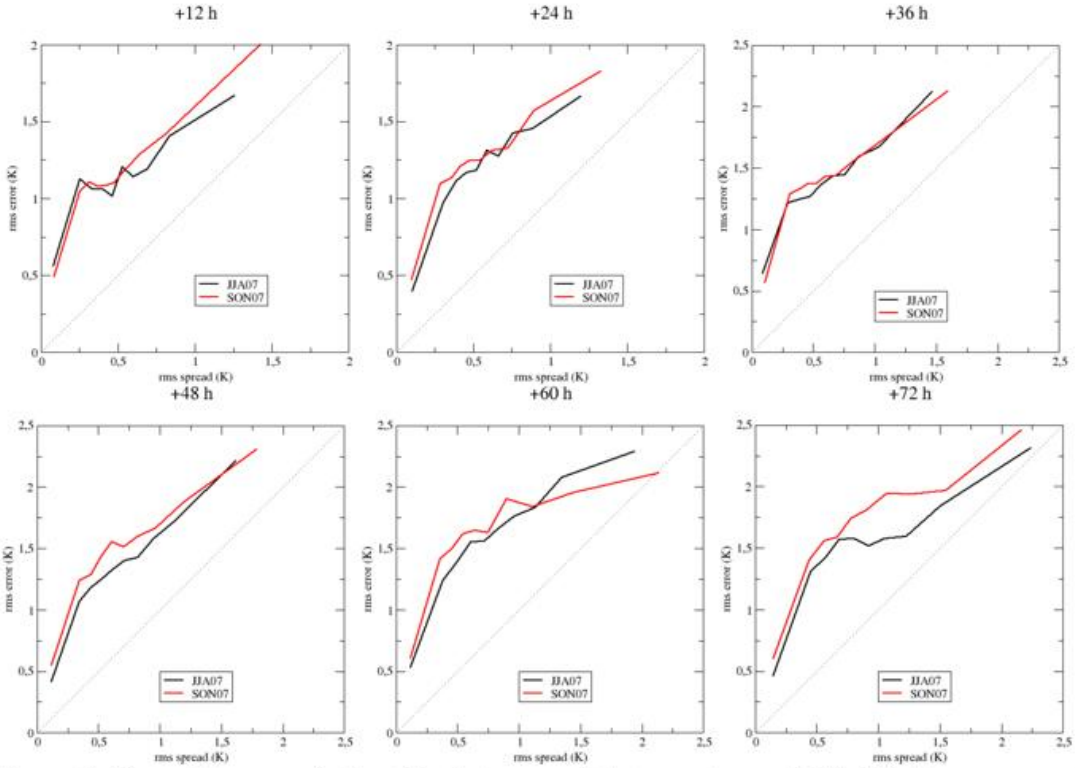

Figure 8: Spread/error relationship in terms of temperature at 850 hPa for summer (black line) and autumn (red line) 2007 for different forecast ranges (+12h, +24h, +36 h in the upper row, +48h, +60h, +72h in the lower row). Data are from the COSMO analyses.

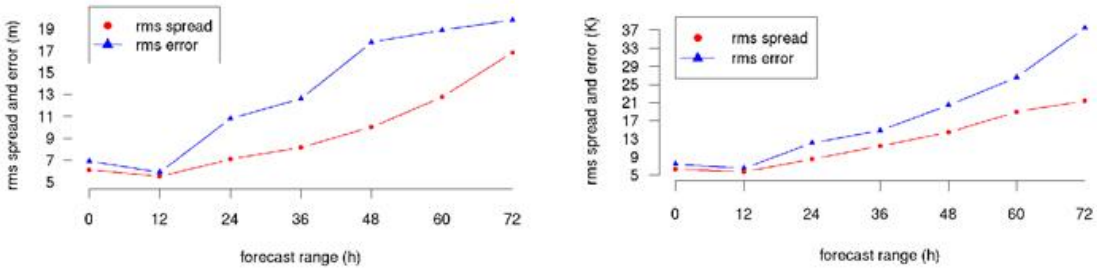

Figure 9: COSMO-SREPS spread (red) and error (blue) in terms of geopotential height at 500 hPa for summer (left) and autumn (right) 2007. Data are from the analysis of the COSMO model itself.

In Fig. 9, spread and error values in terms of geopotential at 500 hPa are shown. For this mid-tropospheric variable the ensemble spread is better able to describe the error, especially for the autumn season (right panel).

3.2 How different perturbations contribute to the spread

In order to quantify the contribution of each type of perturbation to the generation of spread in the ensemble, we have analyzed how the inner spread varies according to the two different methods used to group the ensemble elements. The 16 members can be subdivided into 4 groups of 4 elements each, in 2 different ways:

- considering groups of elements homogeneous in terms of initial and boundary conditions, but distinct for the model parameterizations;
- considering groups of elements homogeneous in terms of the model parameters, but distinct in terms of initial and boundary conditions.

The spread internal to the groups of the first type is due to parameter perturbations only (parameter spread), while the spread internal to the groups of the second type is due to driving-model perturbations only (driving-model spread). Each group is referred to after the common feature of their members, e.g. the group named *ecmwf* contains all the runs driven by the ECMWF global model, which have different parameter perturbations, while the group named *p1* contains all the runs with the same physics perturbation No. 1, with different initial and boundary conditions. For a complete characterizations of the 16 elements, see Tab. 2. In Fig. 10 the different spread components in terms of geopotential height at 500 hPa are shown.

The 4 upper lines represent the contribution to the spread due to different driving models only, while the 4 lower lines represent the contribution to the spread due to different physics parameters only. The driving-model spread is quite larger than the parameter one and increase rapidly with the forecast range. In terms of this mid-tropospheric variable, the perturbation of the parameters plays an almost negligible role, the parameter spread being about one order of magnitude lower than the driving-model one. In Fig. 11, the contributions to the spread are shown in terms of temperature at 850 hPa.

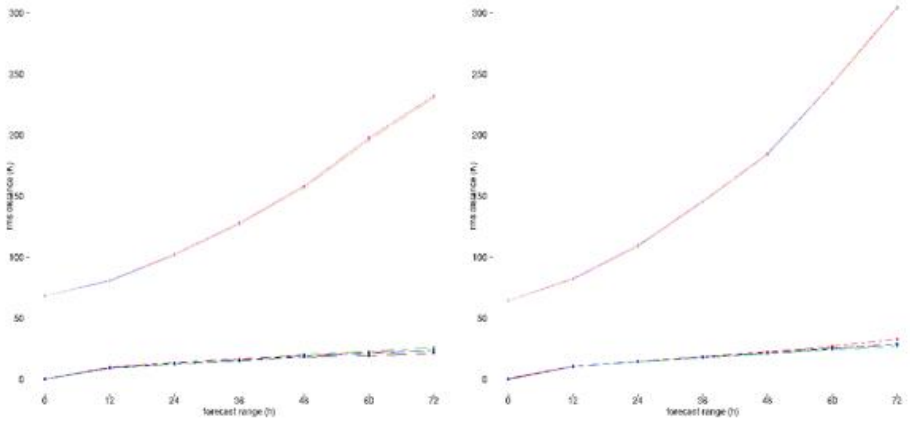

Figure 10: Spread (root-mean-square distance) of the ensemble members for the different forecast ranges, in terms of geopotential height at 500 hPa for the 50 summer runs (left panel) and for the 49 autumn runs (right panel). Each line represents the inner spread relative to a particular 4-member sub-ensemble. For each line, the legend denotes the feature which is common for a particular configuration of the 4-member sub-ensemble.

For this variable the driving-model spread is greater than the parameter one, but the two contributions are of the same order of magnitude. Parameter perturbations produce a spread of about 0.4-0.8 K, almost constant as forecast range increases, while driving-model perturbations produce a spread which ranges from 1 to 2 K, increasing with the forecast range.

Considering a surface variable, namely 2m temperature (Fig. 12), the spread components exhibit a different behaviour. In both season a larger contribution to the spread comes from the use of different initial and boundary conditions. In the summer season (left panel), the contribution is twice the one related to model physics perturbations, this holding throughout the entire forecast range. In the autumn season (right panel), instead, the contribution to the spread due to different initial and boundary conditions is only slightly larger than the one due to different physics configurations and the difference between the two tends to increase with increasing forecast range. It is worth mentioning that, locally on sub-areas or for single events, the main contribution can be provided for certain time ranges by the physical perturbations (not shown). It is also interesting to notice that the parameter spread (four lower lines in the panels) does not vary considerably depending upon the global model used to provide initial and boundary conditions to the COSMO-SREPS runs at which perturbations are then applied. As for the driving-model spread (four upper lines in the panels), this does not vary considerably depending upon the physics set-up adopted for the runs, with the exception of perturbation *p4* (grey line), which tends to give rise to lower spread.

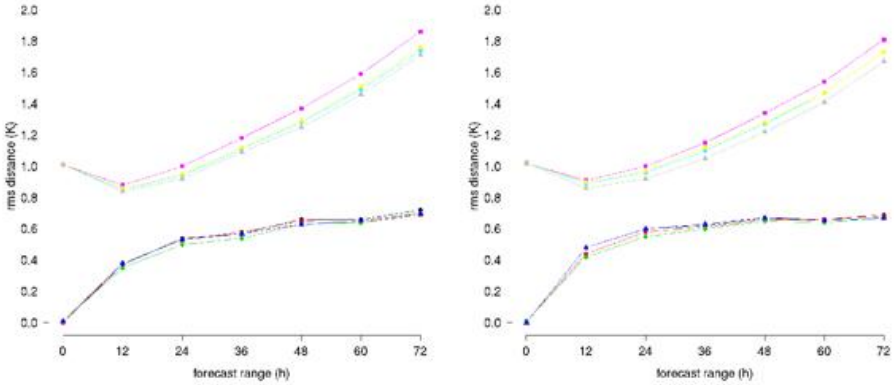

Figure 11: Same of Figure 10 but for temperature at 850 hPa.

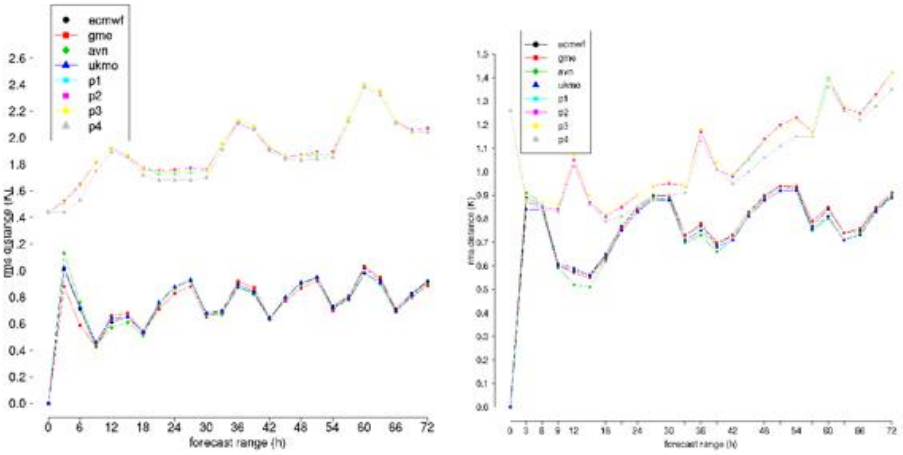

Figure 12: The same as in Figure 10 but in terms of 2-metre temperature. The sample is the high-res Italy dataset.

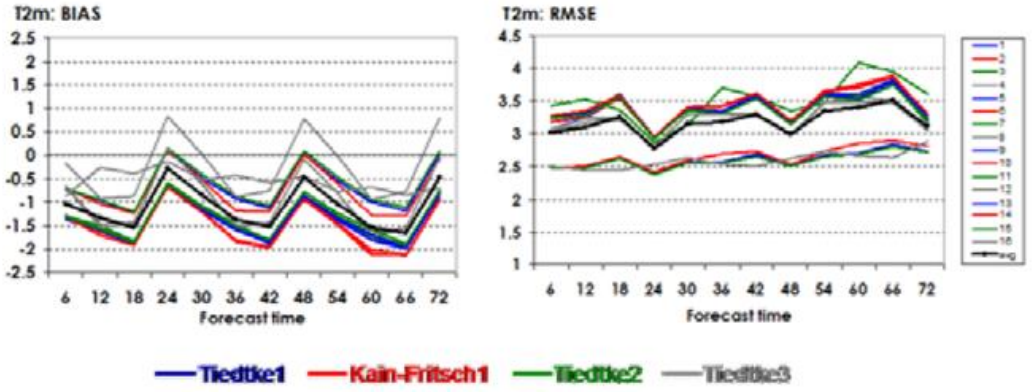

Figure 13: Bias and RMSE for temperature over Greece plotted with respect to effect of physical parameterisation. The thick black line represents the average of all the ensemble members.

A similar evaluation of the spread contribution in terms of 2m temperature was made over Greece (Fig. 13). Temperature Bias and RMSE of each ensemble member have been grouped with respect to the physical parametrization used for that member. It is indicated that that physics parameter perturbations were not producing a big impact in differentiating the scores obtained by the members.

3.3 How different perturbations contribute to the skill

In order to assess the contribution to the skill of the system provided by the different ensemble members, verification of the performances of the 16 runs has been also made, both in terms of temperature and precipitation. Results in terms of 2m temperature for summer 2007 are shown in Fig. 14 for northern and central Italy.

It is evident that the Bias of the GME-driven members is different from that of the other members, which are quite mixed up. In particular, GME-driven members are always warmer than the others. In terms of MAE, again the GME-driven members exhibit a peculiar behaviour, their error being the lowest. This indicates that the errors of the members of this group have lower absolute values, but probably most of them are of the "warmer type", hence sum up in the Bias with equal sign determining a Bias increase. Instead, the non-GME-driven members probably have some more "colder type" contributions to the Bias, though not enough to obtain a non-Biased forecast. Another interesting feature is the fact that members with physics perturbation *p4* (*pat_len*=10000) have the largest errors in the minimum temperatures (chain-dashed line with squares). The different behaviour of the GME-driven members is indeed present in both regions, as appears by considering the similar analysis carried out over Greece (Fig. 15). Nevertheless, conclusions about the Bias are different over the two areas: in Italy all the forecasts generally overestimate temperature, while in Greece all members underestimate temperature. This is an effect of the different climate conditions between the two regions. Looking at the error (mae or rmse) it seems that GME-driven members have better performance over both regions. It is worth pointing out that only the initial and boundary conditions provided to the GME-driven members are

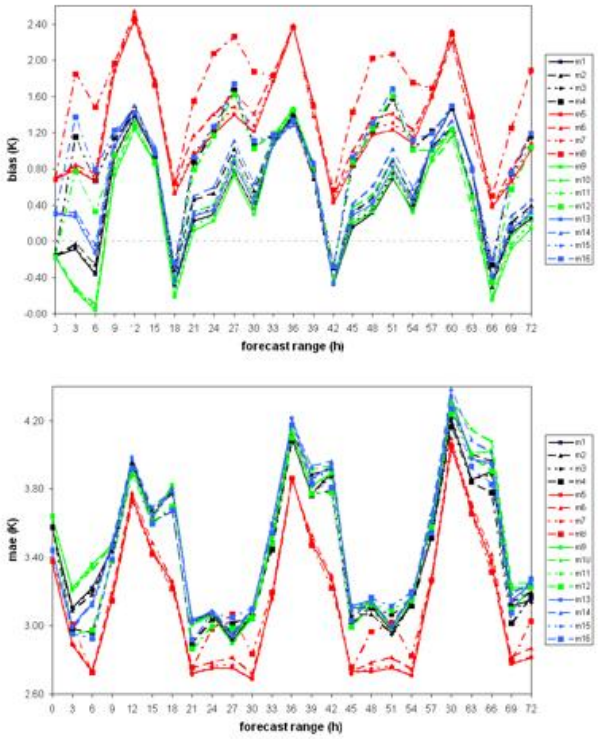

Figure 14: 2m temperature Bias (upper panel) and MAE (mean-absolute-error, lower panel) for the 16 COSMO-SREPS runs, computed over an alpine area (synop alpine dataset) for summer 2007.

characterized by a coherence between soil and atmosphere. In fact, in the 25-km COSMO runs performed by INM, the atmospheric fields are provided by the 4 different global models, while the soil fields are always provided by the GME run. Hence, the coherence between atmosphere and soil in the "father" runs can have a positive influence on the forecast of 2m temperature by the GME-driven members.

In order to identify the effect of the different months on temperature errors, both Bias and RMSE of the ensemble mean are calculated for each month (Fig. 16). It is clear that during summer months, especially June and July 2007, temperature is extremely underestimated. In fact, these two months were exceptionally warm with strong heat waves (the maximum temperature in Athens reached 46.2 °C in June). In autumn (here December is included as an autumn month), RMSE values remain close to 2 °C which is a statistically acceptable error value. It is worth underlining that the daily cycle of the error is inverse between summer and autumn months having its maxima during midday in the summer (also in September) and during night in autumn/winter. This is usual outcome for limited area models which is driven by soil parameterizations affecting the fluxes between soil and atmosphere. In Fig. 17, results in terms of 2m temperature for autumn 2007 are shown for northern and central Italy. During autumn, all the members exhibit a negative Bias, while in summer it was positive, but the error magnitude is almost the same (3-4 K). The 16 forecasts are quite mixed up, and the GME-driven members are included among the others. The performance of the IFS-driven members is slightly worse than the others, especially at the beginning of the forecast range. Members with physics perturbation *p4* are still characterized by a slightly different Bias, being generally warmer. Considering 24h precipitation forecast, the ensemble scores have been computed for each of the 4 groups of 4 elements which have been described at the

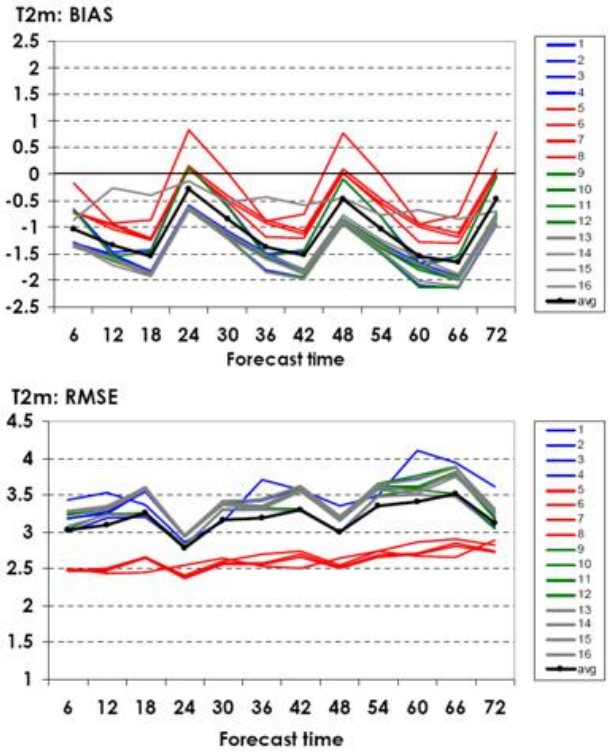

Figure 15: 2m temperature Bias (upper panel) and RMSE (lower panel) for the 16 COSMO-SREPS runs, computed over Greece for the whole period (June to December 2007).

beginning of section 3.2, in order to assess how the different forecast characteristics in terms of driving model and parameter contribute to the skill. The ROC area of the 4-member sub-ensembles are shown in Fig. 18 for the summer season and for the alpine area. The light blue line of each panel represents the ROC area of the full 16-member ensemble, which gives an indication of the COSMO-SREPS skill in forecasting precipitation for that period and in that particular area.

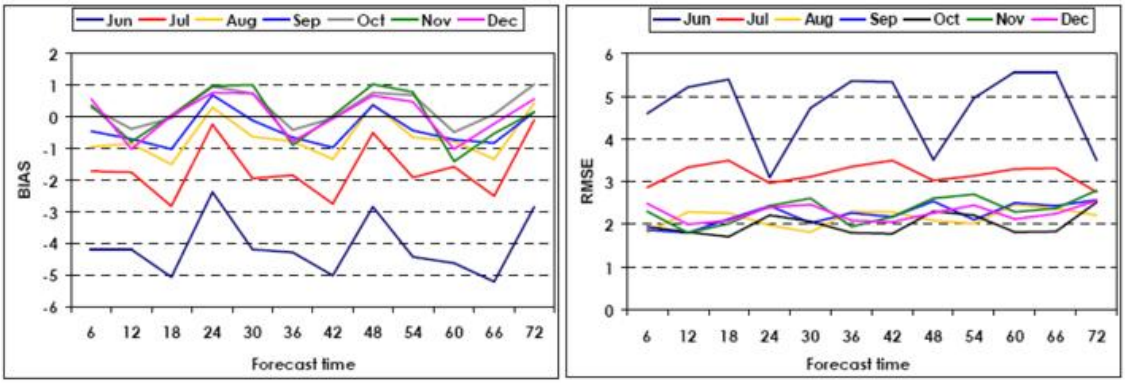

Figure 16: 2m temperature Bias (left panel) and RMSE (right panel) for the COSMO-SREPS ensemble mean, computed over Greece for the different months.

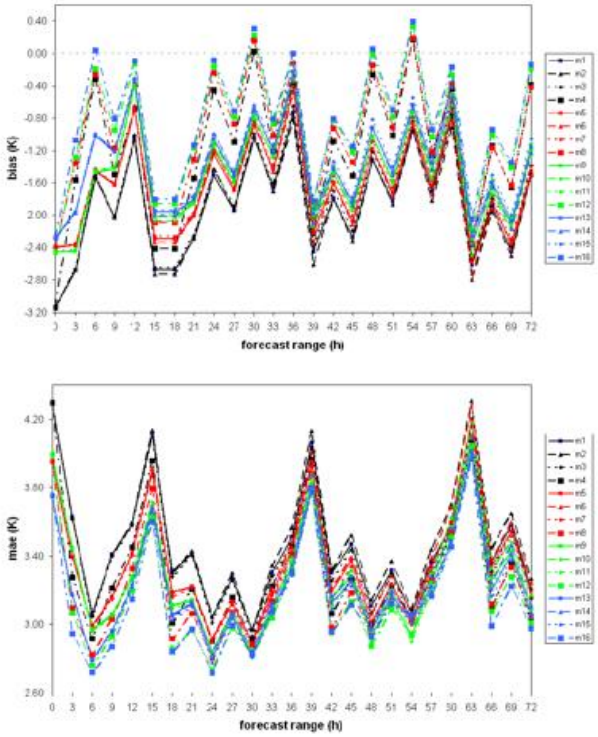

Figure 17: 2m temperature Bias (upper panel) and MAE (mean-absolute-error, lower panel) for the 16 COSMO-SREPS runs, computed over the alpine area (synop alpine dataset) for autumn 2007.

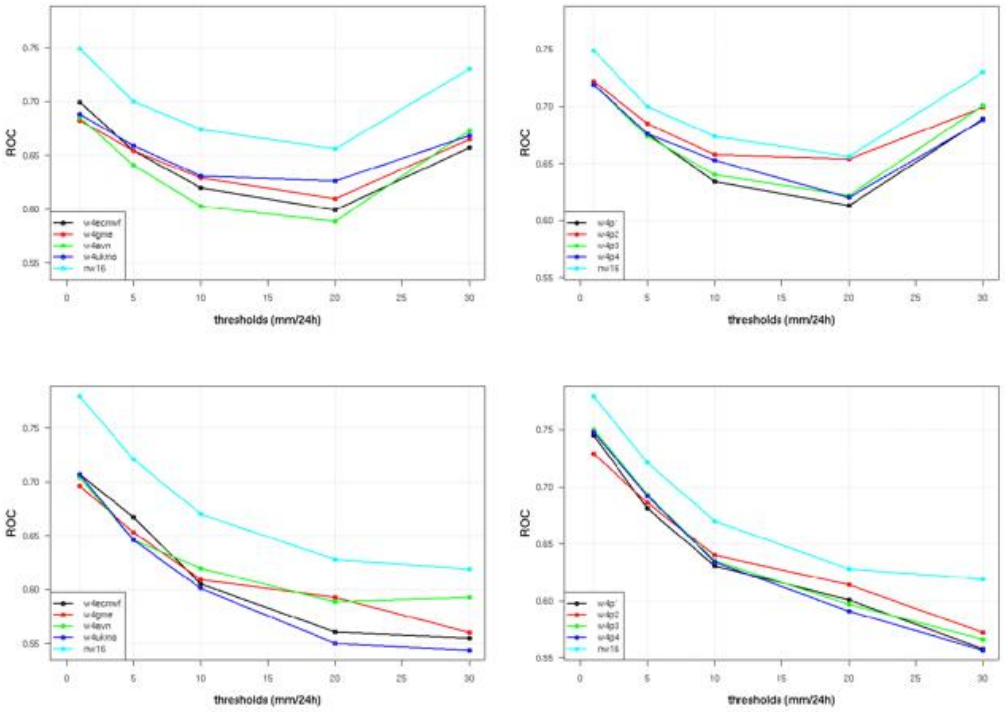

Figure 18: ROC area as a function of threshold for 24hr accumulated precipitation in the alpine area (high-res alpine data set) for the summer season. Left panels: full 16-member COSMO-SREPS (light blue line) vs. 4-member ensembles with identical 'mother run' (black: ECMWF, red: GME, green: GFS, blue: UKMO). Right panels: full 16-member COSMO-SREPS (light blue) vs. 4-member ensembles with identical physical perturbation (black: p1, red: p2, green: p3, blue p4). The upper panels are for the +30 h forecast range, while the lower panels are for the +54 h forecast range.

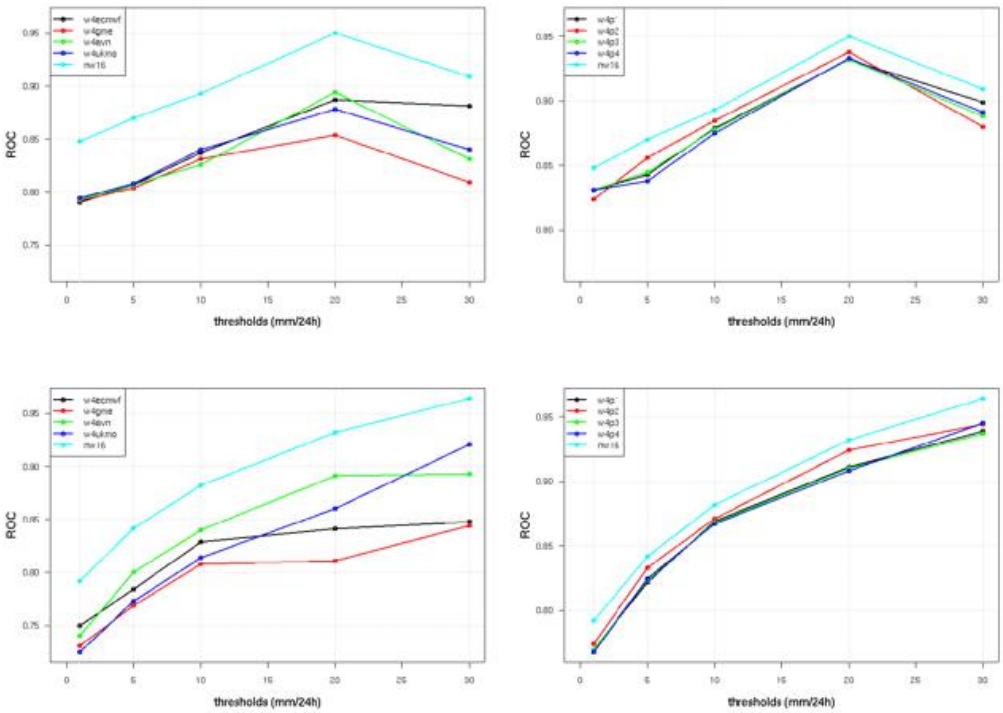

Figure 19: same of Fig. 18 but for the autumn season.

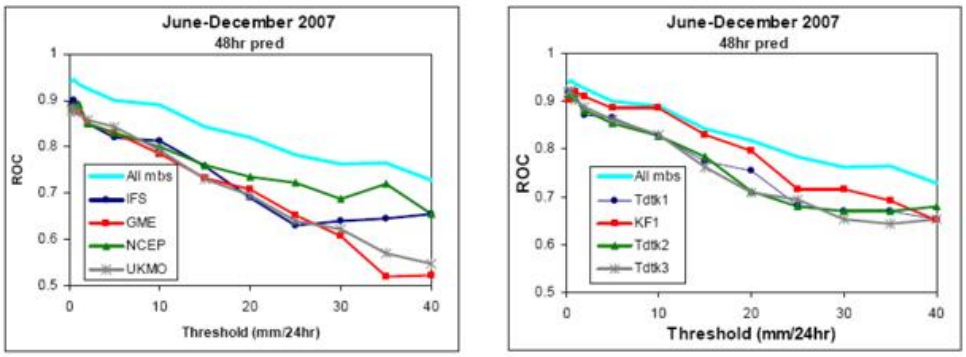

Figure 20: ROC area as a function of threshold for 24hr accumulated precipitation over Greece (synop Greece data set) for the whole period (June to December 2007). Left panel: full 16-member COSMO-SREPS (light blue line) vs. 4-member ensembles with identical 'mother run' (blue: ECMWF, red: GME, green: GFS, grey: UKMO). Right panel: full 16-member COSMO-SREPS (light blue) vs. 4-member ensembles with identical physical perturbation (blue: p1, red: p2, green: p3, grey p4). The forecast range is +48 h.

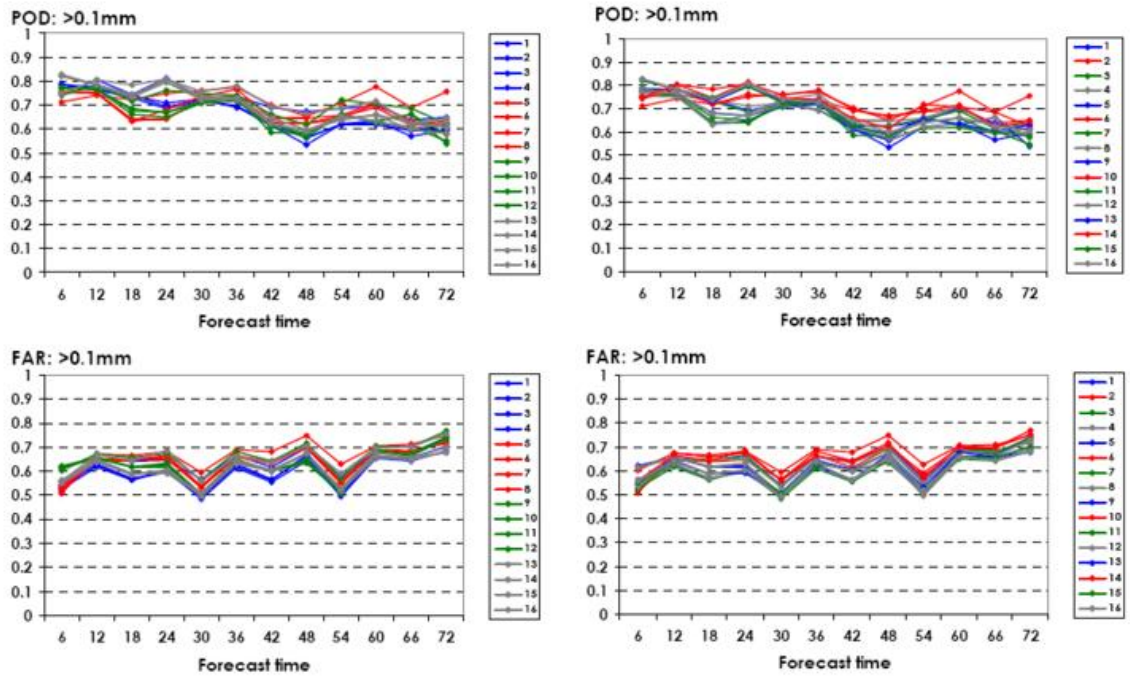

Figure 21: Probability of Detection (upper panels) and False Alarm Rate (lower panels) as a function of threshold for 6h accumulated precipitation over Greece (synop Greece data set) for the whole period (June to December 2007). In the left panels each line is coloured according to the driving-model of the member, while in the right panels each line is coloured according to the parameter set-up.

In the left panels, the other lines show the ROC area values of the 4-member ensembles made up by the 4 members nested on one particular global model. The 4 members are differentiated only in terms of the set-up of the physical parameterizations. Therefore, these represent the skill of ensembles, which are only model-perturbed, having the same initial and boundary conditions. Apart from the decrease in skill evident when passing from a 16-member to a 4-member ensemble, which is expected, it is worth pointing out that the different 4-member ensembles have different skill, which varies with the considered forecast range and also with threshold. In the right panels, the 4-member ensembles made up from identical physics perturbations are shown. Therefore, these represent the skill of ensembles, which are perturbed in the initial and boundary conditions only, but have the same model set-up. The comparison of each right panel with the corresponding left one suggests that perturbation of initial conditions generally yields more skillful performance than physical perturbation only. This is an indication of the fact that, the higher degree of diversity among members introduced by perturbing initial and boundary conditions determines a greater amount of skill with respect to the smaller-scale diversity introduced by the physics perturbations. As for the role of the different parameterizations, the 4-member ensemble where model perturbation *p2* (Kain-Fritsch convection scheme) is applied to each member (red line on the right panels) turns out to be more skillful that other 4-member ensembles. Results for the autumn season are shown in Fig. 19. It appears that scores for the autumn season are quite higher than those relative to the summer season, but the general features are the same. Again driving-model diversity gives rise to a more skillful forecast with respect to parameter diversity and the members of the Kain-Fritsch group tend to have more skill in terms of ROC area. The same evaluation has been performed also for Greece. Scores over Greece are shown in Fig. 20, for the whole period and at a +48h forecast range. It is

evident that larger skill resulted by varying the driving model only (lines in the right panel), compared to varying the physical parametrization only (lines in the left panel). The effect of the different initial conditions is not evident, while Kain-Fritsch parameterization provides the best score as the higher ROC area values suggest. From these results it is difficult to judge which driving-model leads to more skillful forecast, the results being dependent on the geographical area, on the season, on the forecast range and on the precipitation threshold. As for the different parameter choice, we should be careful in the evaluation of the Kain-Fritsch members. They have the best performance in terms of ROC area but the worst in terms of BSS (not shown). This is due to the fact that they always tend to produce slightly too much rain, as it is shown in Fig. 21, where Probability of Detection and False Alarm Rate for the 16 members over Greece is shown, in terms of 6-hour accumulated precipitation. Kain-Fritsch members have higher POD but also higher FAR. This result is confirmed over the alpine area (not shown).

3.4 Study on parameter perturbations

Beside the COSMO-SREPS suite, a parallel suite, called CSPERT, was implemented and run continuously at ECMWF (but not in real time) for the whole Autumn 2007 (September-October-November, 91 runs). Since the preliminary tests on COSMO-SREPS had identified a lack of spread due to an incomplete description of model uncertainty sources, this parallel suite was generated to choose more parameter perturbations for future implementation in COSMO-SREPS. This is necessary to increase the spread to values closer to the COSMO model error, especially for surface variables. The 16 perturbations involve also physical packages such as cloud and land schemes which had not been considered before (see Tab. 3). Initial and boundary conditions for the 16 runs were provided by the same run: the operational deterministic integration of ECMWF. The runs started daily at 00 UTC and the forecast range was 24 hours only, not 72 as in the COSMO-SREPS suite. This was done to save computer time, restricting the analysis to the shorter forecast range, where a good representation of the "error of the day" was needed also for data assimilation purposes.

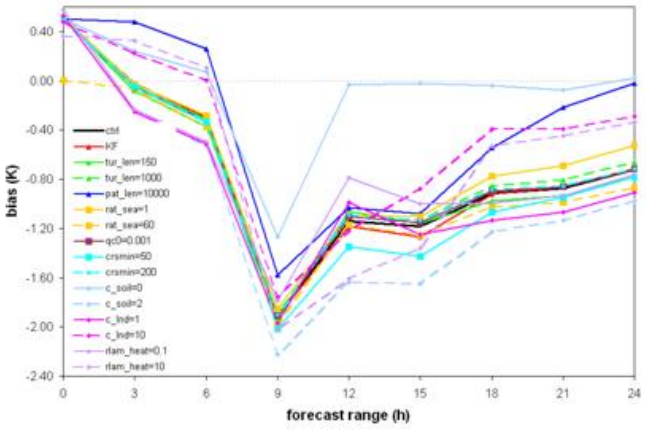

Figure 22: Mean Error (or BIAS) relative to the 16 CSPERT members in terms of 2m temperature, compared against observations over northern Italy for Autumn 2007.

In Fig. 22 and Fig. 23, an evaluation of the 16 runs is shown in terms of 2m temperature. The forecasts issued by the 16 members of the CSPERT suite were compared with non-GTS observations covering northern Italy (high-res Italy data-set, about 400 stations) for the

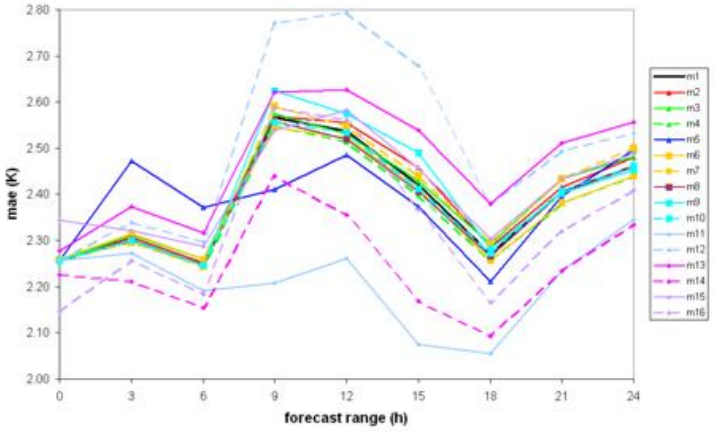

Figure 23: Mean Absolute Error (MAE) relative to the 16 CSPERT members in terms of 2m temperature, compared against observations over northern Italy for Autumn 2007.

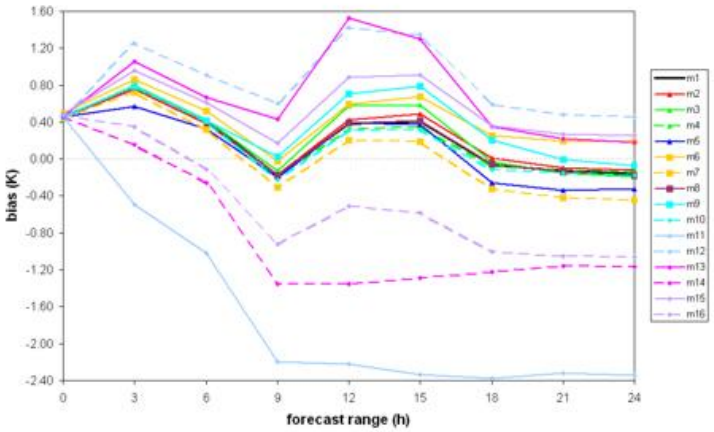

Figure 24: Mean Error (or BIAS) relative to the 16 CSPERT members in terms of 2m dew-point temperature, compared against observations over northern Italy for Autumn 2007.

whole Autumn 2007 period. This analysis shows that the perturbation of some parameters does not produce a detectable impact (at least in terms of 2m temperature), measured by the difference in score values between the run with that particular parameter set-up and the control run (thick black line). This is the case for the *qc0* and *tur_len* parameters. On the other hand, the perturbation of some parameters has a marked impact and could induce a significant increase of the ensemble spread. This is the case for the *c_soil*, *c_lnd* and *pat_len* parameters. It has to be underlined that if a particular parameter change produces a model integration which results to be statistically more or less skillful than the control run, this could be considered as a change to be implemented into all the runs to improve model performance and should not be used to produce ensemble perturbations. Of course we must be careful in this evaluation, the positive or negative impact should involve all the interesting meteorological variables and not just one. Furthermore, it is advisable to test the impact also on other seasons, characterized by different soil conditions and climatology. The good result obtained for 2m temperature by setting *c_soil*=0 should be regarded as suspicious, since this setting implies the suppression of any evaporation from

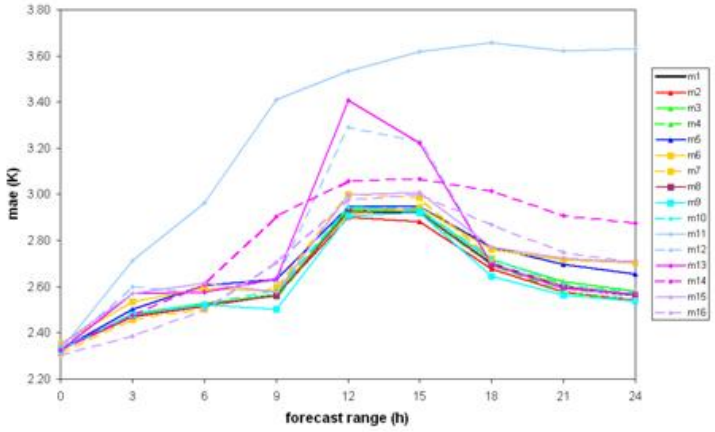

Figure 25: Mean Absolute Error (or MAE) relative to the 16 CSPERT members in terms of 2m dew-point temperature, compared against observations over northern Italy for Autumn 2007.

the bare soil. This is also evident by considering verification for other variables. Results of the evaluation in terms of 2m dew-point temperature are shown in Fig. 24 and Fig. 25. As it was expected, the run with *c_soil*=0 has the largest negative Bias and the largest error. The major impact is given by the runs with perturbation of the parameters *c_soil*, *c_lnd* and *rlam_heat*. Verification has been made also in terms of 6h precipitation forecasts (Fig. 26). The parameters producing the greater impact are *pat_len*, *c_soil*, *rlam_heat*, *rat_sea*. The major impact for the highest precipitation threshold is obtained by changing the scheme used for convection parametrization, namely using Kain-Fritsch instead of Tiedtke (perturbation *p2*, red line), as expected. As already underlined, the use of this scheme produces a positive Bias in precipitation, causing too many false alarms. The impact of the different set-up of the 16 runs on the selected meteorological variables is summarized in Tab. 4. The scores obtained by the 15 perturbed runs are evaluated against the score of the control run and a colour is assigned according to the performance:

- red: the perturbed run is worse than the control
- yellow: the perturbed run is slightly worse than the control
- light green: the perturbed run is slightly better than control
- dark green: the perturbed run is better than the control
- grey: the perturbed run is equivalent to the control
- white: no evaluation is possible, since the result changes with the forecast range

Looking at Tab. 4 it is evident that none of the runs performs continuously better than the control, so that its set-up can be used as the new control set-up. Some improvement is possible by choosing *rlam_heat*=10, *crsmin*=200 and *tur_len*=1000, but it is yet to be investigated what effect will be if these three values were implemented in the same run. Instead, the choice of *rlam_heat*=0.1, *c_lnd*=1, *c_soil*=2 and *tur_len*=150 has lead to a worsening of the performances. The fact that statistical behaviour of the various parameter set-ups "fluctuates" with respect to the control run (it is not always better nor worse) should

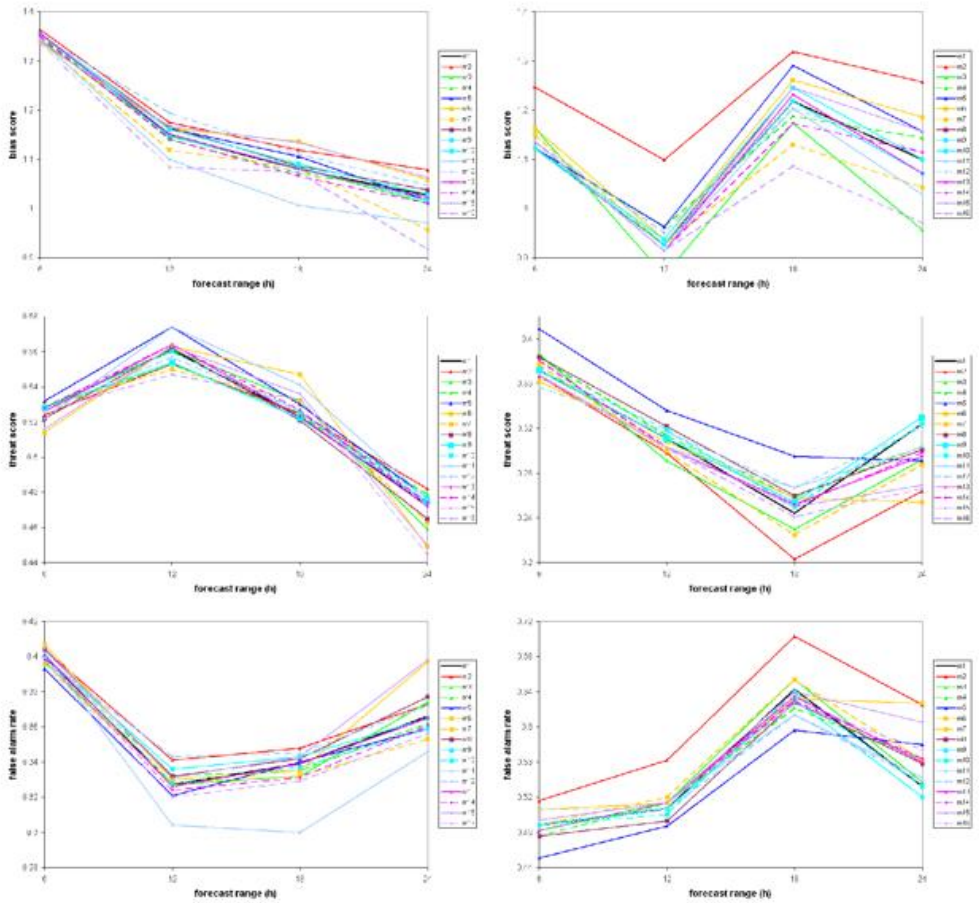

Figure 26: Bias Score (upper panels), Threat Score (middle panels) and False Alarm Rate (lower panels) relative to the 16 CSPERT members in terms of 2m 6h accumulated precipitation, for the 1mm/6h (left panels) and 10 mm/6h (right panels) thresholds.

be regarded as a positive outcome in this ensemble framework, since ensemble perturbations should be almost equivalent. The only set-ups which should be discarded are those which do not produce any (or a very small) impact (e.g. *tur_len* parameter). The analysis of these impacts is currently under study and will be completed during the CONSENS Priority Project. In particular, the CSPERT suite will be run for at least another season, probably summer, in order to assess the impact of the changes of the parameters in a quite different climatological situation. The outcome of the analysis will lead to the definition of a set of parameter perturbations to be applied in the future COSMO-SREPS suite.

4 Open points

- The system is under-dispersive (from the spread/skill relationship), hence there is a need to add more model perturbations
- It is difficult to assess in a statistically robust manner which parameters should be perturbed, since a large sample is needed. In fact, some values of the parameters can improve the forecast only for a certain season or for a certain meteorological variable. Furthermore, it is difficult to understand which choices of the parameter values can be made simultaneously in a run, unless some combinations are tried for a testing period
- Problems in running the system with continuity due to the difficulty of getting initial and boundary conditions every day
- The issue of perturbing the lower boundary was not addressed for reasons of lack of time and human resources
- The issue of perturbing the initial conditions at the mesoscale was not addressed for reasons of lack of time and human resources and it is abandoned for the moment

5 Resources used

- The computational resources needed to run the system are the Billing Units at ECMWF. These were provided by:
  - COSMO members (Germany, Italy (not for year 2008), Switzerland, Greece)
  - ECMWF through Special Projects: SPITLAEF and SPITFEAR

  The run of the system was computationally quite demanding, especially to carry on the testing of the new parameter perturbations.
- The verification task required quite an amount of resources in terms of FTEs, since it is a demanding task to obtain a statistically robust evaluation of the system performances. This had to be done for different seasons, different geographical regions and for a number of meteorological variables.

6 Lessons learned

Some Project tasks were not addressed due to lack of time and/or human resources: this was due mainly to a lack of experience in evaluating how much work was needed for a particular task, but also to the fact that, during the project, it was judged that it was more important to continue and further develop a certain line of research (not planned) instead of opening a new one. This is partly inherent in scientific research, since according to the results new questions can arise. Furthermore, since the work for the Priority Project is usually not the only one a scientist has to do, but it is done in addition to other operational and/or research work, new priorities can arise for her/him, which are not COSMO priorities but National or Regional Service ones. Finally, it happened that a task was temporally extended or shifted, for the same reasons already underlined, without undermining the project outcome. This should be considered in the project planning, allowing some flexibility in the time extension of the tasks.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW) and Romania (NMA). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Project report

1.1 Introduction

Quantitative precipitation forecasting (QPF) is an important reason to run a numerical weather prediction model - for forecasters and customers. Unfortunately, precipitation is also a very difficult parameter to quantitatively forecast. There are indications from verification and from forecasters in various COSMO countries, that the COSMO model - like other weather forecast models - has some serious deficiencies in quantitatively forecasting precipitation. This priority project aims at looking into the COSMO model deficiencies concerning QPF. The study is focused on the bias in area averaged accumulated precipitation rather than on local skill scores.

The QPF quality suffers from different sources of uncertainty such as inaccurate initial and boundary conditions, inaccuracies of numerical methods, and the incomplete description of physical processes. Especially, not all physical processes involved in the formation of precipitation are fully understood (Beard and Ochs, 1993), not to mention adequately represented in the model. Further limitations result from the fact, that some situations have a low predictability causing large errors in the precipitation forecast resulting from small errors in the initial conditions. This limited predictability especially occurs in situations which involve moist convection (Zhang et al., 2002; Walser et al., 2004; Hohenegger et al., 2006). The COSMO model, formerly known as Lokal Modell (LM, Steppeler et al., 2003), is a limited-area non-hydrostatic model that is developed within the consortium for small-scale modelling (COSMO). The model is designed for applications in the meso-β (20-200 km) and meso-γ (2-20 km) range and is used operationally at meteorological services in Germany, Greece, Italy, Poland, Romania, and Switzerland. A brief description of the model configuration and setup is given in Section 1.2. The objective verification of the operational forecasts as well as feedback by forecasters reveals deficiencies in the forecasts of precipitation. The kind of typical QPF error differs depending on the setup of the model for the operational forecasts in the different countries. The individual setups differ regarding size and location of the model domain, initial and boundary conditions as well as numerical methods or physical parameterizations. The aim of the present study is to investigate which parts of the modelling system have a significant impact on QPF. Investigations are focussing on numerical methods and physical parameterizations, while the effect of inaccurate initial and boundary conditions is disregarded in this study. Identifying the most important and/or weakest parts of the model will not necessarily lead to direct improvements, but can at least provide guidance for future research and development.

Investigations within the framework of this project are based on numerical sensitivity studies. Three to four test cases are selected for every implementation of the model representing typical forecast errors in the respective region. The test cases are selected such that the forecast error is unlikely to be caused by wrong synoptic conditions in the initial or boundary data. Altogether 25 test cases are selected that are representative for forecast errors in different geographical regions in Europe and for different meteorological situations (Section 1.3). For each of these test cases, 22 sensitivity studies regarding initial conditions, numerical methods and physical parameterizations (Section 1.4) are performed, and the effect and the importance of changes on the 24h area averaged precipitation is investigated (Section 1.5). The results and their implications are discussed in Section 1.6.

1.2 Configuration and setup of the COSMO model

The COSMO model is a non-hydrostatic limited-area atmospheric model developed within the Consortium for Small-scale Modelling (COSMO) for applications on the meso-β and meso-γ scale (Steppeler et al., 2003). The model is based on non-hydrostatic, fully compressible hydro-thermodynamical equations in advection form. The prognostic variables are horizontal and vertical wind components, pressure perturbation, temperature, specific humidity, cloud water and ice content, specific water content of rain and snow and turbulent kinetic energy. Generalized terrain-following height coordinates with rotated geographical coordinates are used.

The model equations are solved on an Arakawa C-grid with user-defined vertical grid staggering. They are spatially discretized with second-order finite differences. Time integration uses a second order leapfrog HE-VI (horizontally explicit, vertically implicit) time-split integration scheme including extensions proposed by Skamarock and Klemp (1992). A 4th order linear horizontal diffusion is calculated. 3-dimensional divergence damping and off-centering are applied in split time steps. Damping at the top of the model domain is done by Rayleigh damping in the upper layers. Data at the lateral boundaries are prescribed using a Davies-type one-way nesting.

Subgrid-scale turbulence is parameterized by a prognostic turbulent kinetic energy closure at level 2.5 including effects from subgrid-scale condensation and thermal circulations. The surface layer parametrization is based on turbulent kinetic energy and includes a laminar-turbulent roughness layer.

The formation of precipitation is described by a bulk microphysics parametrization including water vapor, cloud water and ice, rain and snow with a fully prognostic treatment of precipitation, i.e. three-dimensional transport of rain and snow is calculated. Condensation and evaporation are parameterized by saturation adjustment while depositional growth/sublimation of cloud ice is calculated using an explicit non-equilibrium growth equation. Subgrid-scale cloudiness used for radiation calculations is parameterized by an empirical function depending on relative humidity, ice content and height.

Moist convection is parameterized using a mass-flux scheme with an equilibrium closure based on moisture convergence following Tiedtke (1989). Radiation is calculated using a two-stream scheme for short- and longwave fluxes (eight spectral intervals) including a full cloud-radiation feedback. A multi-layer version of the soil model solving the heat conduction equation is applied. The simulations are performed using COSMO model version 3.19. Initial and boundary data are taken from GME forecasts (Majewski et al., 2002), no data assimilation is used. The horizontal grid size is 7 km and the number of vertical levels is varying between 40 and 45 for the different model implementations. The position of the model domain and its size also depends on the model implementation and is close to the operational setup of every involved meteorological service (Fig. 1).

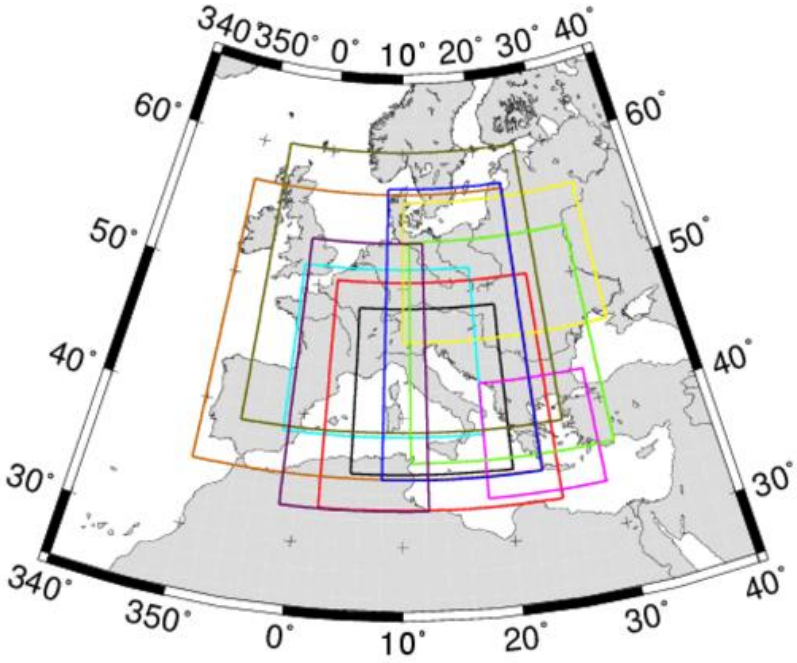

Figure 1: Position and size of the different model domains used for this study.

1.3 Selection and description of the test cases

The present study is focussing on the 24h precipitation sum of the first forecast day, that is, precipitation amounts between 6 and 30 hours lead time excluding the first 6 hours of the forecast (spin-up period). The first forecast day is chosen in order to ensure that initial and boundary conditions are close to reality and deficiencies of model forecasts are mainly due to numerical methods and physical parameterizations. The criterion for the test case selection is a poor forecast of the 24h precipitation sum on the first forecast day. The region of interest is specific for every involved meteorological service (Fig. 1).

The test cases are selected taking into account the typical QPF problems of the different regions of interest. No standard procedure for the selection is prescribed since operational verification procedures at the involved meteorological services are different. Based on operational QPF verification results and the experience of forecasters typical QPF errors are identified and single test cases are collected which reflect the most severe QPF errors and, hence, serve as a kind of prototype events for the observed QPF problems. In order to avoid wrong boundary forcing as a reason for bad QPF, the large-scale flow is checked to be reasonably well predicted. This selection resulted in a list of 53 test cases that were re-simulated with a COSMO reference version in order to exclude QPF errors due to out-dated model versions or inappropriate model settings. The reference version was COSMO model version 3.19, the newest version at that time, in the configuration described in Section 1.2. The boundary values for the reference simulations were taken from GME forecasts. If the QPF error disappeared or was completely changed in the re-forecast, the test case was excluded. The 25 test cases for which the original error was reproduced with the reference version remained on the list. Those test cases were characterized regarding the kind of QPF error (under-, overestimation), the kind of precipitation (mainly stratiform or convective) and the influence of fronts or orographic forcing. Three to four test cases per model implementation were selected by participants covering, if possible, different kinds of QPF errors. The test cases and their characteristics are summarized in Tab. 1.

The test cases fall into two main groups: underestimation of precipitation in convective weather situations (7 test cases) and overestimation of stratiform precipitation (9 test cases). There are 3 additional test cases with convective over- and 5 test cases with stratiform underestimation of precipitation and 1 test case that does not have a significant bias. The two dominant QPF errors correspond to specific geographical regions: 6 test cases of convective underestimation occur in regions where the weather is strongly affected by the vicinity to the Mediterranean Sea (Greece, Italy), and nine test cases of stratiform overestimation occur in countries in which the weather is less affected by the sea (Germany, Romania, Switzerland, and Poland). Thus, the geographical region and the kind of forecast error are closely related.

The QPF is evaluated based on the area averaged precipitation values calculated in evaluation regions that depend on the region of interest. The evaluation regions for the different test cases are defined in Section 4. The observed area averaged and maximum 24h precipitation values are compared with the simulated ones for all test cases (Fig. 2). Observed and simulated area averaged precipitation values are ranging from approximately 0.01 to 60 mm, differing strongly depending on the test case. Most of the test cases show significant differences between observed and simulated values except for the test cases 11 and 20, where the QPF error is not reflected by differences of area averaged or maximum precipitation values. Test case 11 is a situation with severe convective precipitation in the Piemonte region on the 17th of August 2006. The forecast error is underestimation of precipitation in the Toce catchment, while precipitation in the Ticino catchment is overestimated. The area averaged precipitation is calculated for a larger region and, thus, doesn't reflect the (large)

forecast error. A detailed description and discussion of this test case is given in Milelli et al. (2008). Test case 20 is a situation with stratiform precipitation on the 4th of August 2005. In the south-eastern part of Poland the forecast underestimates precipitation in a small region and north of this region the forecast overestimates precipitation. As a result, over- and underestimation are virtually canceling out and the area average is almost perfectly simulated. A discussion of both test cases is given in Section 4.

Table 2: Overview of sensitivity studies regarding initial conditions.

No.	Sensitivity study	Expected	Kind of study
1	Reduction of soil moisture by 20%	Homogenous reduction of precipitation	idealized
2	Increase of soil moisture by 20%	Homogenous increase of precipitation	idealized
3	Reduction of initial humidity by 10%	Homogenous reduction of precipitation	idealized
4	Increase of initial humidity by 10%	Homogenous increase of precipitation	idealized

Table 3: Overview of sensitivity studies regarding numerics.

No.	Sensitivity study	Expected	Kind of study
5	Halved time step	Optimal case: nothing	idealized
6	Leapfrog, tri-cubic semi-Lagrange advection of QR and QS	Less diffusive advection of precipitation	option
7	Runge-Kutta, tri-cubic semi-Lagrange advection of QV, QC, QI QR and QS	Less diffusive, improved flow over terrain, improved advection of all moisture variables	option
8	Runge-Kutta, flux-form advection of QV, QC, QI, QR and QS	Less diffusive, improved flow over terrain, improve advection and mass conservation of all moisture variables	option
9	Runge-Kutta, flux form advection and T'-p' dynamics	Less diffusive, improved flow over terrain, improved advection and mass conservation and a better treatment of buoyancy terms	option
10	increased orography filtering	Slightly decreased orographic precipitation	idealized

1.4 Description of the sensitivity studies

Sensitivity experiments are divided into studies regarding initial conditions, numerical methods, and physical parameterizations. An overview of sensitivity experiments and expected changes is given in Tab. 2 to Tab. 4. The sensitivity experiments include idealized studies with changes that are not considered a possible configuration for operational applications (labeled 'idealized'), studies with optional schemes already included in the model ('option'), and studies with schemes that are currently under development and might be included soon ('development'). Sensitivity experiments regarding initial conditions, namely initial soil moisture and humidity are idealized studies. They are performed to have a reference in order to weight the effects of the other sensitivity experiments.

The sensitivity experiments regarding initial conditions are set up in an idealized way (Tab. 2). Soil moisture is increased (decreased) at all land grid points by 20%. The change is horizontally homogenous and is prescribed in all layers of the multi-layer soil model. The atmospheric water vapor mixing ratio is increased (decreased) by 10% in cloud free regions.

Table 4: Overview of sensitivity studies regarding physical parameterizations.

No.	Sensitivity study	Expected	Kind of study
Microphysics			
11	New warm rain scheme (Seifert and Beheng; 2001)	Reduced drizzle	option
12	Strong changes of ice microphysics and new warm rain scheme	Reduced drizzle and precipitation amount and increased transport of precipitation to mountain lee side	idealized
13	Moderate changes of ice microphysics and new warm rain scheme	Reduced drizzle and precipitation amount and increased transport of precipitation to mountain lee side	development
Convection			
14	Modified Tiedtke scheme	Weaker convection	development
15	Kain-Fritsch/Bechtold scheme	Modified convection	development
16	No parameterization of deep convection	Unrealistic up-scaling of convection, deteriorated forecast	idealized
Planetary boundary layer			
17/18	Decreased/increased scaling factor of height of laminar boundary layer for heat	Increased/decreased vertical exchange of heat and moisture	idealized
19/20	Decreased/increased stomata resistance	Increased/decreased vertical exchange of moisture	idealized
21/22	Decreased/increased laminar scaling factor for heat over sea	Increased/decreased vertical exchange of heat and moisture	idealized

Increased values might result in exceedance of the saturation value. In that test case the exceeding water vapor fraction is transformed to cloud water or cloud ice, respectively, but without considering latent heat release and, thus, a change in temperature.

Sensitivity experiments regarding numerical methods are changes of the time integration scheme in combination with different advection schemes (Tab. 3). For sensitivity experiments 7 to 9 the time integration scheme is changed from a leapfrog scheme to a two time-level 3rd order Runge-Kutta split-explicit scheme (Wicker and Skamarock, 1998). Advection of moisture variables in the reference simulation is calculated explicitly with a mix of various second-order spatial discretization, e.g., centered differences for moisture and cloud water, but upwind advection for cloud ice. Additional sensitivity studies are performed using a higher-order flux-form advection (Bott, 1989), a tri-cubic semi-Lagrange advection for water vapor and hydrometeors and a version using so-called T'-p'-dynamics, which is basically a reformulation of the dynamical core using perturbation temperature instead of total temperature. A sensitivity study with a halved time step is performed in order to confirm that the solution is insensitive against time step changes. The model orography is filtered in order to avoid numerically inaccurate solutions caused by mountain tops and valleys that are represented by only one grid point. The strength of filtering is increased in a sensitivity experiment in order to investigate its effect on orographically induced precipitation.

Sensitivity experiments regarding physical parameterizations are performed for microphysics, convection, and planetary boundary layer parameterizations. Microphysics studies include a sensitivity experiment using a one-moment variant of the warm rain scheme of Seifert and Beheng (2001) instead of the simpler Kessler-type formulation of autoconversion and accretion, and two studies with strong and moderate changes of ice microphysics (especially size, geometry of snow particles, and fall speed). Sensitivity experiments regarding convection include an idealized study without parametrization of deep convection, and a study using the mass flux Kain-Fritsch/Bechtold convection scheme (Bechtold et al., 2001) that is based on a CAPE closure instead of moisture convergence as used in the Tiedtke scheme. A further study is performed using the Tiedtke convection scheme with modifications regarding evaporation, turbulent entrainment and mixed-phase saturation adjustment. Three changes of the parameters of the planetary boundary layer parametrization change the vertical transport of heat and moisture. The vertical transport is decreased (increased) by a factor of 10 (50) in experiment 17 (18), by a factor of 3 (1.7) in experiment 19 (20), and by a factor of 20 (2) in experiment 21 (22). The change of stomata resistance affects the vertical exchange over land and is expected to be important for countries without strong influence by the sea (exp. 19/20). On the other hand, the change of the parameter affecting evaporation from the sea is expected to be important for countries with strong influence of the sea (exp. 21/22).

1.5 Results of the sensitivity experiments

The sensitivity experiments are performed and evaluated by the participating meteorological services. Model code and namelists are provided to everybody in order to ensure a consistent performance of sensitivity experiments. All sensitivity experiments (Tab. 2 to Tab. 4) are performed for all test cases (Tab. 1). However, some sensitivity experiments are missing for some test cases due to technical problems on different computational platforms.

A joint evaluation based on the area average of the 24h precipitation sum of lead times between +6 and +30 hours is performed. The area averaged precipitation value is calculated for the region of interest of every meteorological service. The evaluation regions are chosen sufficiently large in order to avoid changes by small-scale spatial shifts. The smallest evaluation region is about 100 km times 100 km. The evaluation regions are documented in

Section 4. The aim of the joint evaluation is an overview on the effect and its magnitude for different sensitivity experiments. Detailed investigations, e.g., of temporal development or small-scale spatial changes, are excluded from this joint evaluation. They are investigated by the participating groups individually. Due to the variety of details, these results are however not presented in this report.

1.5.1 Change of the area averaged precipitation relative to the reference simulation

We start with a joint evaluation based on the relative difference (Δrel) of the 24h area averaged precipitation of the sensitivity experiments (P_{exp}) with respect to the 24h area averaged precipitation of the reference simulation (P_{ref}):

$$\Delta rel = (P_{exp} - P_{ref})/P_{ref}. \tag{1}$$

The relative difference Δrel is very large for test cases 1, 4, and 12 because the area averaged value of the reference simulation P_{ref} is very small. Due to this dependency on the area averaged precipitation value of the reference simulation, relative differences are not comparable among different test cases. Thus, the relative difference allows comparing the effect of different sensitivity experiments, but not the test cases against each other.

An overview on the results for all sensitivity experiments and all test cases is given in Fig. 3, while Fig. 4 facilitates the comparison between different sensitivity experiments by condensing these results as follows: the sum for all test cases of the absolute values of the relative difference $\sum|\Delta rel|$ is shown as black bars whereas the sum of relative differences $\sum \Delta rel$ is given as grey bars. If a sensitivity experiment is causing an increase or decrease for most of the test cases, $\sum|\Delta rel|$ is about the same as $|\sum \Delta rel|$. On the other hand, the sum of absolute values is much higher than the sum of relative changes, if test cases with an increase and decrease of area averaged precipitation are canceling out.

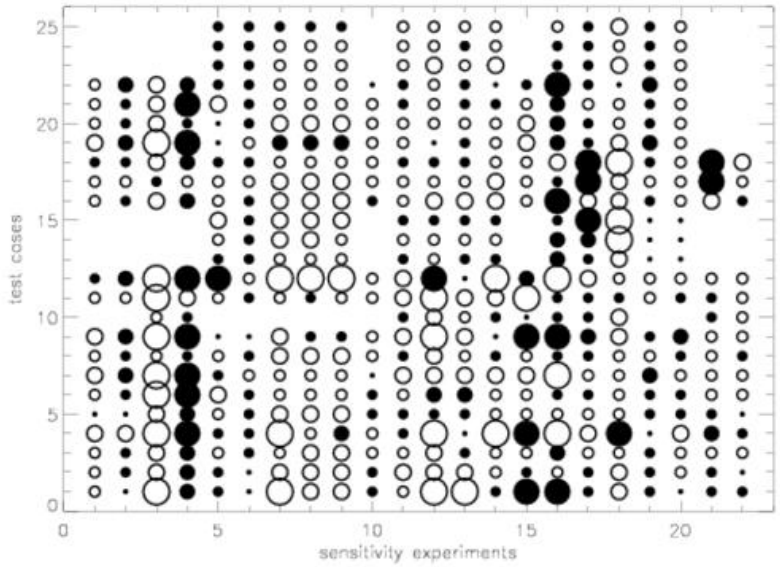

Figure 3: Difference of 24h area averaged precipitation in the sensitivity study and in the reference simulation relative to the 24h area averaged precipitation in the reference simulation Δrel [%]. Filled (empty) circles indicate an increase (decrease) of precipitation relative to the reference simulation. The big circles indicate a change bigger than 30%, medium ones between 10% and 30%, small ones between 0% and 10%, and tiny circles indicate cases with no change at all.

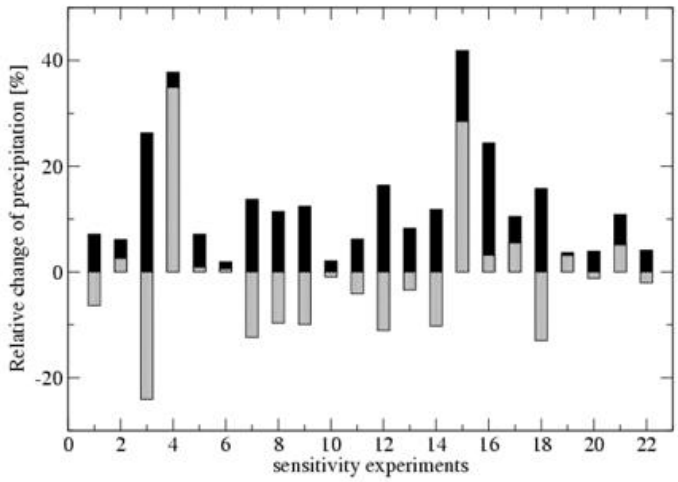

Figure 4: Relative difference of the 24h sum of area averaged precipitation in the sensitivity studies. The sum of the absolute values of the relative changes of area averaged values $\sum|\Delta rel|$ is given as black bars, whereas the sum of relative changes of area averaged precipitation $\sum \Delta rel$ is given as grey bars. The relation between grey and black bars indicates whether changes have predominantly one direction.

Initial conditions

Besides the Kain-Fritsch/Bechtold convection scheme (see below), the strongest changes in area averaged precipitation sums occur in the sensitivity experiments with changed initial humidity (exp. 3 and 4; cf. Fig. 4). The increase (decrease) of initial humidity by 10% causes an increase (decrease) of precipitation of more than 30% in about half of the test cases and between 10% and 30% for most of the other test cases (cf. Fig. 3). The change of initial humidity is predominantly acting as expected: an increase of initial humidity increases the average precipitation by 40% and a decreased initial humidity decreases it by 22%. Compared to the initial humidity changes, the average effect of the soil moisture changes by 20% results in a change in Δrel of less than 10% (exp. 1 and 2; cf. Fig. 3 and Fig. 4). The effect of initial soil moisture has a clear direction, and in those test cases where the change acts in the opposite direction, the effect is typically small. An explanation for the small effect of soil moisture changes might be that the first forecast day is evaluated. Soil moisture might act on a longer time scale and might be more important for longer forecast periods.

The strong impact of initial humidity is not surprising. Verifications of COSMO model results hint at an overestimation of atmospheric humidity. An example is the verification of the COSMO-EU model for the year 2007 using about 20 radio soundings in Europe. The comparison is carried out in the frame of the General Observation Period of the Priority Programme "Quantitative Precipitation Forecasts" of the German Research Foundation. Monthly bias and RMSE of mixing ratio are presented on the web page

http://gop.meteo.uni-koeln.de/gop/doku.php?id=data_quicklooks.

The monthly verification of the mixing ratio bias shows a great variety depending on radiosonde station and season. Examples for the radiosonde stations Lyon, Payerne, and Greifswald for January and July 2007 are shown in Fig. 5. The results show that the mixing ratio is overestimated above approximately 1000 m above ground in the model simulations during winter for these three radiosonde stations. The bias of initial humidity is generally relatively small, but increases significantly during the first 3 hours of simulation. In the summer months the overestimation of the mixing ratio in the model simulations is less pronounced. On the contrary, the mixing ratio bias at radiosonde stations in Italy and France show a tendency of underestimated humidity in the model simulations. Thus, over- and underestimation of simulated humidity might be an explanation for stratiform overestimation as well as convective underestimation. These results are only based on results of one model implementation, COSMO-EU, and for just one year, 2007. Still, the results motivate further investigations regarding the connection between simulated humidity and QPF deficiencies and possible reasons for over- or underestimated humidity in the COSMO model. The sensitivity studies confirm the expected great importance of simulated humidity for the precipitation forecast and, thus, it needs to be investigated if QPF deficiencies are partly based on wrong humidity.

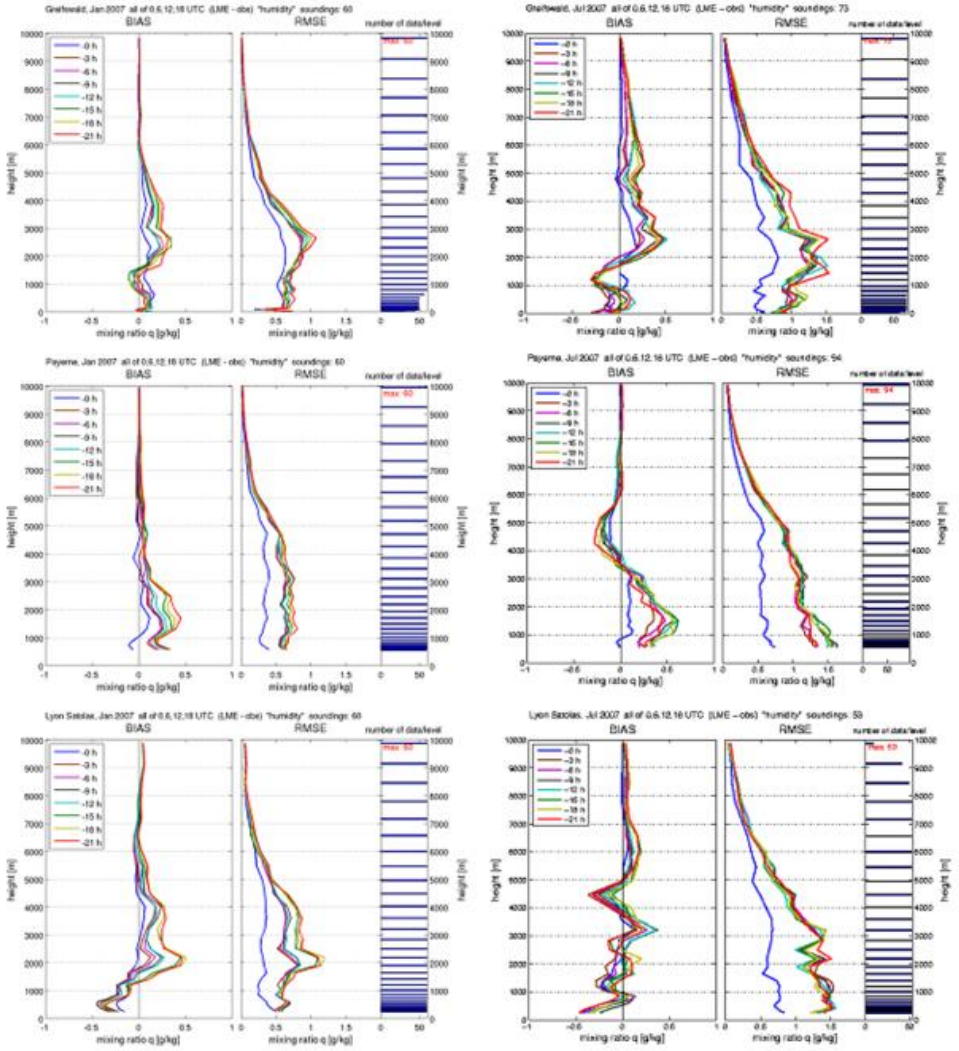

Figure 5: Monthly average Bias and Rmse for the observed and simulated vertical profile of mixing ratio at the radiosonde stations Greifswald (top), Payerne (middle), and Lyon (bottom) in January 2007 (left panels) and in July 2007 (right panels). The figures are taken from the GOP webpage: *http://gop.meteo.uni-koeln.de/gop/doku.php?id=data_quicklooks*.

Numerical methods

The strongest effect when changing numerical methods is the decrease of average precipitation when using the Runge-Kutta time integration scheme instead of Leapfrog (exp. 7 to 9; cf. Fig. 4). The Runge-Kutta scheme reduces the average precipitation amount by about 10%, for most of the test cases (cf. Fig. 4), stratiform as well as convective (cf. Fig. 3). The reason for this decrease has not yet been investigated. A possible explanation is that the centered differences, which are used in the reference simulation for advection of QV and QC, are not sufficiently accurate or lead to a significant mass error. Compared to this, the effect of the different variants of the Runge-Kutta scheme (exp. 7 to 9) is small. The effect is also small if the Leapfrog scheme is used with different advection schemes for mixing ratios of rain and snow (exp. 6; cf. Fig. 4), which leaves the improved advection of cloud and ice mixing ratios as the only possible explanation for the change in the average precipitation. Unfortunately, it was not possible to test this in a separate sensitivity experiment.

The impact of increased orography filtering and halved time step is negligible (exp. 5 and 10; cf. Fig. 4), i.e., changes remain below 10% for nearly all test cases. Only one test case with underestimated convective precipitation (test case 12) shows a significant relative increase of precipitation when changing the orography filtering, which is mainly due to the low area averaged precipitation value in the reference run. The absolute change from 0.92 mm in the reference run to 1.30 mm in the sensitivity experiment is small. Orography filtering and time step are part of the numerical methods and they should not have a significant impact on the results. Thus, insensitivity with respect to changes of orography filtering and time step is a positive result.

Physical parameterizations

The biggest change, besides the initial humidity changes, is caused by using a different convection scheme: Kain-Fritsch/Bechtold instead of Tiedtke (exp. 15). The sum of absolute values of relative changes of precipitation $\sum |\Delta rel|$ is about 40% resulting in an average increase of 30% (cf. Fig. 4). Changes are acting in both directions and there are many test cases with reduced average precipitation (cf. Fig. 3). Still, relative changes with increased average precipitation are bigger. This result is consistent with results from a comparison of the Kain-Fritsch/Bechtold and the Tiedtke scheme for Switzerland for summer 2006. The comparison showed that the Kain-Fritsch/Bechtold scheme tends to simulate higher area averaged precipitation values (Dierer and Schubiger, 2008). A test case with underestimated convective precipitation (case 4) is showing significantly better results with the Kain-Fritsch/Bechtold scheme which is triggering convection while the Tiedtke scheme misses the convective activity (Section 4).

Switching off convection causes average changes of 25% (exp. 16; cf. Fig. 4) with nearly neutral impact regarding increase or decrease of precipitation. There are some convective test cases where the lack of stabilization by the convection scheme causes an over-compensation by grid-scale precipitation (cases 9 and 16). In other convective test cases switching off the convection scheme reduces the average precipitation significantly or even inhibits precipitation (cases 4, 7, and 12). The effect for situations that are dominated by stratiform precipitation is typically small.

The sensitivity experiments with modified Tiedtke scheme tend to reduce the average precipitation by 11% (exp. 14; cf. Fig. 4) with the strongest impact on convective test cases. Regarding underestimation of convective precipitation, the other important QPF deficiency of the COSMO model besides stratiform overestimation, the modifications of the Tiedtke scheme seem not to improve QPF. The modified version of the Tiedtke scheme is further tested by DWD, e.g. exploring a revised formulation of evaporation of rain within the con-

vection scheme.

The strongest effect when changing microphysical schemes is caused by combining the changes of the warm rain scheme with the substantial changes in snow physics (exp 12): this sensitivity experiment causes an average change of 15% and an average reduction of precipitation of 11%. The snow microphysics changes of this sensitivity experiment are probably not realistic and lead to a significant overestimation of cloud cover in some test cases. The moderate changes in the microphysics scheme (exp. 13) cause differences of 7% with an average reduction of 4% (cf. Fig. 4). The number of test cases with increased and decreased average precipitation is approximately the same, but the effect of reducing average precipitation is bigger. There is no evidence that the change is acting differently on stratiform and convective precipitation.

The effect of changing the vertical exchange of heat and moisture is generally small (exp. 17 to 22; cf. Fig. 4), and most of the test cases are quite insensitive to changes of the vertical exchange (cf. Fig. 3). Only a strong decrease in the vertical exchange of moisture and temperature by a factor of 50 (exp 18) results in a significant average reduction of precipitation of 12% (cf. Fig. 4). The test cases that show a significant sensitivity towards change in the vertical exchange of heat and moisture are cases 15, 17, and 18. Two of these test cases are mainly convective (cases 15 and 17) and one is mainly stratiform (18), and all of them are influenced by the sea. Consistently, parameters changing evaporation from the sea (exp. 21 and 22) cause strong differences for these cases (no results available for case 15), while changes of stomata resistance hardly affect the results (exp. 19 and 20).

The ratio of grid-scale to parameterized convective precipitation varies by about 4% for the different sensitivity experiments and, thus, is hardly affected (not shown). The only exception is the sensitivity experiment with the modified Tiedtke scheme (exp. 14). For this sensitivity experiment, the ratio of grid-scale to total precipitation is on average increased by 10%, while the amount of total precipitation is decreased by about 11% (not shown). Thus, it seems that the modified Tiedtke scheme produces less convective precipitation without compensating the loss by grid-scale precipitation.

The maximum precipitation values are changing similar to the area averaged precipitation values, that is, the relative differences of maximum and area averaged precipitation values for the same sensitivity experiment and for the same test case are typically comparable (not shown). There are a few sensitivity experiments that show a different behaviour for maximum precipitation than for area averaged precipitation. Simulations with a tri-cubic semi-Lagrange advection scheme (exp. 6 and 7), the changes of the warm rain scheme (exp. 11 and 13), and the increase of vertical heat and moisture exchange over sea (exp. 21) cause changes of maximum precipitation that are significantly different from the difference in the area averaged values. The effects on maximum precipitation values in the sensitivity experiments with changed advection or warm rain scheme do not show a consistent picture: maximum values are decreased as well as increased for convective as well as for stratiform test cases (not shown). The major effect of the sensitivity experiments with changed vertical exchange is an increase of maximum values in one stratiform and two convective test cases (cases 7, 17, and 18; not shown).

The above results reflect the fact that the sensitivity experiments were originally designed to mainly investigate cases of stratiform precipitation overestimation. Just a few sensitivity experiments have the potential to increase the simulated precipitation for test cases with convective underestimation.

1.5.2 Change of the bias relative to the reference simulation

In this section, the evaluation of the sensitivity experiments is based on the absolute value of the ratio of the 24h area averaged precipitation bias of the sensitivity experiments and the 24h area averaged precipitation bias of the reference simulation:

$$|bias_{exp}/bias_{ref}| = (P_{exp} - P_{obs})/(P_{ref} - P_{obs}). \quad (2)$$

The evaluation of test case 20 is excluded from this evaluation, since the bias in the reference simulation is quasi-zero for this case. Test case 20 is discussed in Section 4.

The evaluation is focussing on some of the sensitivity experiments with significant relative difference Δrel, only: change of initial humidity (exp. 3 and 4), using Runge-Kutta (exp. 7 to 9), change of warm microphysical scheme and moderate snow physics changes (exp. 13), and using the modified Tiedtke (exp. 14) or Kain-Fritsch/Bechtold convection scheme (exp. 15). The idealized study of changed initial humidity is considered because of its strong impact on simulated precipitation and the hints that there are systematic errors of simulated humidity in the COSMO model. The other sensitivity studies considered are all realistic alternative options for running the model. The test cases are classified depending on their main characteristics: overestimation of stratiform and convective precipitation (Fig. 6, left) and underestimation of stratiform and convective precipitation (Fig. 6, right). The number of test cases in the different categories reflects the main QPF deficiencies found in the COSMO model. The two dominant errors are stratiform overestimation, which mainly occurs in countries not predominantly affected by the sea, and convective underestimation, mainly occurring in Mediterranean countries.

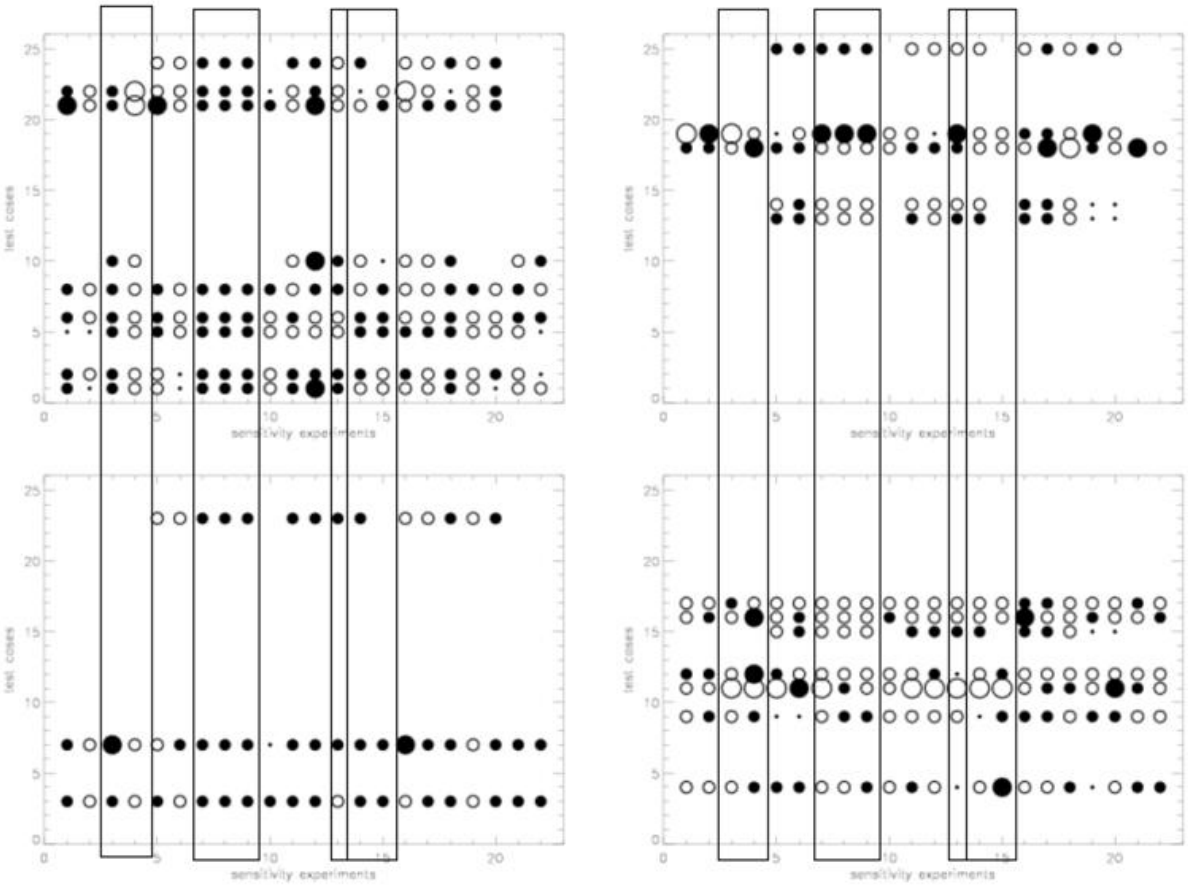

Figure 6: Ratio of the bias of the reference simulation and of the sensitivity study $|bias_{exp}/bias_{ref}|$ for cases with overestimation of stratiform (left, upper panel) and convective (left, lower panel) precipitation and with underestimation of stratiform (right, upper panel) and convective (right, lower panel) precipitation. Filled circles indicate a smaller bias, while empty circles indicate a higher bias than in the reference simulation. Big circles show a more than halved (doubled) bias and small circles an up to halved (doubled) bias. Points indicate no change. Case study 20 was excluded from this figure, because the bias was quasi-zero in the reference study.

Test cases with precipitation overestimation

The sensitivity experiments with decreased initial humidity and with Runge-Kutta time integration cause a decrease of area averaged precipitation for nearly all test cases (Section 1.5.1). For that reason, improved QPF for the test cases of overestimated precipitation can be expected. The decrease of initial humidity has a positive effect on all test cases with overestimation (Fig. 6, left), both for situations with stratiform as well as convective precipitation. On the other hand, an increase of initial humidity causes an even stronger overestimation. The Runge-Kutta time integration scheme, too, has a positive effect on all test cases with overestimated stratiform and convective precipitation. The sensitivity experiments with changes of warm rain scheme and moderate snow physics cause improvements but also worsening of QPF, the overall effect being slightly positive (Fig. 6). The effect of using the modified Tiedtke or the Kain-Fritsch/Bechtold scheme is small and mixed for the stratiform overestimation, but clearly positive for convective overestimation.

To summarize, reducing initial humidity and using Runge-Kutta time integration has a positive effect on overestimation of stratiform precipitation. These changes also have a positive effect on convective overestimation which are additionally reduced by using the modified Tiedtke scheme or the Kain-Fritsch/Bechtold convection scheme.

Test cases with precipitation underestimation

Increasing the initial humidity improves the QPF for most of the test cases. The results of the GOP (Section 1.5.1) show that there are stations in France and Italy where the COSMO-EU is underestimating the observed humidity. Since Italy is one of the countries with several test cases of underestimation, underestimated humidity in the atmosphere should be investigated as a possible reason affecting the underestimation of precipitation.

The Runge-Kutta time integration scheme tends to reduce the area averaged precipitation and, hence, gives overall worse results for the test cases with underestimated precipitation. Still, there are both convective and stratiform test cases with underestimated precipitation that are improved by using Runge-Kutta (4, 9, 19, and 25).

The change of warm rain scheme and moderate changes of the snow microphysics and the Kain-Fritsch/Bechtold scheme have a mixed impact, improving some (mainly stratiform cases for the former and mainly convective cases for the latter) and worsening other test cases. The modified Tiedtke scheme has a predominantly negative effect on QPF for test cases with precipitation underestimation.

Concerning convective underestimation, only, the sensitivity experiments don't reveal changes of numerical methods or physical parameterizations that have a clear positive impact on all these test cases. The sensitivity to the initial atmospheric humidity is however fairly large, and a good simulation of atmospheric humidity is mandatory for a decent QPF. Changing the convection scheme nevertheless has a significant impact on the results and, thus, further investigations regarding the convection scheme is the most promising step for these test cases. This is an ongoing task within COSMO: the IFS convection scheme has been implemented into the COSMO model and its performance is currently being tested.

The sensitivity experiments were also evaluated depending on the existence of fronts or orographic forcing of the precipitation, but no special characteristics were found. The characteristics of the sensitivity experiments described above remain valid independent of a frontal passage or orographic forcing.

Table 5: Overview of cross experiments.

No.	Sensitivity study
23	COSMO 4.0
24	COSMO 4.0 + 90% initial humidity + Runge-Kutta
25	COSMO 4.0 + Kain-Fritsch/Bechtold
26	COSMO 4.0 + 90% initial humidity + Runge-Kutta + Kain-Fritsch/Bechtold
27	COSMO 4.0 + modified Tiedtke scheme
28	COSMO 4.0 + 90% initial humidity + Runge-Kutta + modified Tiedtke scheme

1.5.3 Cross experiments

The cross experiments are set up to explore the positive effects of multiple changes. The focus is the overestimation of stratiform precipitation because several sensitivity experiments showed potential to improve this QPF deficiency. Changes of initial humidity, the Runge-Kutta time integration scheme, modified microphysics and modifications of the convection scheme had positive effects on test cases with overestimated stratiform precipitation. These changes are combined in the cross experiments that are described in Tab. 5. - Even if being highly idealized, the simulation with decreased humidity is included in the cross experiments due to indications that atmospheric humidity might be overestimated in the model and due to its great sensitivity to QPF.

The cross experiments are performed using version 4.0, the latest version of the COSMO model. This version is differing from the reference version (version 3.19) mainly by microphysics changes that are similar to the changes in the warm rain scheme and changes of snow physics in sensitivity experiment 13. The term 'reference version' will be used in the following for the reference simulation performed with COSMO 3.19. The modifications of the Tiedtke convection scheme for the cross experiments are, compared to the previous studies, expanded by an exchange of cloud water and cloud ice with grid-scale variables.

The comparison of simulated 24h area averaged precipitation values shows similar results with the reference version and with version 4.0 (Fig. 7). The simulations with version 4.0 reduce the average precipitation by 1 to 3 mm for most of the test cases. There are only two test cases (18 and 25) where the area averaged precipitation is significantly increased, and these are cases where (stratiform) precipitation is underestimated with the reference version. With the exception of the underestimated convective cases 9 and 11, this results in a neutral or slightly improved simulation of area averaged precipitation for all test cases. There are two test cases of stratiform overestimation that are clearly improved by using version 4.0 (cases 8 and 10). For test case 8 the overestimation is reduced by 2.5 mm, which is about 30%, and for test case 10 the overestimation is reduced by 11 mm, corresponding to 80% of the bias. Thus, COSMO version 4.0 has a significant positive impact on some test cases of overestimated stratiform precipitation and generally slightly improves the precipitation simulation.

The comparison of the results of the cross experiments to those of the reference version show a strong reduction of average precipitation for nearly all test cases and cross experiments (Fig. 8; compare with Fig. 3 for individual sensitivity experiments). Version 4.0 (exp. 23), as discussed before, has the tendency to reduce the area averaged precipitation, on average by 10 to 30%. The reduction of initial humidity and the use of the Runge-Kutta time integration scheme (exp. 24) reduce the area averaged precipitation by at least 10%, but for most of the test cases by over 30%. Comparing the effect of the cross experiment with reduced initial

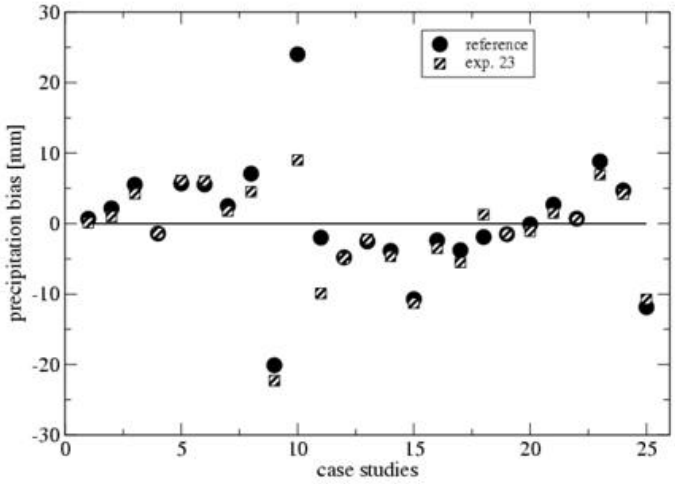

Figure 7: Bias of reference version (filled circles) and of the COSMO 4.0 version (striped squares).

humidity and Runge-Kutta scheme with their single effects leads to the conclusion that the effects of reduced initial humidity and Runge-Kutta time integration are adding up linearly without further non-linear amplification.

The test cases are again divided into cases with stratiform overestimation (Fig. 9) and cases with convective underestimation (Fig. 10) in order to study the effect of the cross experiments on different QPF deficiencies.

The results confirm that the cross experiments are reducing area averaged precipitation for most of the test cases and, thus, the bias of the test cases with overestimated stratiform precipitation is significantly improved for most of the cross experiments. 4 test cases have the best QPF results when using Kain-Fritsch/Bechtold, reduced initial humidity, and Runge-Kutta (exp. 26), 2 test cases when using only Kain-Fritsch/Bechtold (exp. 25) and 2 test cases when using the modified Tiedtke scheme, reduced initial humidity, and Runge-Kutta (exp. 28).

For test cases of underestimated convective precipitation the overall effect of the cross experiments is negative. Still, for two of the test cases (cases 4 and 16), the bias gets essentially zero if COSMO 4.0 is used together with the Kain-Fritsch/Bechtold scheme (exp. 25). For two other test cases (12 and 17), the bias is slightly improved using the Kain-Fritsch/Bechtold scheme. The increase of average precipitation in test case 12 is stronger than in the respective sensitivity experiment 15 that was performed with version 3.19 (Fig. 8 and Fig. 3) More generally, comparing the effect of using Kain-Fritsch/Bechtold in COSMO 3.19 and COSMO 4.0 seems to show that there is a tendency of a stronger impact of changing the convection scheme in version 4.0 (not shown). These results confirm that the convection parametrization is the most promising part of the model to concentrate on in order to improve the test cases with underestimated convective precipitation.

To summarize the effect of the cross experiments, 18 out of 25 test cases have been significantly improved by one of the cross experiments, including all 9 (3) test cases with overestimated stratiform (convective) precipitation. 5 test cases show the smallest bias if

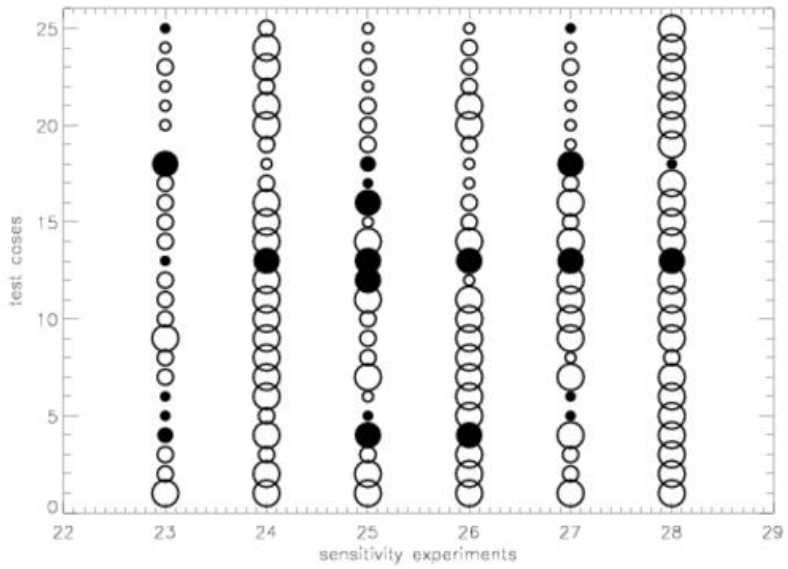

Figure 8: Difference of 24h area averaged precipitation in the cross experiments (23-28) and in the reference simulation relative to the 24h area averaged precipitation in the reference simulation Δrel [%]. Filled (empty) circles indicate an increase (decrease) of precipitation relative to the reference simulation. The big circles indicate an absolute change bigger than 30%, medium ones between 10% and 30% and small ones between 0% and 10%, tiny circles indicate cases with no change at all.

COSMO 4.0 is used with the Kain-Fritsch/Bechtold convection scheme. QPF of 3 test cases each is improved using reduced initial humidity, Runge-Kutta time integration, and Kain-Fritsch/Bechtold or modified Tiedtke scheme, respectively. 7 test cases are hardly affected or worse, 4 (3) of them being test cases of underestimated convective (stratiform) precipitation. The latter result is a consequence of the main focus of the cross experiments.

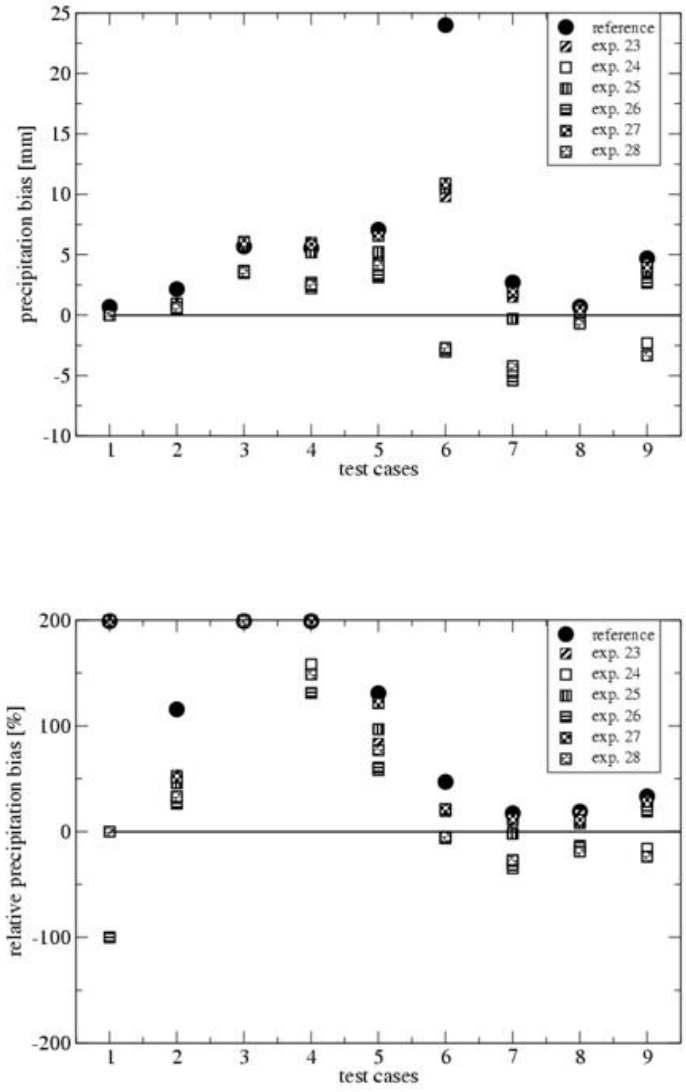

Figure 9: Absolute (upper panel) and relative (lower panel) precipitation bias ($(P_{exp} - P_{obs})$ and $(P_{exp} - P_{obs})/P_{obs}$, respectively) of the reference simulation (black circles) and the cross experiments compared to the observations for cases with overestimation of stratiform precipitation. The test cases are 1, 2, 5, 6, 8, 10, 21, 22, and 24.

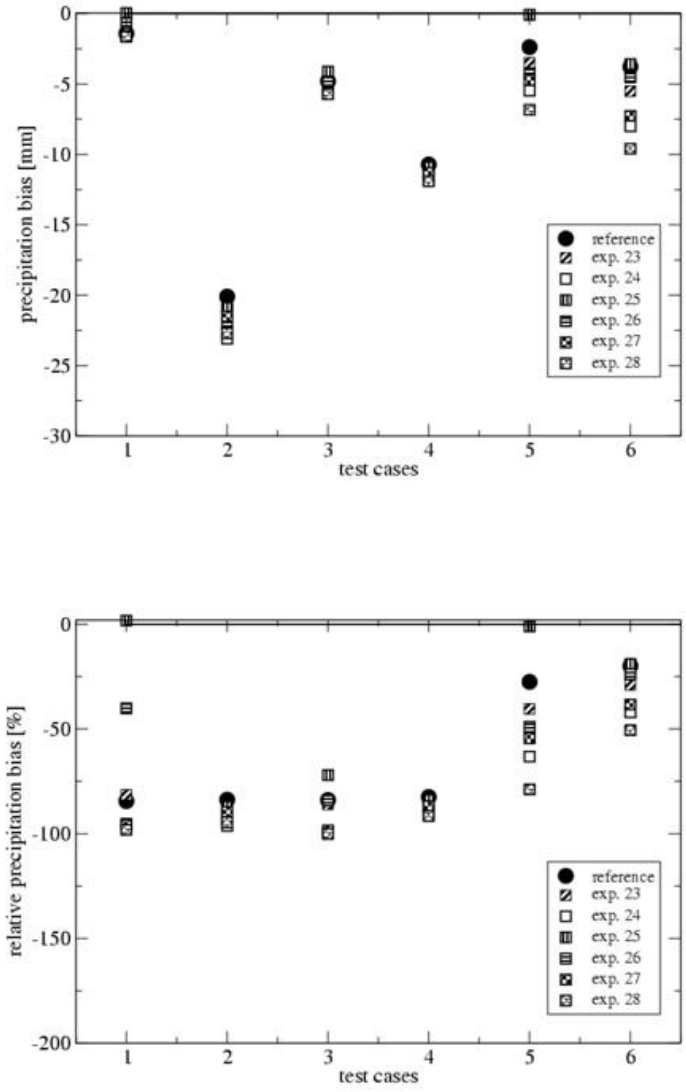

Figure 10: Absolute (upper panel) and relative (lower panel) precipitation bias ($(P_{exp} - P_{obs})$ and $(P_{exp} - P_{obs})/P_{obs}$, respectively) of the reference simulation (black circles) and the cross experiments compared to the observations for cases with underestimation of convective precipitation. The test cases are 4, 9, 12, 15, 16, and 17.

1.6 Summary and conclusions

Quantitative precipitation forecasting (QPF) is difficult ! Verification results and forecaster feedback suggest that the operational implementations of the COSMO model (7 to 14 km horizontal grid spacing), like many other numerical weather prediction models, have some problems in quantitatively forecasting precipitation. This was the motivation to launch the COSMO Priority Project 'Tackle deficiencies in quantitative precipitation forecasts'. The aim was to determine which parts of the modelling system have a significant impact on QPF quality and, thus, might have the potential to improve QPF. The focus of the project was on numerical methods and physical parameterizations, while the effects of inaccurate initial and boundary data were largely neglected.

In the first step of the project test cases were selected that reflect typical forecast errors for the different regions of interest of the participating meteorological services. To ensure that the observed COSMO model forecast deficiencies are not due to an old model version or a specific local model implementation, all test cases were re-run with a COSMO model reference version using a 7 km grid spacing. From the test cases, for which the COSMO model reference version reproduced the reported QPF problem, a list of 25 test cases was selected. The selected test cases thereby fall into two prominent groups of forecast errors: 9 test cases with stratiform overestimation, mainly in Germany, Switzerland, and Poland, and 7 test cases of convective underestimation, mainly in Italy and Greece. As a second step, a set of sensitivity studies concerning initial conditions, numerics, and model physics has been prepared. The list includes 22 sensitivity experiments as well as 6 cross-sensitivity runs that are simulated for all test cases. All in all, some 700 simulations had to be performed and analyzed. The evaluation of the sensitivity experiments is based on the 24h area averaged precipitation for selected evaluation regions with a minimum size of 100 km times 100 km. Hence, the focus is on large scale over- or underestimation of QPF. Problems of wrong small-scale localization or wrong temporal simulation are not looked at. The results of these sensitivity studies provide a broad overview of which parts of the modelling system are most relevant for QPF and suggest potential model variants that may lead to better quantitative precipitation forecasts.

The sensitivity experiments show that the strongest influence on QPF is caused by changes of the initial humidity and by using the Kain-Fritsch/Bechtold convection schemes. Both sensitivity experiments result in average relative differences of the area averaged precipitation values in the range of 30-40%. Using the Runge-Kutta time integration scheme instead of the Leapfrog scheme, applying a modified warm rain and snow physics scheme or a modified Tiedtke convection scheme all change the area averaged precipitation by roughly 10%. Finally, but only for the Roman and Greek test cases, which all have a strong influence from the sea, the heat and moisture exchange between surface and atmosphere is of great importance and can cause changes in the range of up to 25%.

The great importance of *atmospheric humidity* for the area averaged precipitation is not surprising. Still, these studies re-affirm this fact and the necessity to investigate the effect of humidity regarding QPF errors. There are indications from verification that there are indeed deficiencies in the humidity simulation. The comparison of radiosonde data and COSMO-EU profiles of mixing ratio performed in the frame of GOP shows that the model systematically overestimates atmospheric humidity, especially in the northern part of Europe. It also shows underestimation, especially in summer, in the southern part of Europe. These errors in the simulated atmospheric humidity field may strongly correspond to prevailing QPF errors of overestimated stratiform precipitation and underestimated convective precipitation. No detailed analysis of this interrelation has been performed that would allow to draw firm

conclusions, but the results of the sensitivity experiments provide motivation to have a closer look at the simulation of atmospheric humidity in order to prove or disprove its influence on QPF deficiencies.

The other important parameter influencing QPF, the *convection parametrization*, is also an expected one. The Kain-Fritsch/Bechtold scheme gives better results for 9 and worse results for 8 test cases. Test case 4, a case of underestimated convective precipitation, is significantly improved by using the Kain-Fritsch/Bechtold scheme. The scheme was tested in a quasi-operational test chain at MeteoSwiss in 2006 and showed promising results, especially regarding the diurnal cycle of precipitation. However, the test chain also revealed deficiencies. Further adaptations in order to avoid spin-up effects and overestimation of low precipitation amounts are required. Since no institute is currently developing this scheme or using it operationally, it was decided to implement and adapt the operational IFS convection scheme rather than continuing work on the very similar but unsupported Kain-Fritsch/Bechtold scheme. The other convection scheme used in the sensitivity experiments is the modified Tiedtke scheme which over all has a slightly negative impact on QPF. It improves the simulation of test cases with overestimated convective precipitation and has a neutral effect on overestimated stratiform precipitation, but it worsens test cases with underestimation of precipitation. This variant of the Tiedtke scheme is currently being revised and tested at DWD. Investigations regarding convection in the COSMO model are hence going on and it will be interesting to see how the new or further modified schemes perform in the COSMO model.

Using the *Runge-Kutta* time integration scheme instead of the Leapfrog scheme shows astonishing results: the area averaged precipitation values are significantly reduced,(by typically 10%) for most of the test cases. It is not yet fully understood why the scheme is predominantly reducing the precipitation amount, but it might be related to insufficient accuracy of the centered differences which are used in the reference simulation for advection of humidity and cloud water. Few test cases show an increase of area averaged precipitation with the Runge-Kutta scheme, and for those test cases it is a change in the right direction. Thus, the Runge-Kutta scheme has a positive effect on QPF for all cases with overprediction of precipitation as well as for some cases with underprediction of precipitation, and *is recommended for use.*

The *microphysics* changes similar to sensitivity experiment 13 are already included in COSMO version 4.0. They showed a positive impact on QPF for many test cases. The positive effect is confirmed by the comparison of COSMO version 4.0 to version 3.19 that shows a neutral or slightly positive impact on QPF for almost all the test cases when using the new model version.

The *cross experiments*, mainly targeted at the cases with overpredicted stratiform precipitation, confirm the main findings summarized above: Use of COSMO version 4.0 and the Runge-Kutta time integration scheme is encouraged, and more work on the simulation of atmospheric humidity as well as on further improvement of the convection schemes in needed to obtain better quantitative precipitation forecasts.

There are some limitations of this study which have to be kept in mind. To give just one example, all simulations were based on the same initial conditions, which can lead to an overestimation of the model sensitivity, since in a full NWP system that includes data assimilation, the initial conditions will always adjust to the new model physics or numerics. This effect of somewhat inconsistent initial conditions might, for example, contribute to the strong sensitivity of the accumulated precipitation which was found for the new microphysics in COSMO 4.0. Some of the reduction might be caused by the inconsistency of the old initial conditions, which are based on COSMO 3.19, and only the rest by the new microphysics in

COSMO 4.0. Still, the sensitivity studies shown here can provide some guidance and insight for improving or at least tuning the model to give better QPF results.

2 Workshops and meetings

- LM User Seminar, Langen, Germany, 8 March 2006
- COSMO General Meeting, Bucharest, Romania, 18 September 2006
- LM User Seminar, Langen, Germany, 8 March 2007
- Visit of Axel Seifert at MeteoSwiss, 24-25 April 2007
- COSMO General Meeting, Athens, Greece, 21 September 2007

4 Test cases description

4.1 Germany

Simulation domain: 333 x 333 grid points, 7 km grid spacing, startlat = -9.75, startlon = -12.75, pollat = -40, pollon = -170

Evaluation domain: Germany

Responsible scientists: Uli Damrath (Task 1), Axel Seifert (Task 2)

Test case 06.12.2004

QPF problem: widespread overestimation of drizzle

Best sensitivity study: COSMO 4.0 with RK solves the problem. COSMO 4.0 with LF gives similar results. The main effect is due to the modification of the cloud microphysics in COSMO 4.0, especially the autoconversion rate.

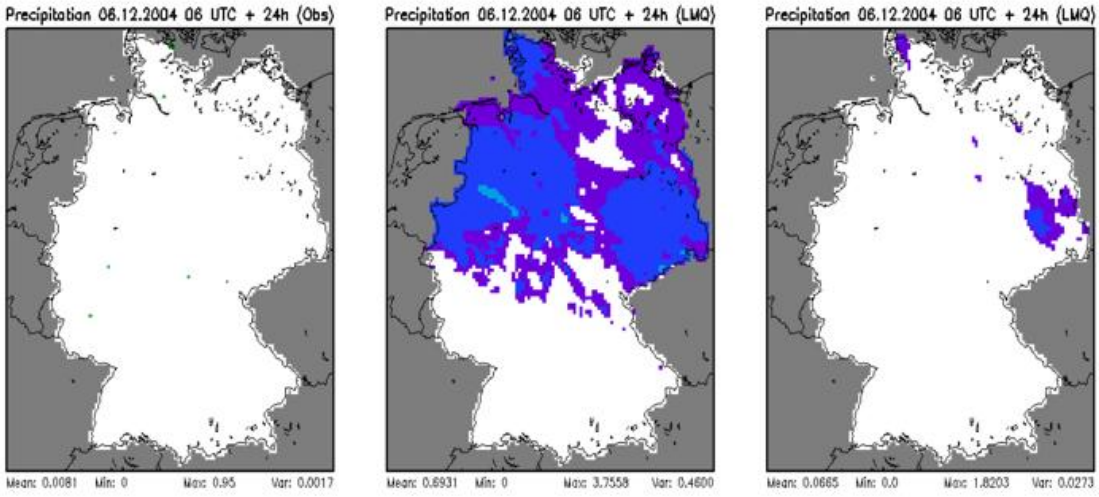

Figure 11: 24h precipitation sum from 06.12.2004, 06 UTC - 07.12.2004, 06 UTC from surface observations (left), the reference simulation (centre) and the sensitivity study with COSMO 4.0 and Runge-Kutta time integration (right).

Test case 18.03.2005

QPF problem: overestimation of stratiform precipitation

Best sensitivity study: no single sensitivity study was able to solve this case. The best improvement can be achieved by a combination of modifications which help to reduce the precipitation amounts in general, e.g. the cross-experiment A4 using COSMO 4.0 with Runge-Kutta core, KFB convection scheme and a reduction of the initial humidity.

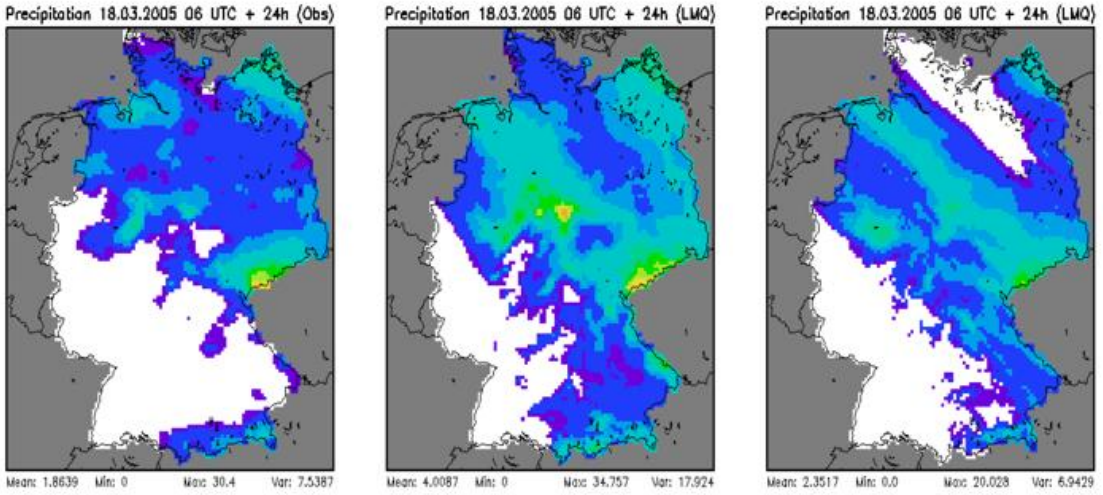

Figure 12: 24h precipitation sum from 18.03.2005, 06 UTC - 18.03.2005, 06 UTC from surface observations (left), the reference simulation (centre) and the sensitivity study with COSMO 4.0, Runge-Kutta time integration, KFB convection scheme and reduced initial humidity (right).

Test case 03.05.2005

QPF problem: overestimation of precipitation in a summertime event due to 'double-counting' of grid-scale and convective precipitation. Mean and maximum values are much too high. Probably caused by upscaling of convective motions to the grid-scale.

Best sensitivity study: COSMO 4.0 with Runge-Kutta and the modified Tiedtke convection scheme. The COSMO 4.0 with Runge-Kutta and KFB convection scheme does also a good job, but in this setup more of the overestimation of precipitation remains in the forecast. Detrainment of condensate from the convection scheme seems to help in this case.

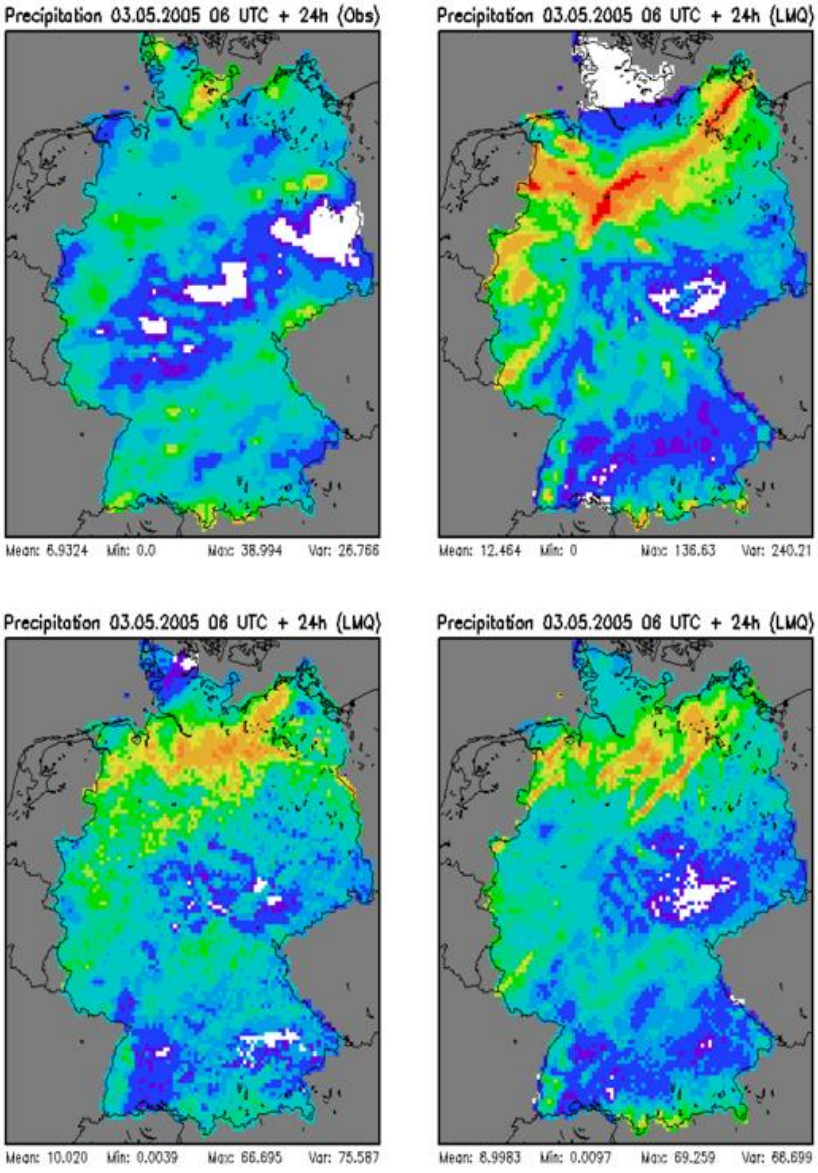

Figure 13: 24h precipitation sum from 03.05.2005, 06 UTC - 03.05.2005, 06 UTC from surface observations (upper left), the reference simulation (upper right), the sensitivity study with COSMO 4.0, Runge-Kutta time integration and KFB convection scheme (lower left) and an additional cross-sensitivity study COSMO 4.0 + Runge-Kutta + modified Tiedtke scheme.

Test case 21.06.2005

QPF problem: underestimation of the amount of precipitation in a convective event.

Best sensitivity study: the KFB scheme captures this event very well leading to a good forecast. This is a robust result independent from other choices, e.g. using RK vs LF or COSMO 3.19 vs 4.0.

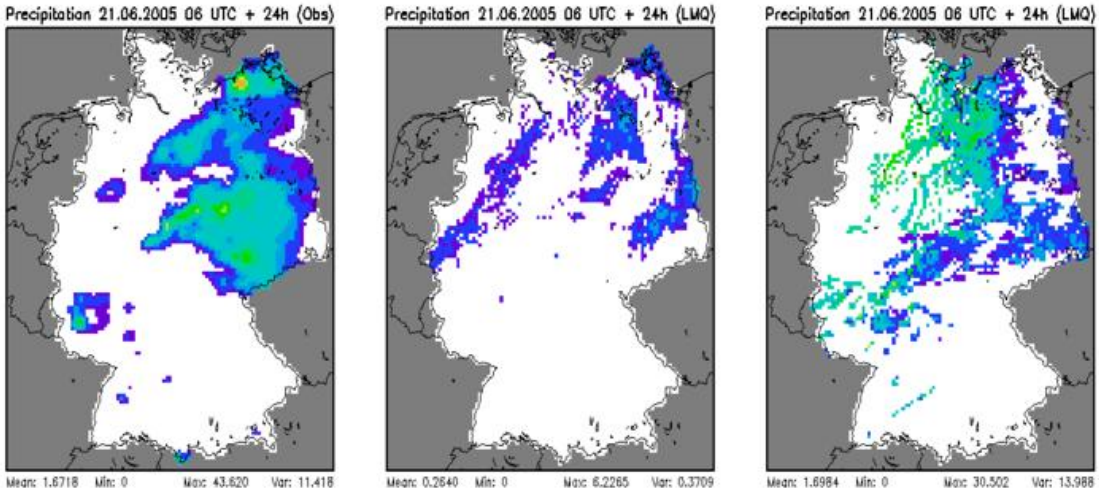

Figure 14: 24h precipitation sum from 21.06.2005, 06 UTC - 22.06.2005, 06 UTC from surface observations (left), the reference simulation (centre) and the sensitivity study with COSMO 3.19 and the KFB convection scheme (right).

4.2 Switzerland

Simulation domain: latitude 35.17/57.50; longitude -8.0/23.24

Evaluation domain: latitude 45.8/47.7; longitude 6.0/10.5

Responsible scientists: Silke Dierer and Francis Schubiger (Task 1), Silke Dierer (Task 2)

Test case 02.02.2005

QPF problem: northerly flow at 500 hPa, occluded front passing northeast of Switzerland. In the morning snow starting from north, locally rain. In the afternoon decaying snowfall. Overestimation of precipitation at the northern slopes of the Alps and in the mountains. Typical error pattern for situations with northerly flow.

Best sensitivity study: Runge-Kutta (independent of advection, in this case flux-form advection, exp. 8)

Best cross experiment: COSMO 4.0 with Kain-Fritsch/Bechtold, Runge-Kutta and reduced initial humidity (exp. 26)

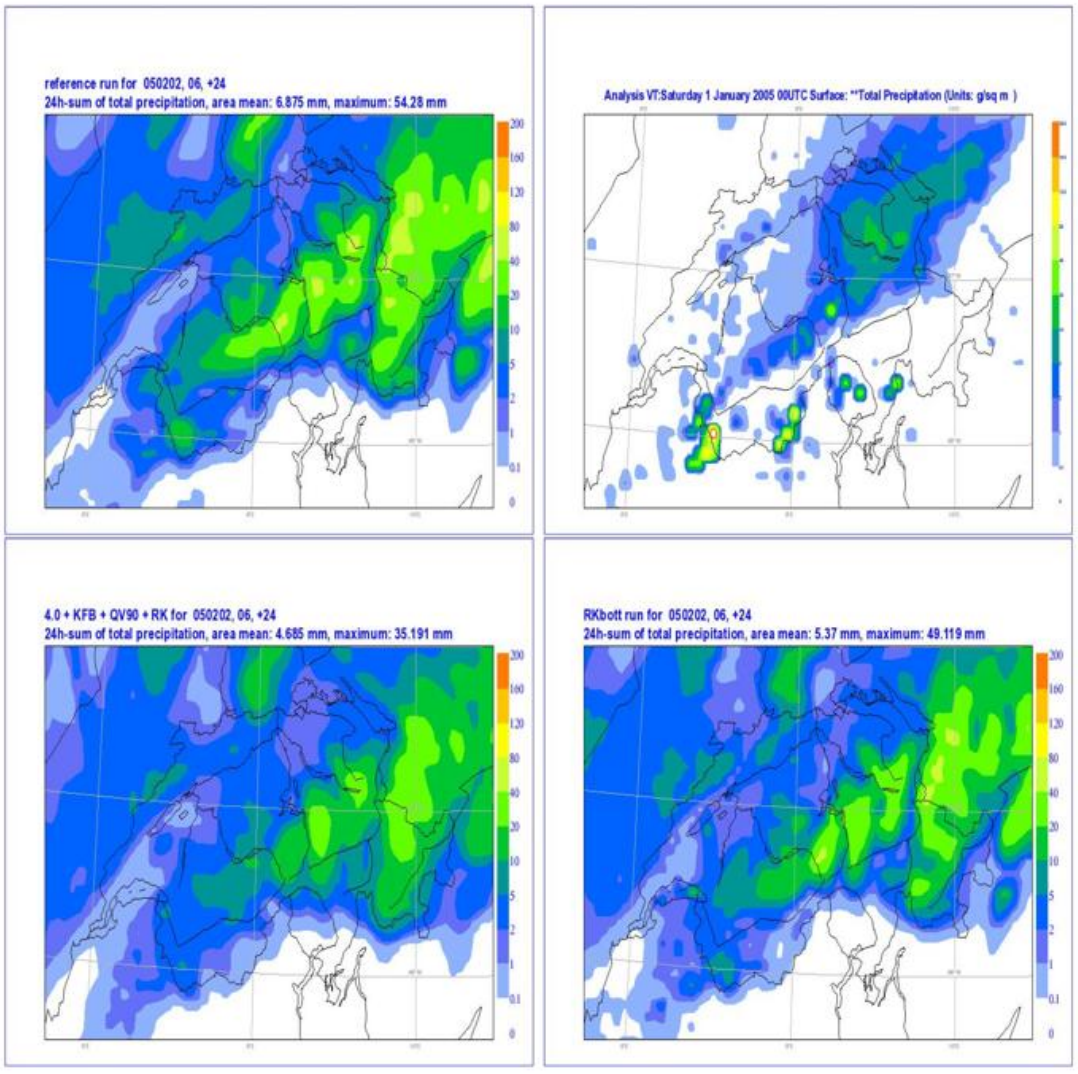

Figure 15: 24h precipitation sum from 02.02.2005, 06 UTC - 03.02.2005, 06 UTC from radar observations (upper panel, left), in the reference simulation (upper panel, right), in the sensitivity study with Runge-Kutta and flux-form advection (exp. 8, lower panel, left) and in the cross experiment with COSMO 4.0, Kain-Fritsch/Bechtold, Runge-Kutta and reduced initial humidity (exp. 26, lower panel, right).

Test case 22.03.2005

QPF problem: Switzerland is influenced by a high pressure system at 500 hPa with a weak south-westerly flow. A warm front is crossing Switzerland and, later, a cold front is crossing in the north. Overestimation of precipitation, mainly in the middle and eastern part of Switzerland.

Best sensitivity study: reduced initial humidity (exp. 3). Reducing the amount of precipitation to realistic values. Still, the location of precipitation remains wrong.

Best cross experiment: all studies with reduced initial humidity and Runge-Kutta very similar, lowest bias with reduced initial humidity, Runge-Kutta and Kain-Fritsch/Bechtold (exp. 26). Reducing the amount of precipitation to realistic values. Still, the location of precipitation remains wrong.

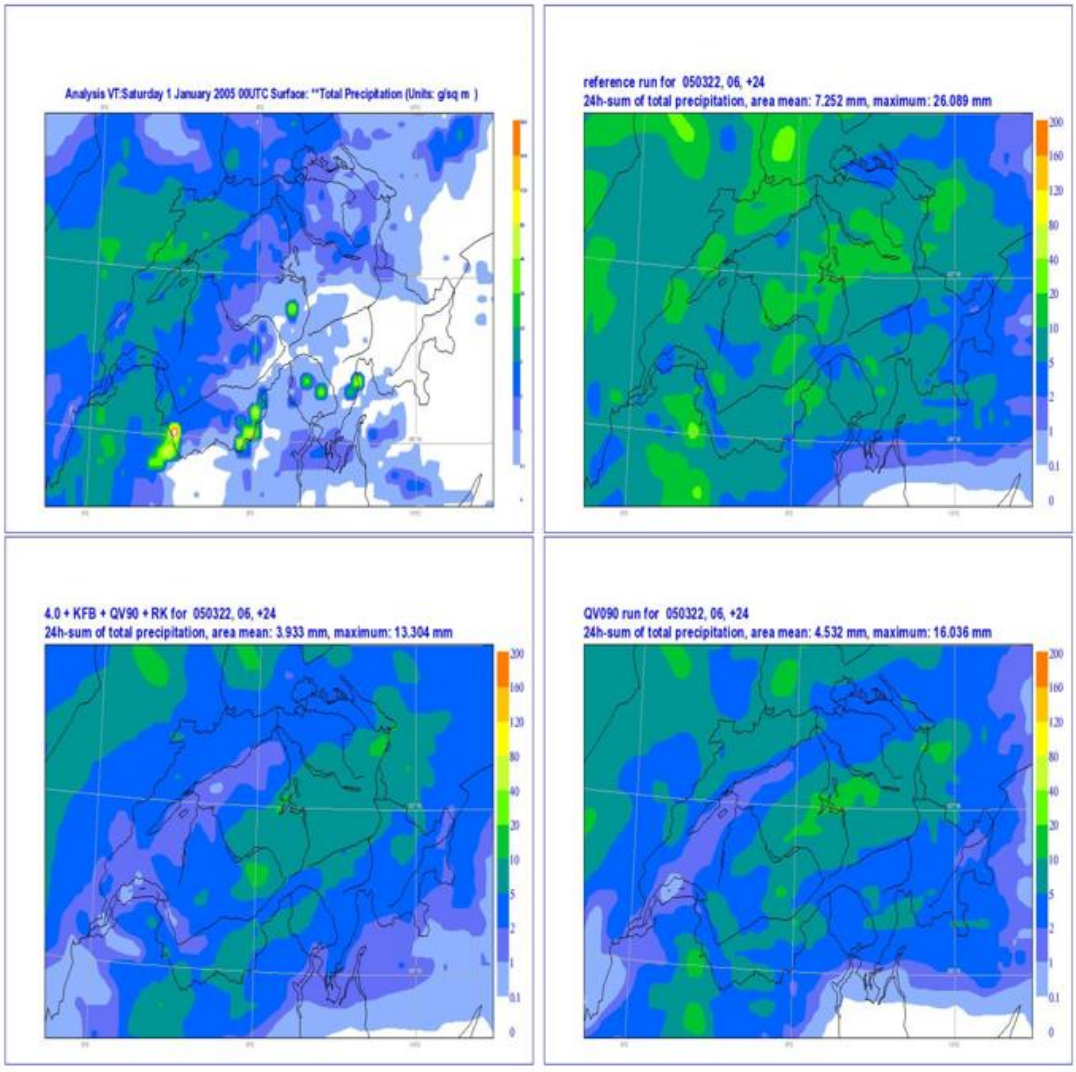

Figure 16: 24h precipitation sum from 22.03.2005, 06 UTC - 23.03.2005, 06 UTC from radar observations (upper panel, left), in the reference simulation (upper panel, right), in the sensitivity study with reduced initial humidity (exp. 3, lower panel, left) and in the cross experiment with COSMO 4.0, Kain-Fritsch/Bechtold, Runge-Kutta and reduced initial humidity (exp. 26, lower panel, right).

Test case 12.07.2005

QPF problem: low pressure system at 500 hPa over Croatia and influence of an Atlantic high pressure ridge towards Ireland: north-easterly flow at 500 hPa over the Alpine area. In the afternoon thunderstorms in Jura and Tessin. Those are hardly captured by the model. Wrong simulation of precipitation in the northern and eastern part of Switzerland.

Best sensitivity study: reduced initial humidity (exp. 3). Reducing and, thus, improving the amount of precipitation. Still, the location of precipitation remains wrong.

Best cross experiment: simulation with COSMO 4.0, reduced initial humidity, Runge-Kutta and Kain-Fritsch/Bechtold (exp. 26) improves the simulation of the precipitation north of Switzerland slightly improves the simulation of precipitation in the Tessin. Simulation of precipitation in the eastern part is reduced, but did not disappear.

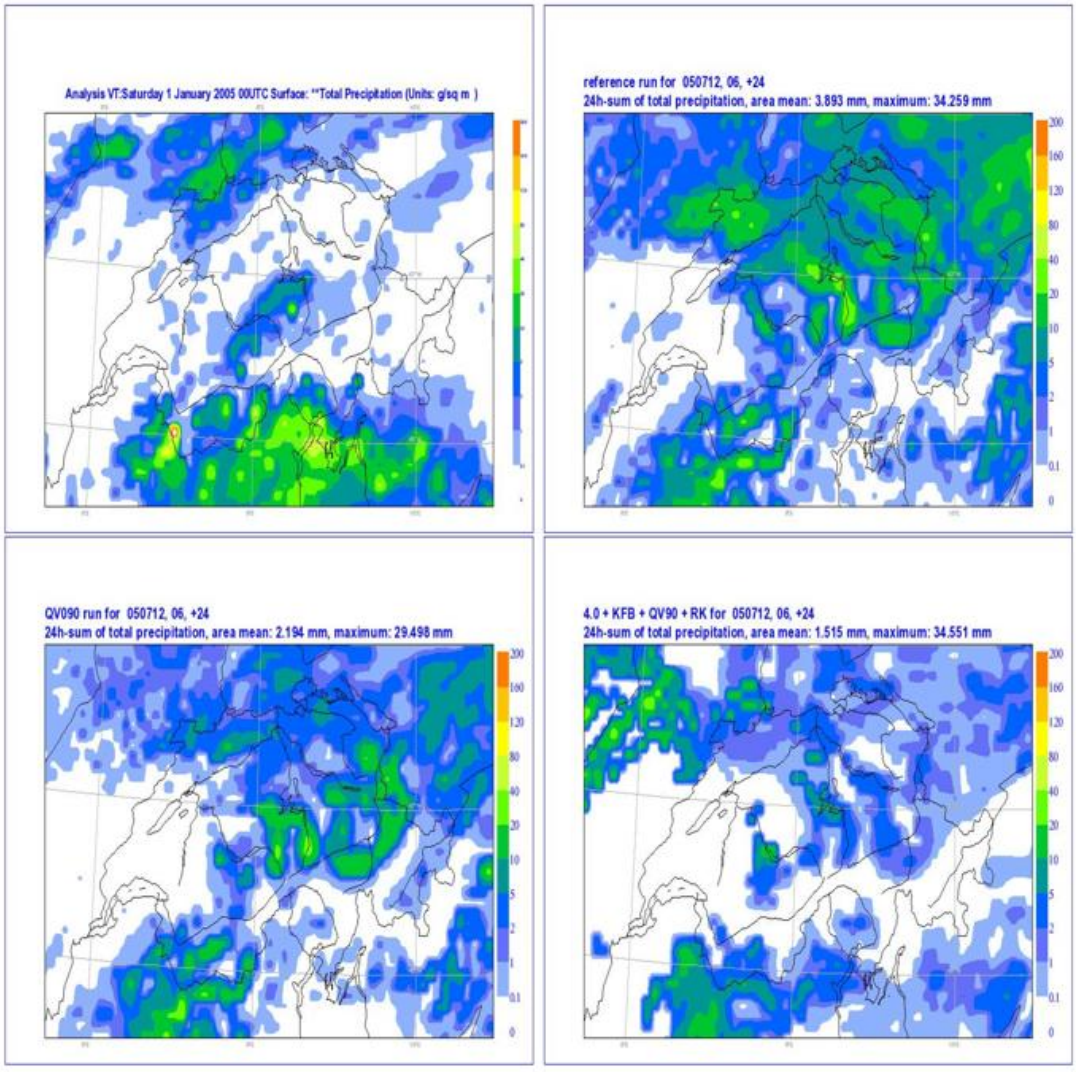

Figure 17: 24h precipitation sum from 12.07.2005, 06 UTC - 13.07.2005, 06 UTC from radar observations (upper panel, left), in the reference simulation (upper panel, right), in the sensitivity study with reduced initial humidity (exp. 3, lower panel, left) and in the cross experiment with COSMO 4.0, Kain-Fritsch/Bechtold, Runge-Kutta and reduced initial humidity (exp. 26, lower panel, right).

Test case 17.12.2005

QPF problem: northwesterly flow at 500 hPa, strong jet from Island to the Alps, very strong temperature gradient at 500 hPa over Switzerland. In the Alps and at the northern slopes constant snowfall, snow shower in the flat regions of Switzerland. Overestimation of precipitation in the middle and in the southern part of Switzerland. Typical error pattern for situations with northwesterly flow.

Best sensitivity study: Runge-Kutta (independent of advection, in this case flux-form advection, exp. 8). The average precipitation is reduced, but the region of precipitation remains too big.

Best cross experiment: COSMO 4.0 with reduced initial humidity, Runge-Kutta and Kain-Fritsch/Bechtold (exp. 26). Using COSMO 4.0 already gives a good reduction of the overestimation and using Runge-Kutta additionally increases this effect. While the amount of precipitation is in much better agreement now, there is still wrong simulation of precipitation in the Jura and in Graubünden.

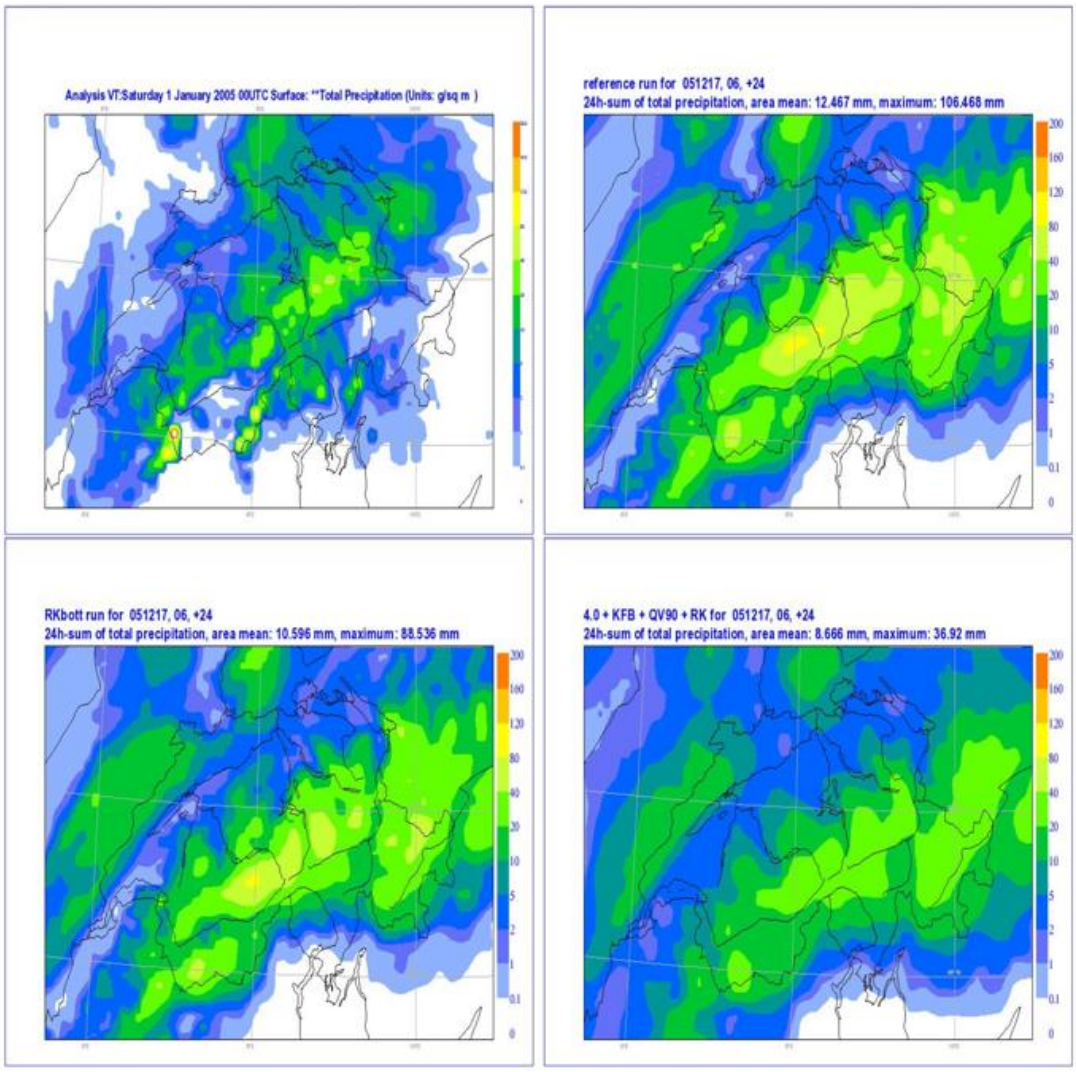

Figure 18: 24h precipitation sum from 17.12.2005, 06 UTC - 17.12.2005, 06 UTC from radar observations (upper panel, left), in the reference simulation (upper panel, right), in the sensitivity study with reduced initial humidity (exp. 3, lower panel, left) and in the cross experiment with COSMO 4.0, Kain-Fritsch/Bechtold, Runge-Kutta and reduced initial humidity (exp. 26, lower panel, right).

4.3 Emilia Romagna, Piemonte, Campania

Test case 24.09.2004

Simulation domain: latitude 32.81/50.51; longitude 2.16/24.76

Evaluation domain: latitude 43.75/45; longitude 10.5/12.2

Responsible scientists: Federico Grazzini (Task 1), Paola Mercogliano (Task 2)

QPF problem: deficiencies in the convection triggering caused by complex orography

Best sensitivity study: the best results for this test case (with stratiform and convective precipitation) has been found: increasing the initial humidity, switch off the convective parametrization; for the two runs in which has been Increased the vertical exchange of heat and moisture (on the soil and on the sea).

Best cross-experiment study: COSMO 4.0 with increased initial humidity, Runge-Kutta scheme for the numerics and Kain-Fritsch for the convection scheme (This particular experiment has not been reported in this paper but it has been considered only for this particular convective test case with strong underestimation).

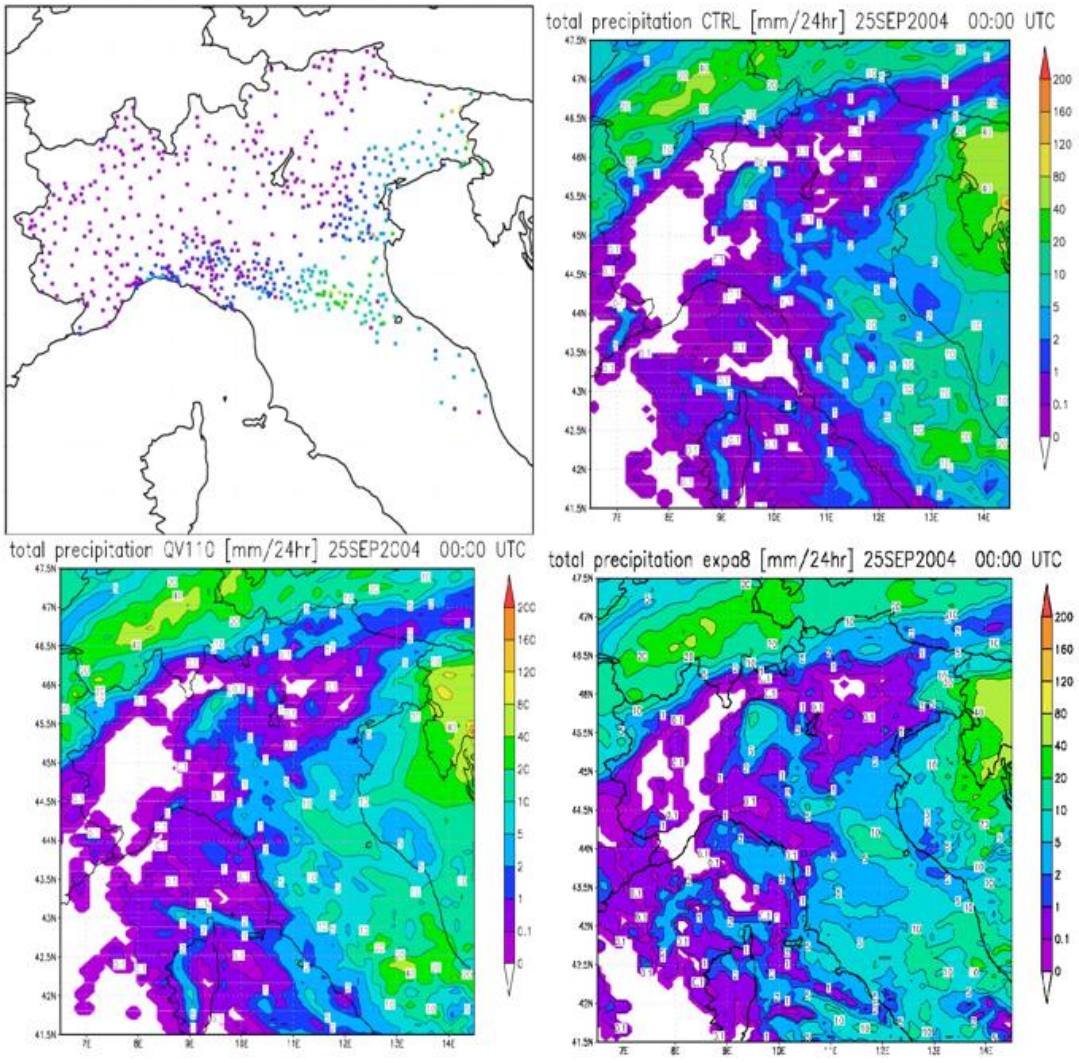

Figure 19: 24h precipitation sum from 24.09.2004, 00 UTC - 25.09.2004, 00 UTC from in situ observations of (upper panel, left), in the reference simulation (upper panel, right), in the sensitivity study with increased initial humidity (exp. 4, lower panel, left) and in the cross experiment with COSMO 4.0, Kain-Fritsch/Bechtold, Runge-Kutta and increased initial humidity (lower panel, right).

Test case 10.04.2005

Simulation domain: latitude 35.4/48.5; longitude 5/20.5

Evaluation domain: approximately 44.8N/43.8N, 10E/12.5E

Responsible scientists: Federico Grazzini (Task 1 and Task 2)

QPF problem: precipitation overestimation in a occluded front linked to a Mediterranean cyclone over Tirrenian Sea.

Best sensitivity study: the largest impact for our case of stratiform precipitation has been found with changes in the microphysics (Micro experiments) and with the introduction of version 4.0. In particular these versions contributed to reduce the overestimate of precipitation. A strong positive impact has been found in SEA40 and QV090.

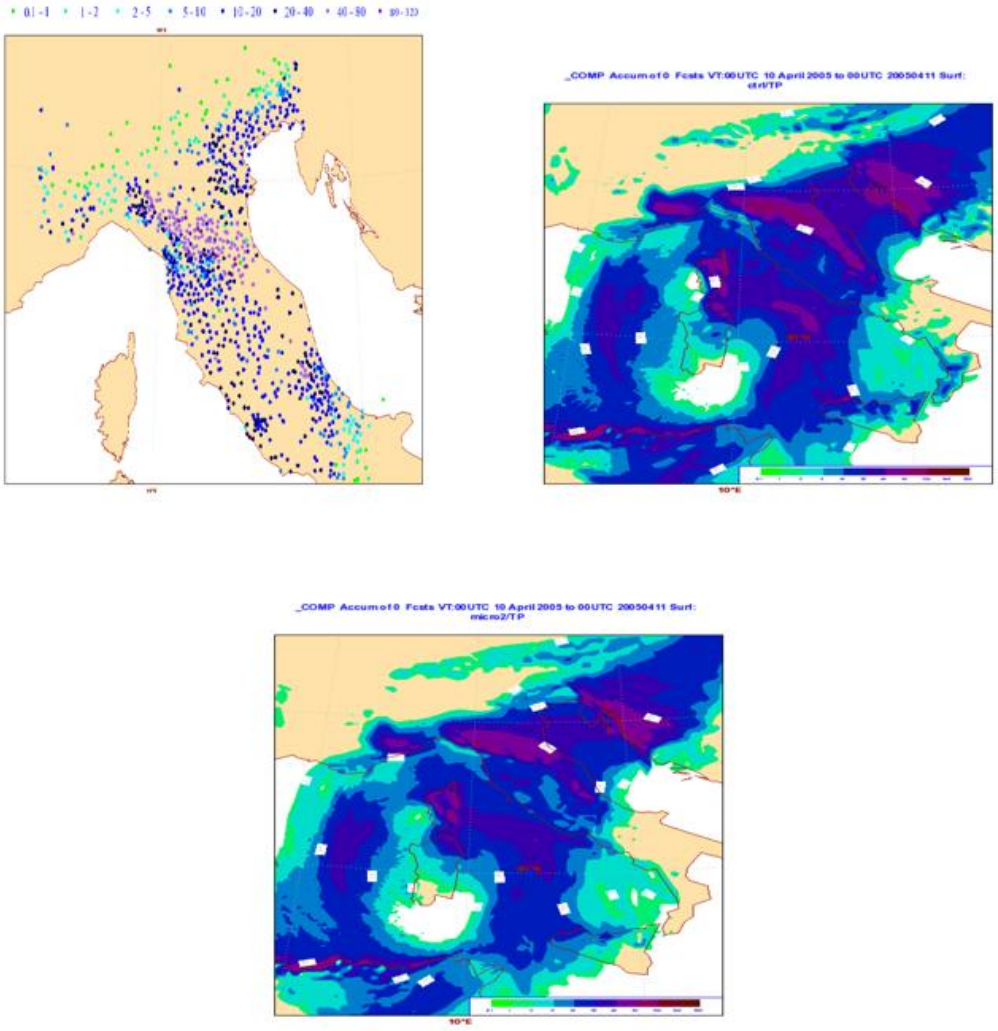

Figure 20: Observed precipitation (upper panel, left), in the reference run (upper panel, right), in the micro2 experiment (lower panel.

Test case 17.08.2006

Simulation domain: latitude 38.52N/51.48N; longitude 1.92W/17.98E

Evaluation domain: latitude 45.3N/46.6N; longitude 7.5E/9.3E

Responsible scientists: Elena Oberto (Task 1), Massimo Milelli (Task 2)

QPF problem: south-westerly flow at 500 hPa; cold frontal system with thunderstorms. Localized underestimation in the northern part of the region, both in the mean and in the maxima over the warning areas. Slight shift of the precipitation peak towards Tessin where the maximum value has been forecasted.

Best sensitivity study: actually it is difficult to find a simulation that gives better results than the ctrl. The stand-alone modifications (RK or QV or microphysics) do not improve the results.

Best cross experiment: a modification of Exp 24 (4.0 + QV090 + RK) in which humidity has been increased by 10% (fak=1.1) instead of being reduced by 10%. It has been called exp a7 (4.0 + QV110 + RK). Only in this case the relative error of the precipitation over the considered area is reduced (slightly) with respect to the other runs. Second place for the ctrl.

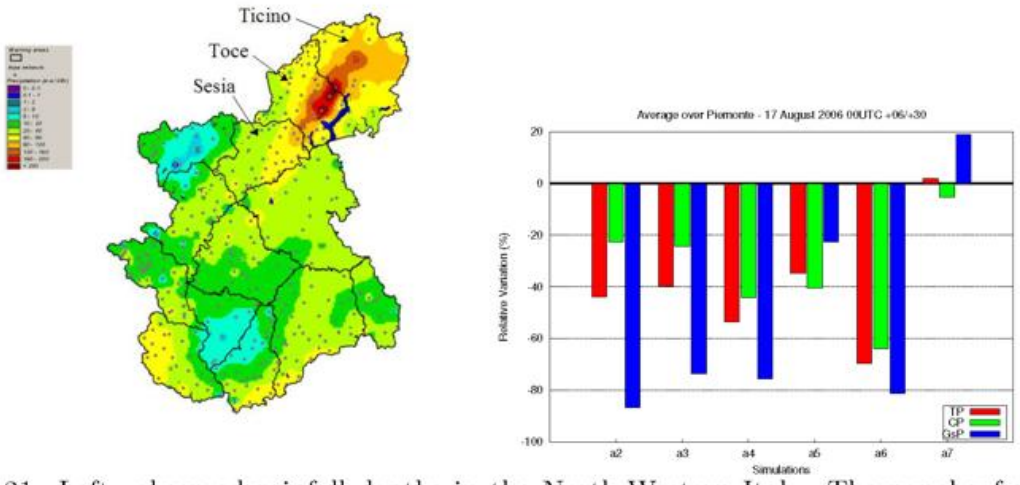

Figure 21: Left: observed rainfall depths in the North-Western Italy. The panel refers to the 24 h cumulated rainfall depth (06 UTC 17 August - 06 UTC 18 August). The rain gauges are plotted in grey and the warning areas in black. The affected areas, indicated with arrows, are Ticino (CH), Toce and, marginally, Sesia. Right: relative bias (%) of the different simulations with respect to the Ctrl run (a1) for different domains in the +6h/+30h time interval. Average performed over Piemonte region. Total Precipitation in red (TP), Convective Precipitation in green (CP) and Grid-scale Precipitation in blue (GsP). See Milelli et al. (2008) for more details.

Test case 09.09.2005

Simulation domain: latitude 32.81/50.51; longitude 2.16/24.76

Evaluation domain: latitude 40.5/41.5; longitude 13.8/15

Responsible scientists: Paola Mercogliano (Task 1 and Task 2)

QPF problem: deficiencies in the triggering of the afternoon convection along the coast line.

Best sensitivity study: the large impact on this convective case on the Italian coastal area has been obtained increasing the initial humidity, and changing the microphysics (in particular the experiment MICRO2).

Best cross-experiment study: COSMO 4.0 with increased initial humidity and using Runge-Kutta scheme fits well the average and the maximum value on the area (This particular experiment has not been reported in this paper but it has been considered only for this particular convective test case with strong underestimation).

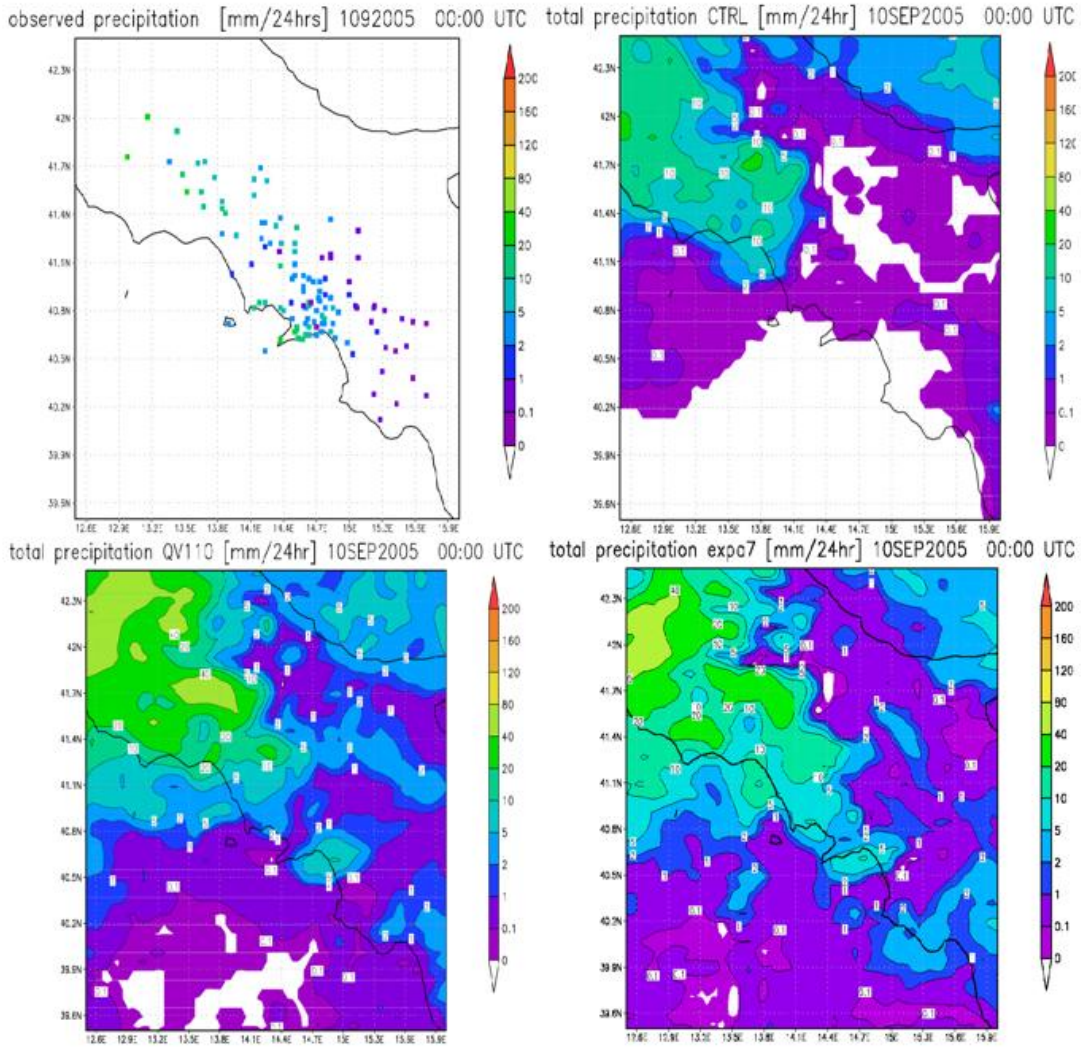

Figure 22: 24h precipitation sum from 09.09.2005, 00 UTC - 10.09.2005, 00 UTC from in situ observations of (upper panel, left), in the reference simulation (upper panel, right), in the sensitivity study with increased initial humidity (exp. 4, lower panel, left) and in the cross experiment with COSMO 4.0, Runge-Kutta and increased initial humidity (lower panel, right).

4.4 Rome

Simulation domain and evaluation domain: dlat=0.0625, dlon=0.0625, ielm_tot=321, jelm_tot=321, kelm_tot=40, pollat=40, pollon=-170.0, startlat_tot=-16.5, startlon_tot=-10.0

Responsible scientists: NN (Task 1), Rodica Dumitrache (Task 2)

Test case 01.12.2005

QPF problem:

- Sicily: 250 l/m^2 observation vs 25-50 l/m^2 model
- Ionian part of Calabria: 5 l/m^2 observation vs 25-50 l/m^2 model

Best sensitivity study: CTR, microphysics, numeric and surface simulations for Standard version tests

Best cross experiment: A1, A2, A6 for the LM 4.0 tests

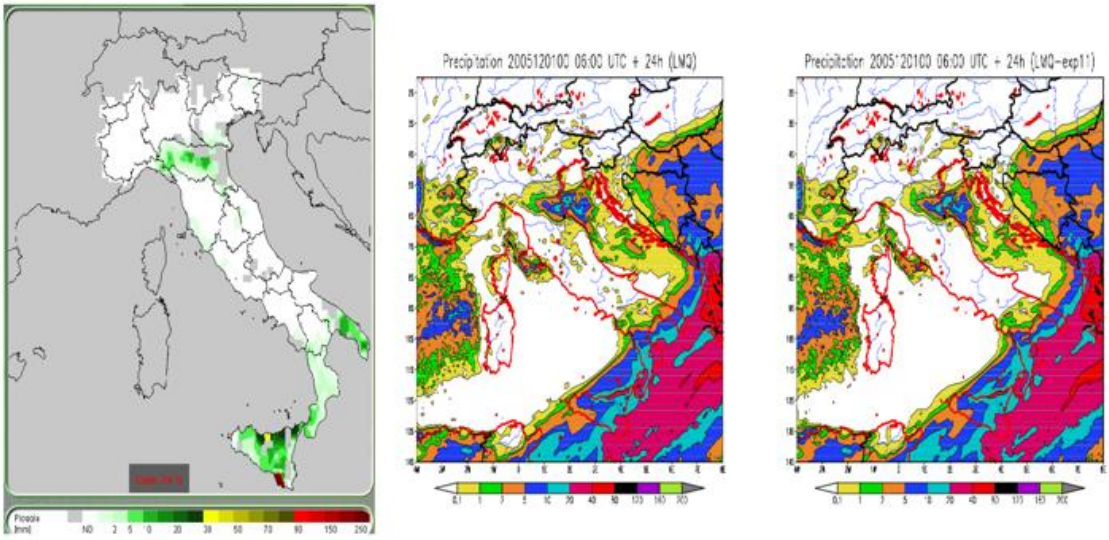

Figure 23: 24 h cumulated precipitation observation (left); 24h cumulated precipitation CTRL run (middle); 24h cumulated precipitation exp11 (right).

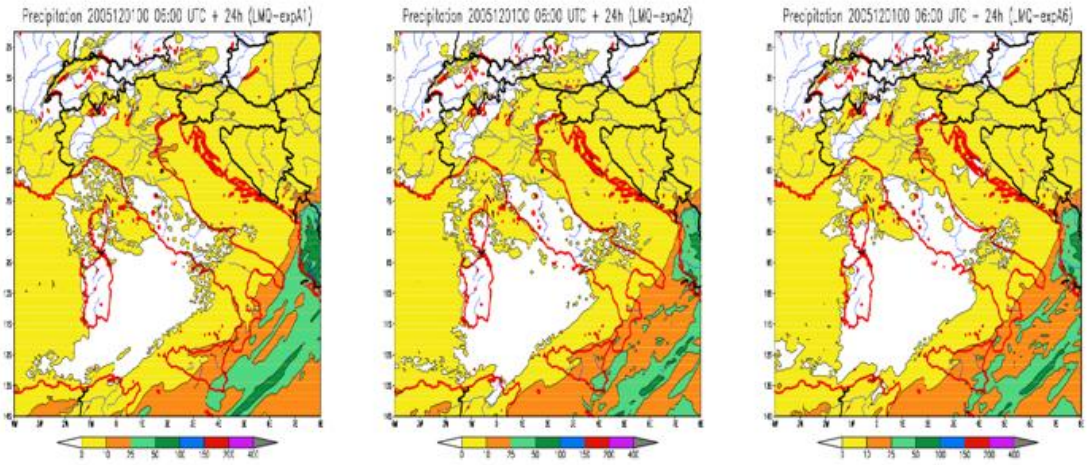

Figure 24: exp A1 (left); exp A2 (middle); exp A6 (right).

Test case 03.12.2005

QPF problem: east part of Liguria and north Toscana: 250 l/m^2 observation vs 0-10 l/m^2 model

Best sensitivity study: RLAM 50

Best cross experiment; CTRL 4.0

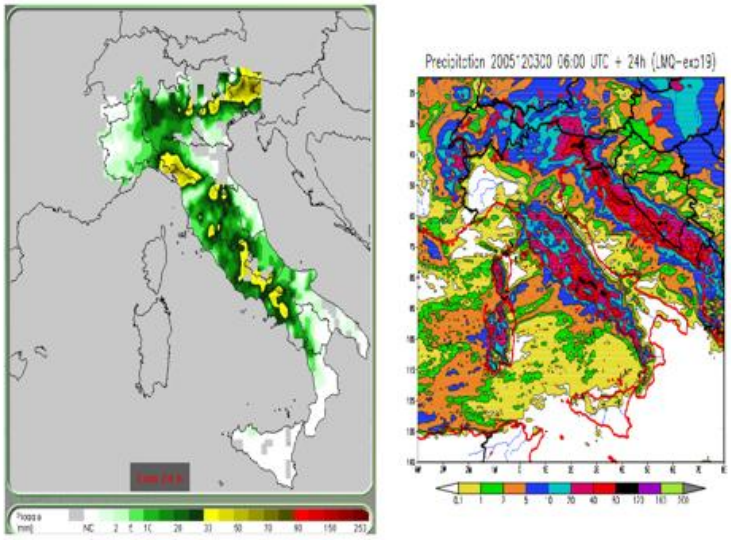

Figure 25: 24 h cumulated precipitation - observation (left); 24h cumulated precipitation exp 19 (right).

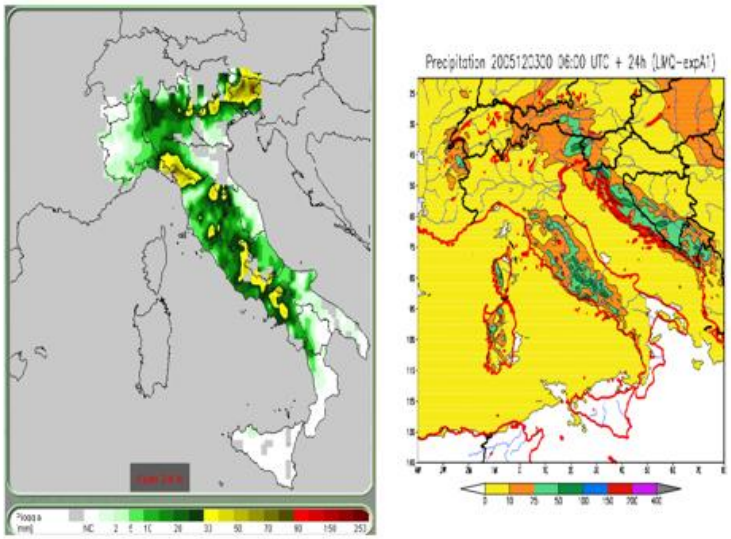

Figure 26: 24 h cumulated precipitation - observation (left); 24h cumulated precipitation exp A1 (right).

Test case 17.12.2005

QPF problem: Tyrrhenian part of Calabria: 10-50 l/m^2 observation vs 250-100 l/m^2 model

Best sensitivity study: numeric and surface simulations.

Best cross experiment: exp A3, A5.

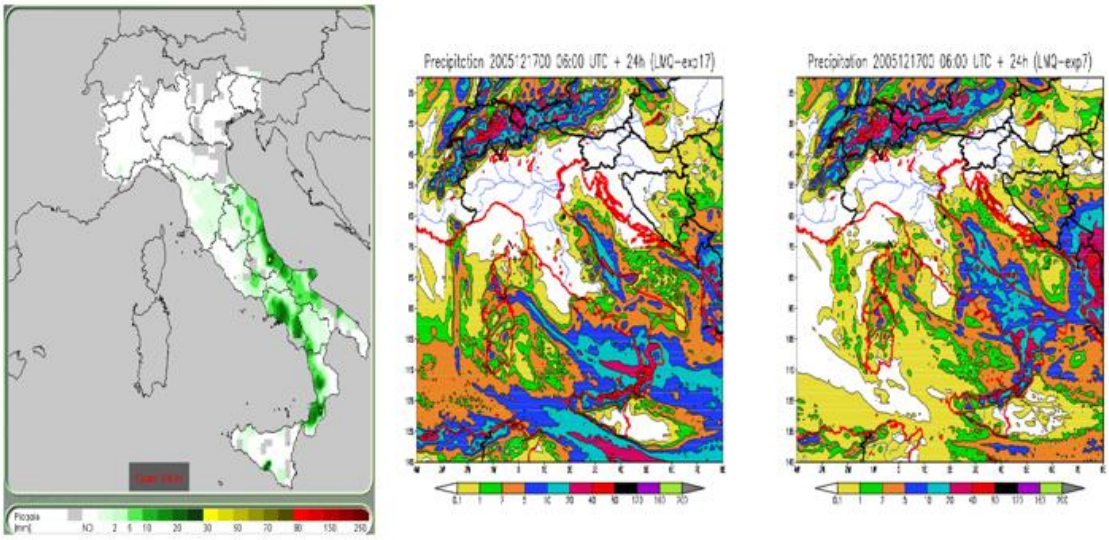

Figure 27: 24 h cumulated precipitation - observation (left); 24h cumulated precipitation exp 17(middle); 24h cumulated precipitation exp 7 (right).

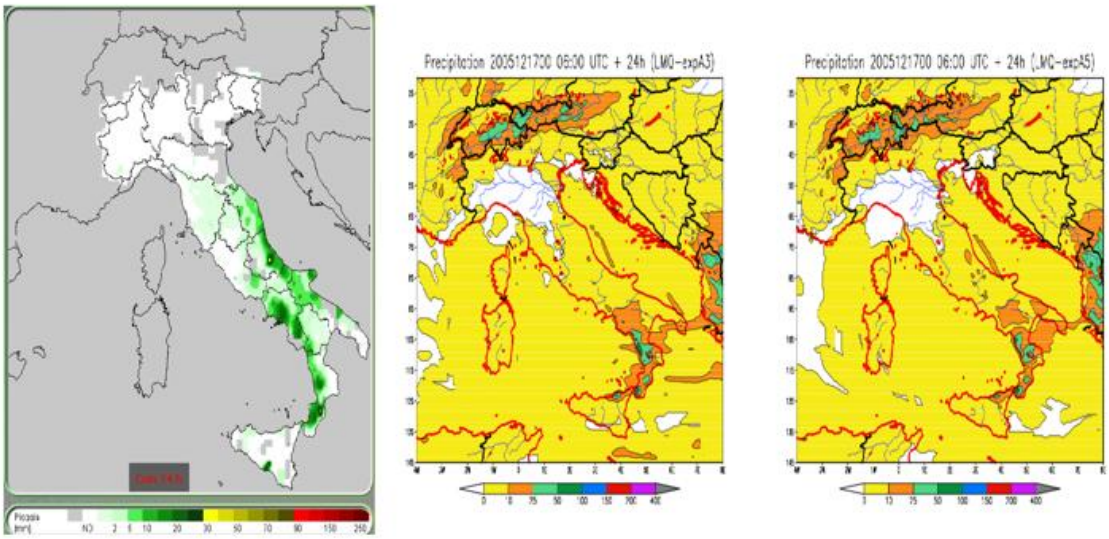

Figure 28: 24 h cumulated precipitations - observation (left); 24h cumulated precipitation exp A3 (middle); 24h cumulated precipitation exp A5 (right).

4.5 Greece

Simulation domain: latitude 33.5/42.5; longitude 18.0/29.0

Evaluation domain: latitude 34.5/41.5; longitude 19.0/28.5

Responsible scientists: P. Fragkouli (Task 1), E. Avgoustoglou (Task 2)

Test case 15.09.2005

QPF problem: trough over Southeast Europe, strong overestimation of precipitation over Crete.

Best sensitivity study: increase of atmospheric water vapor mixing ratio by 10% (exp.4). The average and the distribution of precipitation is improved, but the secondary precipitation centre over Central Aegean is missed.

Best experiment based on COSMO 4.0: in this case, the control run with COSMO 4.0 (exp. 23) showed rather significant preponderance over all cross experiments, however the overall precipitation simulation is poor.

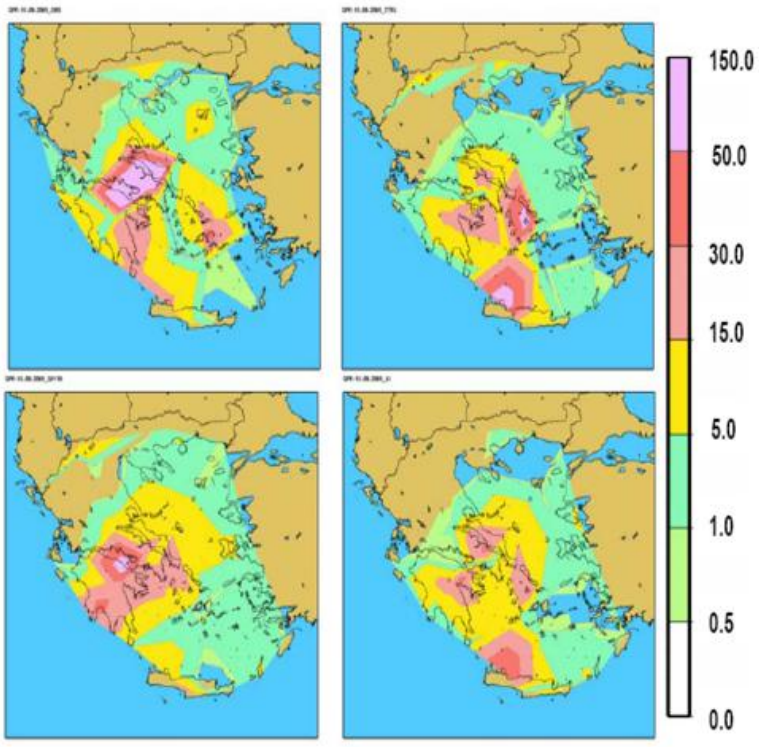

Figure 29: 24h precipitation sum in from 15.09.2005, 06 UTC - 16.09.2005, 06 UTC in the isohyet graphs based on synoptic observations from 63 meteorological stations (upper panel, left), in the reference simulation (upper panel right), in the sensitivity study with increase of water vapor mixing ratio (exp. 4, lower panel, left) and in the control experiment with COSMO 4.0 (exp. 23, lower panel, right).

Test case 23.11.2005

QPF problem: overestimation of precipitation in parts of Northern and Western Greece, eastwards moving fronts with extreme precipitation over Athens.

Best sensitivity study: increase of atmospheric water vapor mixing ratio by 10% (exp.4).The precipitation over the eastern and north-eastern parts of Greece is improved nevertheless underestimated over the central and western parts of the country.

Best cross experiment: COSMO 4.0 with Kain-Fritsch/Bechtold scheme (exp. 25).

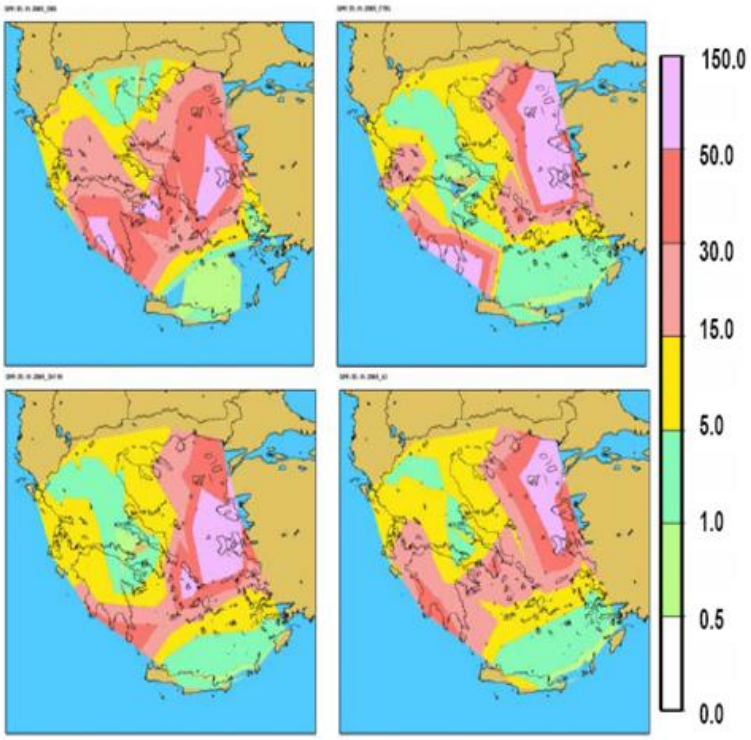

Figure 30: 24h precipitation sum in from 23.11.2005, 06 UTC - 24.11.2005, 06 UTC in the isohyet graphs based on synoptic observations from 60 meteorological stations (upper panel, left), in the reference simulation (upper panel right), in the sensitivity study with increase of water vapor mixing ratio (exp. 4, lower panel, left) and in the cross experiment with COSMO 4.0, Kain-Fritsch/Bechtold (exp. 25, lower panel, right).

Test case 26.11.2005

QPF problem: overestimation of extreme precipitation by a factor of 5 for the first forecast day.

Best sensitivity study: increase of atmospheric water vapor mixing ratio by 10% (exp.4). The average precipitation is improved but the simulation is wrong.

Best cross experiment: COSMO 4.0 with modified Tiedtke scheme (exp. 27).

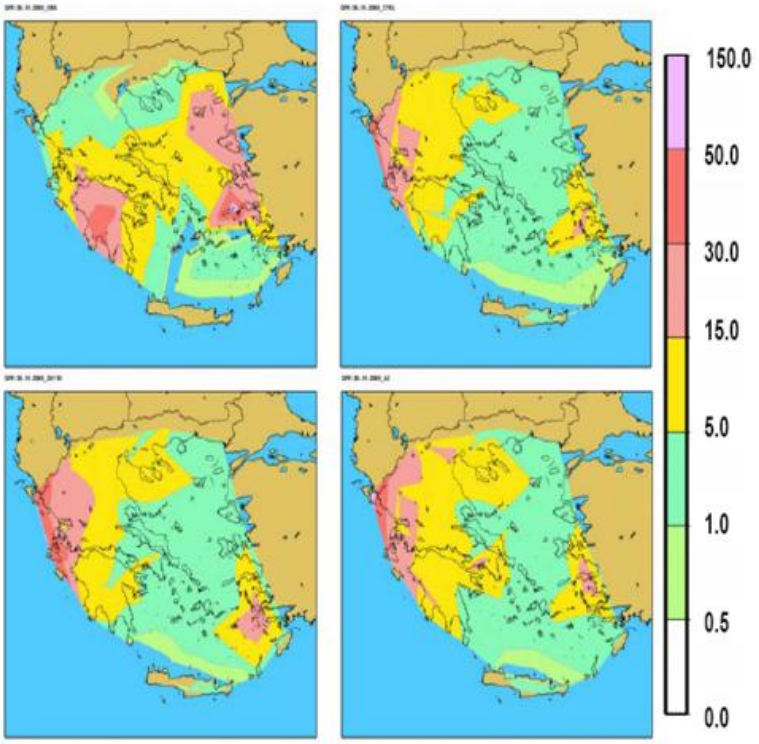

Figure 31: 24h precipitation sum in from 26.11.2005, 06 UTC - 27.11.2005, 06 UTC in the isohyet graphs based on synoptic observations from 59 meteorological stations (upper panel, left), in the reference simulation (upper panel right), in the sensitivity study with increase of water vapor mixing ratio (exp. 4, lower panel, left) and in the cross experiment with COSMO 4.0, modified Tiedtke (exp. 25, lower panel, right).

4.6 Poland

Simulation domain: latitude 45.9/56.5; longitude 10.0/32.8

Evaluation domain: latitude 49.0/54.3; longitude 12.8/26.1

Responsible scientists: Katarzyna Starosta (Task 1 and Task 2)

Test case 03.05.2005

QPF problem: a low with warm front is moving north of Poland from west to east. In the south-east of Poland a second low arises related with heavy precipitation in south-eastern part of the country. Underestimation of precipitation mainly in the south-eastern part of Poland is observed.

Best sensitivity study: the best result which reduces maximum precipitation and increases the average of precipitation to realistic values is observed in experiment 9 (Runge-Kutta, flux form and T'-p' dynamics).

Best cross experiment: these experiments do not increase average precipitation. Experiment with modified Tiedtke scheme reduces maximum precipitation (exp. 27), but the region without precipitation in south-east remains.

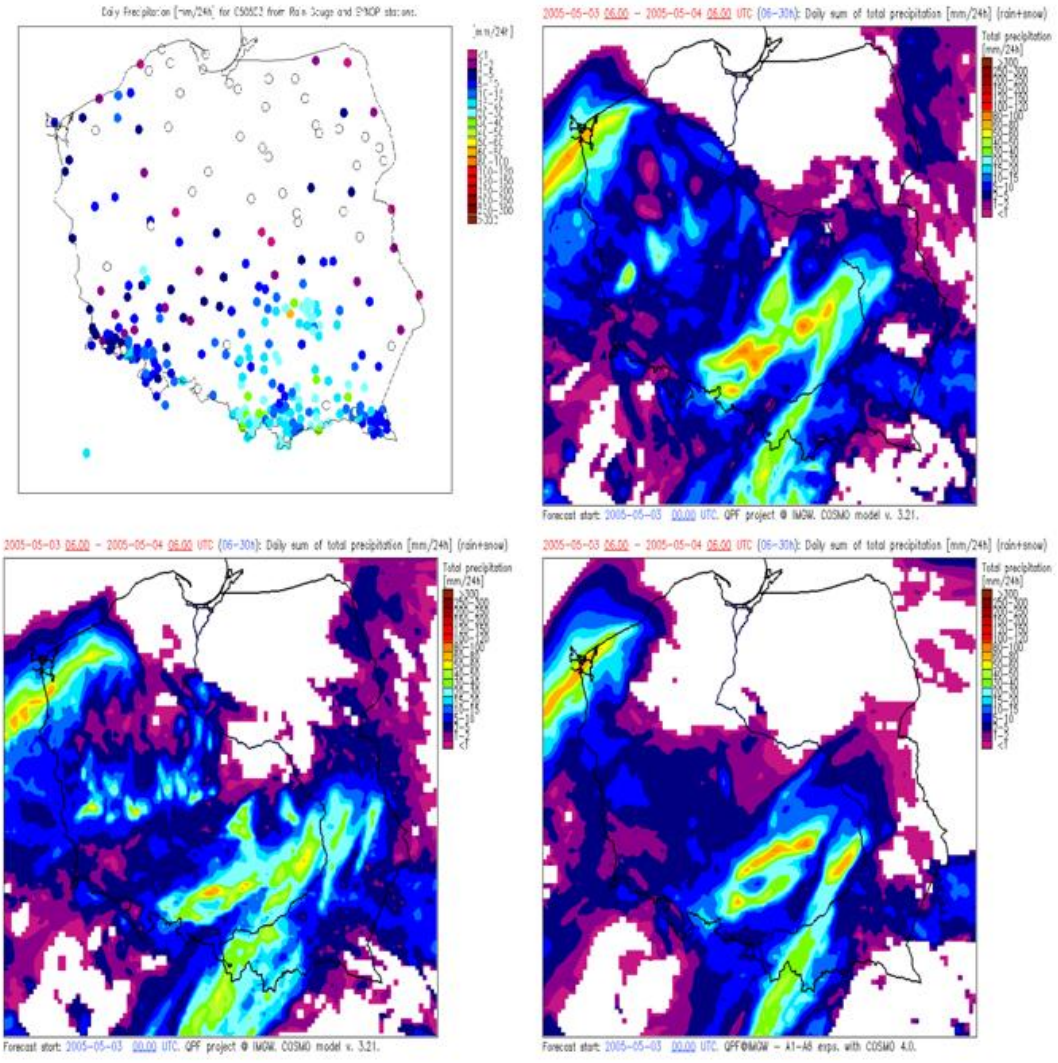

Figure 32: 24h precipitation sum from 03.05.2005, 06 UTC - 04.05.2005, 06 UTC from rain gauges observations (upper panel, left), in the reference simulation (upper panel, right), in the sensitivity study with Runge-Kutta and T'-p' dynamics (exp. 9, lower panel, left) and in the cross experiment with COSMO 4.0, modified Tiedtke scheme(exp. 27, lower panel, right).

Test case 04.05.2005

QPF problem: low over Ukraine moves from south to north provoking heavy precipitation in the south, centre and east of the Polish territory. In the south of the region there is underestimation of precipitation, but over central and eastern parts of territory there is an overestimation. The maximum of precipitation is overpredicted. Locally the difference of maximum precipitation is significant, but taking into account an average precipitation this difference disappears.

Best sensitivity study: the experiment with microphysics reduces the maximum of precipitation (exp. 11, exp. 13). Location of precipitation values still remains wrong.

Best cross experiment: reduction of initial humidity + Runge-Kutta (exp. 24) decreases in general the maximum of precipitation. Still, the location of precipitation values remains wrong.

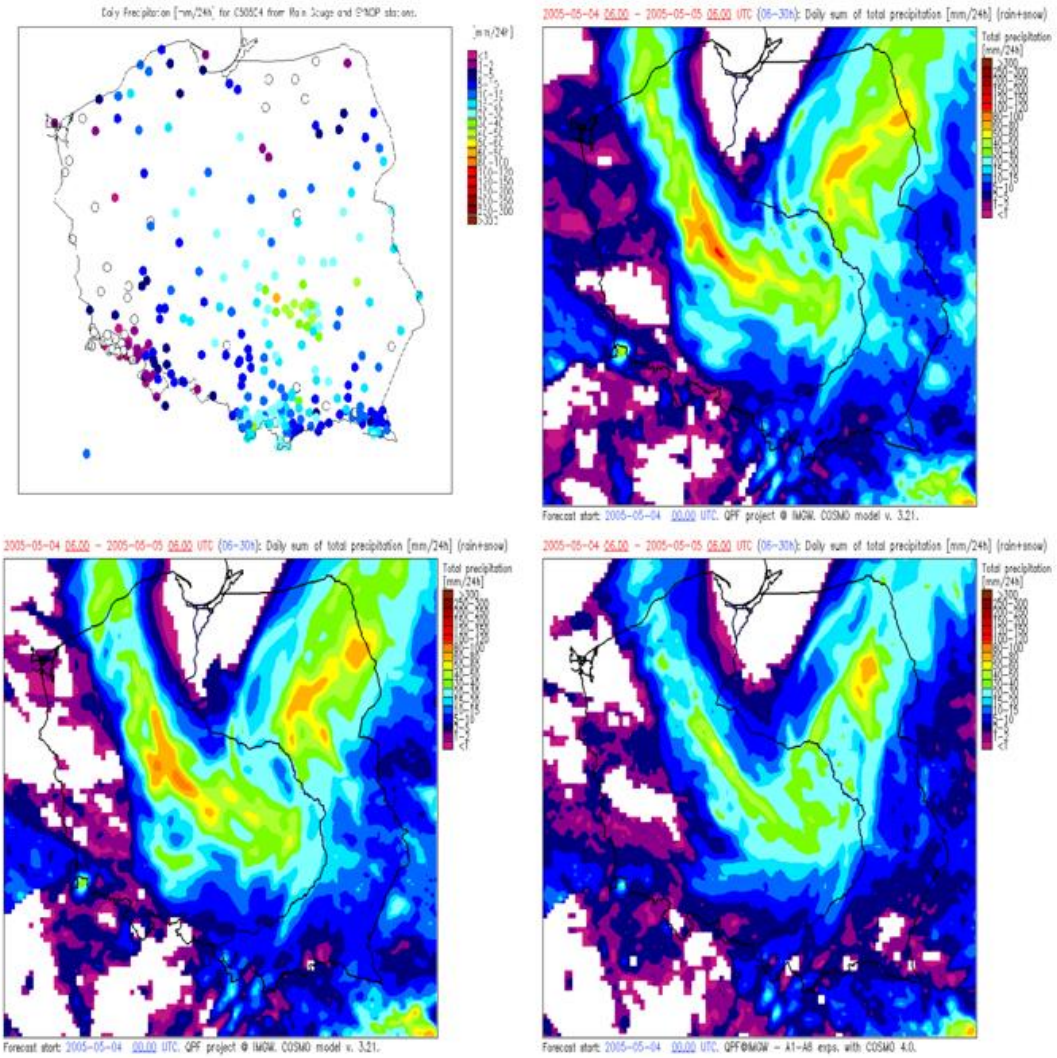

Figure 33: 24h precipitation sum from 04.05.2005, 06 UTC - 05.05.2005, 06 UTC from rain gauges observations (upper panel, left), in the reference simulation (upper panel, right), in the sensitivity study with new warm rain scheme (exp. 11, lower panel, left) and in the cross experiment with COSMO 4.0, Runge-Kutta and reduced initial humidity (exp. 24, lower panel, right).

Test case 10.06.2005

QPF problem: the heavy precipitation in the east is related to a low over Ukraine. The precipitation in western of Poland is connected with cold front. Overestimation is larger in maximum precipitation than in average precipitation. Over south-eastern parts of Poland there is a region where precipitation is not predicted. The region with maximum precipitation is located to the east and not to the south of the country.

Best sensitivity study: the experiments QV090 (exp. 3) and Mikro2 (exp. 12) reduce maximum precipitation but not ideally. Still, the location of precipitation in south-east remains wrong.

Best cross experiment: the experiment Kain-Fritsch/Bechtold (exp. 24) reduces average precipitation, and experiment 28 (reduced initial humidity + Runge-Kutta + modified Tiedtke scheme) reduces maximum value to realistic one, but decrease average value. Wrong location of maximum precipitation and the region with missing precipitation still exists.

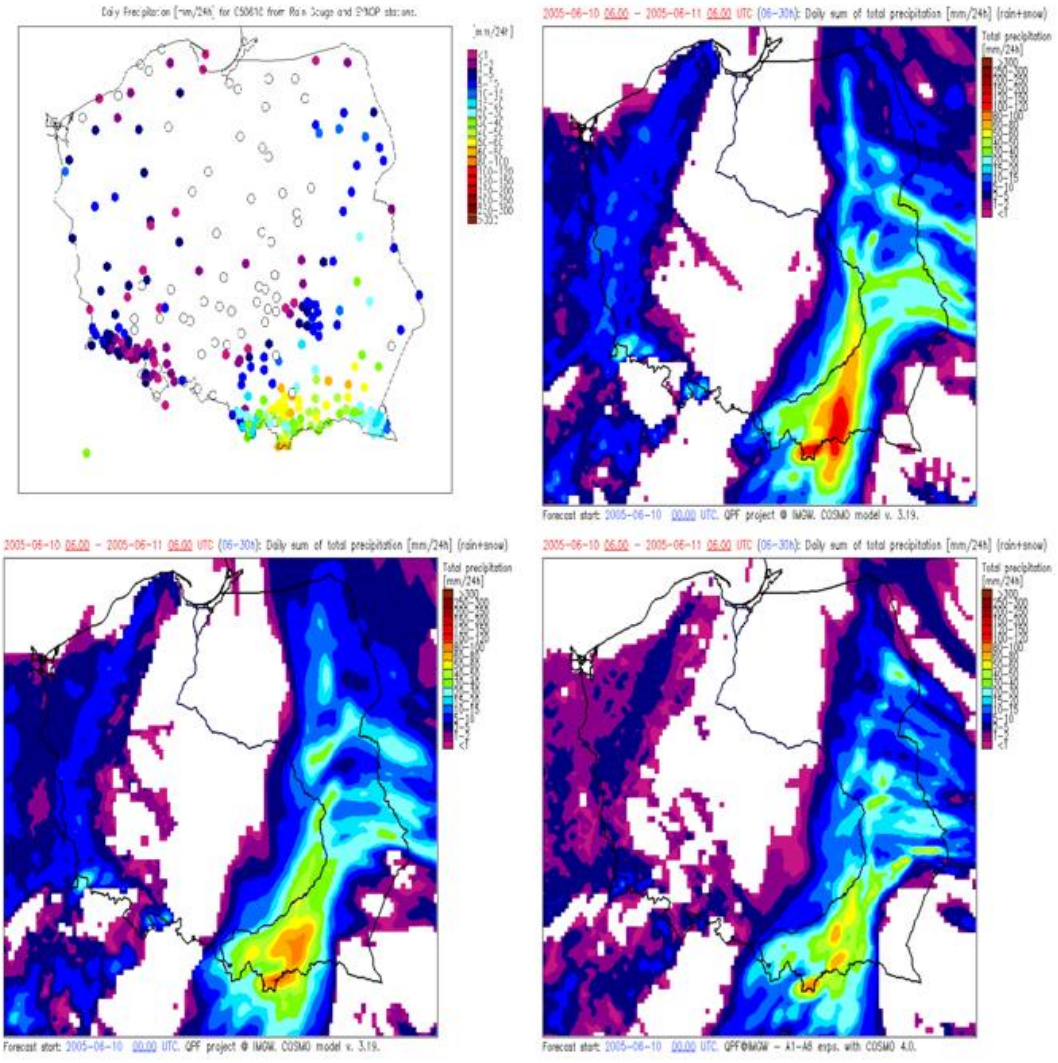

Figure 34: 24h precipitation sum from 10.06.2005, 06 UTC - 11.06.2005, 06 UTC from rain gauges observations (upper panel, left), in the reference simulation (upper panel, right), in the sensitivity study with changes of ice microphysics and new warm rain scheme (exp. 12, lower panel, left) and in the cross experiment with COSMO 4.0, modified Tiedtke scheme, Runge-Kutta and reduced initial humidity (exp. 28, lower panel, right).

Test case 09.08.2005

QPF problem: low moving from Belarus to Latvia. Overestimation recorded especially in north-east of Poland, while underestimation in south-east of Poland.

Best sensitivity study: the experiment with microphysics (exp. 11, 12) reduces the maximum value to realistic one.

Best cross experiment: the model version 4.0 improves the results.

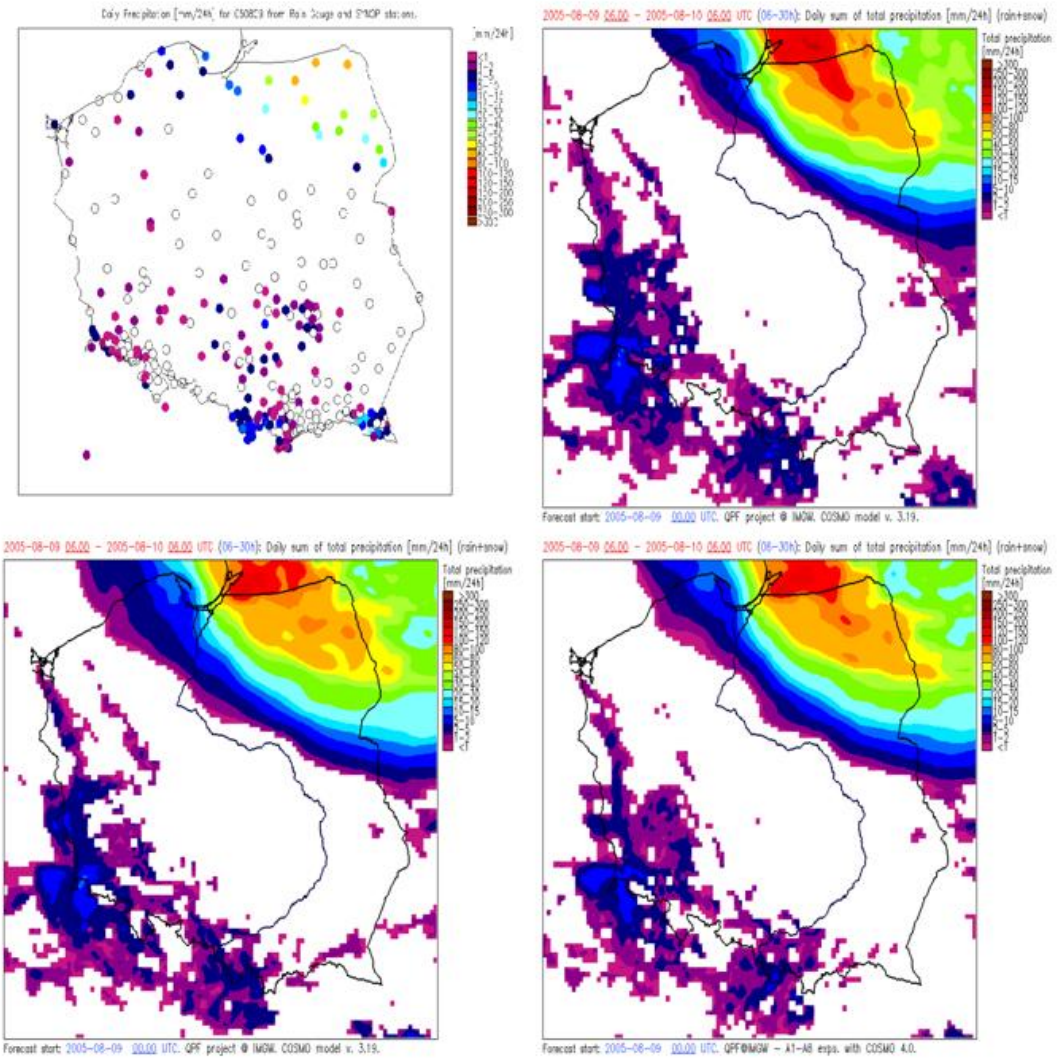

Figure 35: 24h precipitation sum from 09.08.2005, 06 UTC - 10.08.2005, 06 UTC from rain gauges observations (upper panel, left), in the reference simulation (upper panel, right), in the sensitivity study with changes of ice microphysics and new warm rain scheme (exp. 12, lower panel, left) and in the cross experiment with COSMO 4.0, (exp. 23, lower panel, right).

4.7 Romania

Simulation and evaluation domain: dlat=0.0625, dlon=0.0625, ielm_tot=301, jelm_tot=301, kelm_tot=40, pollat=40, pollon=-170.0, startlat_tot=-13.5, startlon_tot=0.625.

Responsible scientists: Rodica Dumitrache (Task 1 and Task 2).

QPF problem:

- E and central Moldova 50-100 l/m^2 observation vs 40-80 l/m^2 model;
- SE 25-50 l/m^2 observations vs 120-160 l/m^2 model overestimation;
- Littoral area 10-25 l/m^2 observations vs 40-80 l/m^2 model overestimation;
- NW - not observed – not simulated;
- SW not observed – 40-80 l/m^2 model overestimation;
- Center 25-50 l/m^2 observations vs 40-80 l/m^2 model.

Best sensitivity study: cloud microphysics, numeric and convective scheme simulations.

Best cross experiment: A2, A6.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW) and Romania (NMA). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Summary

The development of a complete Conditional Verification Tool has been the first priority and outcome of the VERSUS project. From a more general point of view the main purpose of VERSUS is the systematic evaluation of model performances in order to reveal, in a way different from the usual classical verification tools, model weaknesses. Once delivered and applied routinely, it should provide information to the all scientists and modelers, providing them hints which could be the causes of model deficiencies that can be seen in the operational verification. The typical approach to Conditional Verification consist of the selection of one or several forecast products and one or several mask variables or conditions, which would be used to define for example thresholds for the product verification (e.g. verification of T2M only for grid points with zero cloud cover in model and observations).

After the selection of the desired conditions, a classical verification tools is used to get statistical indexes. The more flexible way to perform a selection of forecasts and observations following a certain number of conditions, is to use an "ad hoc database", planned and designed for this purpose, where the mask or filter could be simple or complex SQL statements.

Through the development of VERSUS software we have achieved a unified tool able to perform operational standard verifications, operational conditional verifications along with experimental standard and conditional verifications, in batch and interactive mode.

The modularity of VERSUS easily allows updates and use of new verifications methods through the use and implementation of "R" language software package or even "ad hoc" algorithms (Fortran, C, PHP).

The verification software has been developed with an user friendly graphic interface, that makes easier the registration, modification and management of all the verification activities. The GUI is based on standard Web interface. This means also that the final architecture can be considered client-server kind.

2 Project report

The classical verification of forecast products is generally based on the evaluation of single elements (e.g. T2m, RR) over specific domains in space and time. The resulting numbers, tables and plots present measures of the overall performance of the model with regard to the product considered. Potential interdependencies between various products are a priori ignored (e.g. cloud cover & near surface temperature). The interpretation of classical verification results with regard to systematic deficiencies in the model simulation of specific processes is also far from trivial. Even though obvious failures of the model may be established, finding the reasons behind these failures is hampered by the integral properties of the classical approach, i.e. the averaging over spatial domains (and time) without consideration of specific details of the atmospheric and/or surface situation. However, a tool allowing a process or a situation dependent verification, e.g. the evaluation of the model forecast quality with regard to the diurnal cycle of near surface temperatures in the absence of clouds, would facilitate the task of finding the cause of model shortcomings and the model improvement. Formulating the verification of forecast products in conjunction with the existence of additional criteria, can be defined as Conditional Verification (CV).

The prime purpose of CV is the systematic evaluation of model performance in order to reveal typical shortcomings and the reasons behind them. Applied in a routine mode, it should also have the potential to provide information to the forecasters with regard to the

situation and product dependent model reliability (e.g. typical clear sky forecast errors for T2M in contrast to cloudy sky condition errors). Then the typical approach to CV could consist of the selection of one or several forecast products and one or several mask variables, which would be used to define thresholds for the product verification (e.g. verification of T2M for grid points with zero cloud cover in model and observations only). However, the masking requirements may occasionally be rather complex as in the cases where the forecast product depends strongly on the history of the evolution rather than the current state of a certain variable. For this reason, one could define at least four classes of masks:

- time-independent masks;
- time dependent masks concurrent to the product;
- time dependent masks with possible time-lag to the verified product;
- masks depending on an atmospheric situation classification.

The first class is certainly the simplest to handle, but it carries nevertheless a certain potential with regard to the purpose of the exercise. Apart from obvious masks like the application of a land-sea filter or the stratification of verification results with regard to orographic height, one could envisage masks like the model soil type, plant cover, roughness length etc. The application of such masks might well reveal that certain deficiencies are more pronounced within certain ranges of a particular mask than outside of that range and thereby lead to the detection of a more specific model deficiency.

The second class concerns more the direct interaction between various model products. Typical examples would be the verification of T2M in the presence or absence of snow, but also the verification of products like surface radiative fluxes classified by the cloud cover.

The third class allows in addition to take into account the history of the model (or observation) evolution. E.g. the near surface temperature, as an instantaneous model product, depends among others on the cloud cover which was present in the period before the verification time. In order to obtain a meaningful CV for such a product/mask combination, one would evaluate the verified variable with respect to the previous evolution and the current state of the mask variable.

Finally, the fourth class may need a sophisticated algorithm or even manual intervention in the stratification of all cases with regard to the mask criteria. For example, if we are interested in the performance of the model in stable wintertime conditions, it may not be sufficient to check for a temperature inversion near the earth's surface or relatively high pressure over the domain considered.

Masking conditions may be formulated in model or observation space or both, depending on the application. E.g. in order to obtain a detailed insight in the models ability to simulate the diurnal cycle of near surface temperatures in cloud-free conditions, neither simulated nor observed cloud cover must exceed the specified threshold value.

Generally, several masks may be applied at once, e.g. simultaneous application of cloud cover, soil moisture and plant cover thresholds. Obviously the size of the ensemble will depend on the number of criteria applied. Even though this could be detrimental for the evaluation of a few case studies, in an operational environment this problem would be alleviated by the large number of forecasts generated.

One drawback of CV may be the multitude of verification products arising, if various mask criteria are applied to a set of forecasts.

A generalized CV tool, which can handle all the potential applications mentioned above would require development resources which exceed those available. Consequently, in a first step a tool which is able to handle at least the more basic applications mentioned above, has been created. The name of this tool, as well as the COSMO priority project, is VERSUS (VERification System Unified Survey).

However, VERSUS has been developed in a flexible, user configurable way in order to allow future extensions towards a fully flexible tool. Nevertheless it can be already applied both to operational and experimental forecast products.

In order to give a general idea, in the following table a first attempt was made to define a small set of products to be verified in conjunction with corresponding criteria. This set should only be considered as a starting point. No attempt has been made to order the following table with regard to the expected benefit.

Verified variable	Mask variable(s)	Criteria	Remarks
T2m	CLC(t); local time	lower & upper thresholds in CLC; local time slots	cloud cover thresholds should be applied over the time period preceding the verification time and both to model and observations
T2m	Wsoil	lower & upper thresholds in soil moisture (relative to field capacity)	soil moisture is a multi-layer variable and it may be useful to compute an effective soil moisture as average over several layers
T2m	SHF/LHF	thresholds in Bowen ratio	Bowen ratio as an indirect measure of soil wetness needs to be considered as an average over time
CLC(L)	vertical stability index	stable versus unstable situations	differences in temperatures at various pressure levels may be used as a stability index; the distinction with regard to stability may be considered as an example for situation dependent masking, e.g. to focus on low level stratus or convective regimes
RR	vertical stability index	stable versus unstable situations	regime dependent precipitation verification
U10m	z0	low, medium, large z0	correlation between wind speed errors and roughness length may point to problems in external parameters
T2m	U10m	upper threshold in wind speed	exclude advection dominated situations in temperature verification
Td2m	Wsoil	lower & upper thresholds in soil moisture (relative to field capacity)	determine the error of dew point temperatures in the case of dry soils versus wet soils
T2m	Wsnow	no snow, broken snow, snow	the temperature error is likely to depend on snow cover, hence a broken snow deck might be an indicator for melting snow

The project started in an experimental version using the already developed Common Verification Suite (Fortran package). A number of other Fortran applications were developed to

implement some of the interdependencies of the table above. The results were encouraging because it was clear that applying a mask during the calculation of T2m standard verification, for example cloud/no-cloud, the model behaviour was really different and some clear indication arose from such a conditional verification.

On these basis it was decided to go further and to develop the VERSUS priority project and it was clear that the more flexible way to perform a selection of forecasts and observations following a certain number of conditions, is to design, build and use an "ad hoc database" where the mask or filter could be simple or complex SQL statements.

The project was planned on the development of ten tasks over a period of 3 years.

Of course not only conditional verifications, but also all the standards and common verification scores can be produced by VERSUS. For the comprehensive list of features of VERSUS package you can refer to the User Manual and Technical Manual, available in the installation package, on the VERSUS WEB GUI and soon on the COSMO website.

The following are only some of the most important features that can be found in VERSUS package:

- Verification (conditional or not) can be produced in batch or interactive mode;
- seasonal or monthly period can be produced in batch and interactive mode; any other time period can be produced in interactive way only;
- 3 different kind of users with different kind of privileges have been foreseen in VERSUS (see manuals for details);
- VERSUS can perform standard and conditional verification on continues and binary parameters for surface on-site observations;
- only standard verification is possible at the moment for upper-air observations;
- conditions can be imposed on both observation and forecasts spaces;
- VERSUS can be used not only for COSMO-models but also for, e.g., IFS and GME, provided the right information on the "model registration" module;
- VERSUS can calculate the usual standard statistical scores, both for continues and binary events. More scores can be introduced, through the GUI, using the "R" programming language;
- VERSUS can perform verification on different user-oriented stratifications, in time and/or space;
- all the scores, time series and daily cycles are produced in both text and graphical formats;
- graphic plots are highly configurable;
- all the possible activities are configurable through the web based GUI.

2.1 Open points

VERSUS has not been planned to cover all the existing verification methods, as well as all the possible products from a NWP. Moreover not all types of observation can be used at

present, with VERSUS software, for example observation from satellite and radar. In more detail, the open points in the VERSUS project are:

- development of probabilistic and ensemble forecasts verification;
- development of object-based and fuzzy verification methods applied to precipitation;
- new scores for extreme events (e.g. extreme dependency score);
- more in general, development of User-oriented verification;
- statistical features like Confidence intervals and Bootstrap method;
- use of non conventional obs (e.g. radar, satellite, raingauges) and gridded observations (precipitation analysis).

In order to face and solve these open points, an extension of VERSUS project has been proposed: VERSUS 2.

2.2 Resources used

The development of VERSUS needed the use of resources with special skill in database project, design and management. Of course expertise in verification methods has been used to fulfil and clarify the general requirements coming from documents, discussions, meetings and "wishes" inside the COSMO community.

Resources with skill in PHP programming and implementation of PHP graphic (JPGRAPH) modules have been used to create graphic package inside VERSUS. Resources with some skill in "R" programming language and in statistical packages have been employed too.

Finally, resources with skill in software and DB installation and customization on different LINUX platforms have been employed (e.g. testing phase).

2.3 Lessons learned

The project started at the end of 2005 with no clear technical specification or requirements but only with a joint document coming from WG3-WG5 workshop and some "wishes" from WG3. The lack of a Reference Document made the development of Conditional Verification (CV) package, and later VERSUS, more difficult and the direction and the solutions adopted inside the COSMO community were not clear even inside WG5 itself.

For this reason, the extension of VERSUS (the new project named VERSUS2) will have, as TASK0, the redaction of such a Reference Document (System Architecture Design and Overview), reviewed and accepted by all the members of the COSMO community. This task can be seen as the most important of the whole project. People involved in the actual development of requirements will have a clear reference document to follow, as well as a detailed description of what, why and how they have to implement. This TASK0 should avoid mistakes and delays due to misunderstandings or no full comprehension of the project itself.

The project leader has to "stress" and push people to communicate among them and with the PL himself. Communication is important for the exchange of suggestions, ideas, clarifications, for the release of deliverables and so on. Just to give an example: some parts

of VERSUS project were not really clear to everybody, almost until the end of the project itself, mainly due to poor communications.

COSMO Priority Project "VERification System Unified Survey" (VERSUS): Final Report

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW) and Romania (NMA). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction

In the recent years, more and more emphasis is being devoted to high-resolution rapid-update-cycle (RUC) NWP applications, since weather forecast is focusing more on high-impact weather (HIW) and small-scale intense phenomena (e.g. convection), also aiming at different applications (assistance to aviation, hydrology, civil protection). For this reason, NWP development is concentrating on high-resolution modelling, O(1km), and this is reflected in the COSMO strategy, which has lead to focusing the consortium development on high-resolution data assimilation, high-resolution modelling, high-resolution verification. Ensemble forecast was born to complement deterministic forecast, with products such as ensemble mean for medium-range predictions, ensemble spread to quantify the forecast uncertainty, meteograms for surface weather parameters, to present a spectrum of possible alternative scenarios. With the model resolution increase, the phenomena which are now described by NWP models are more and more stochastic in nature. For moist convection prediction, skill is manifested through the statistical properties of the forecasted convection instead of by deterministic modelling (Fritsch and Carbone 2004). Therefore, the weight given to ensemble forecast is now greater than it was some 10 years ago, since for the convection-permitting NWP models it is crucial to be able to forecast not only the "best scenario" but ideally the whole pdf or, more realistically, a good representation of it. The high-resolution of these systems prevents the possibility of running consortia ensembles, since it is prohibitive to cover a large domain with the required grid spacing. This is leading to the development of high-resolution ensembles on a national scale. Few years ago, DWD has started the development of a convection-permitting ensemble, COSMO-DE-EPS, which is operational over Germany at 2.8km horizontal resolution since May 2012 (Gebhardt et al., 2011). At the time of the COTEKINO PP, the system received initial condition perturbations from the 4 global scale operational analyses of DWD, ECMWF, NCEP and JMA. The four operational global runs of these institutions provides also boundary conditions to 4 COSMO runs at 7km horizontal resolution which drive in turn the COSMO-DE runs. Model physics perturbations are also applied, by changing the value of few parameters of the physics schemes. Then also Switzerland, Italy and Poland have started the development of convection-permitting ensembles in their countries. Furthermore, Russia has developed COSMO-RU2-EPS for assisting the Winter Olympics. Therefore, the need for a good strategy for convection-permitting ensemble has emerged at the Consortium level, requiring coordination among the activities taking place in the different countries, in order to share research and development work and to ensure good and timely exchange of in-

formation. This coordination has been organized through a Priority Project, COTEKINO (COsmo Towards Ensembles at the Km-scale IN Our countries). The COTEKINO Priority Project, which lasted for 2 years, was aimed at bringing to operations the COSMO ensemble forecasting systems for the convection-permitting scale. Several aspects of the design of convection-permitting ensembles have been taken into account, by organizing the Project in three Tasks: Initial Condition (Task 1, Section 2), Model perturbation (Task 2, Section 3) and Lower boundary perturbation (Task 3, Section 4). Boundary Conditions have not be considered in the Project. Anyway, a study about how to provide perturbed BCs to a convection-permitting ensemble has been carried out in Marsigli et al. (2014), showing that a direct nesting in a global ensemble of good quality may be a practicable solution, without the need of an intermediate step with a coarser resolution ensemble. The work carried out within the three Tasks is presented in the following Sections of this Report.

2 Initial Condition perturbations derived from KENDA

It is recognised that for the forecasting horizon of the convection-permitting ensembles, data assimilation plays a crucial role. What dominates ensemble spread in the first six hours are perturbed initial conditions (Peralta et al, 2012, Vié et al, 2011), which should include both a good estimate of the initial condition(s) and a good representation of its (their) uncertainties. Within the KENDA PP, a LETKF scheme for the km-scale has been developed, aiming at providing both deterministic analysis for driving high-resolution COSMO runs and a set of perturbed analyses to drive high-resolution ensembles. Though the KENDA development is included in the KENDA PP, how to set-up the system to provide ICs to a convection-permitting ensemble and how to derive ICs from KENDA was addressed in the COTEKINO PP. In particular, it was organised the communication about experiments and their results, the exchange of dedicated tools and the coordination with the KENDA PP itself. This activity has been carried out by Chiara Marsigli and Tiziana Paccagnella (ARPA-SIMC), Daniel Leuenberger and André Walser (MeteoSwiss), Richard Keane (DWD), from the COTEKINO PP side and by Christoph Schraff, Hendrik Reich and Roland Potthast (DWD) from the KENDA side. The coordination has been performed mainly thanks to meetings organized jointly with KENDA PP (COSMO GM 2014, CUS 2015). Results have been presented and discussed and further experiments have been agreed and planned. Tools for diagnostics have also been shared.

3 Model perturbations

The importance of model perturbations in ensemble forecasting has been recognised since some years. It is found that model perturbations usually play a smaller role with respect to initial conditions (at the beginning of the run) and boundary conditions (later) perturbations, but they may become crucial in specific weather situation (Marsigli et al, 2009; Gebhardt et al, 2011) and a poor representation of the model error may lead to severe underestimation of the ensemble spread (Vié et al., 2011). Several techniques have been developed to represent model error: perturbation of the physics schemes parameters (Marsigli, 2009; Gebhardt et al, 2011), random parameters (Bowler et al, 2008), SKEB (Shutts, 2005; Berner et al., 2009), SPPT (Buizza et al, 1999; Palmer et al, 2009), multi-physics, stochastic physics (Plant and Craig, 2008; Bengtsson et al., 2013). Interesting comparative studies have also been carried out (Berner et al, 2011; Hacker et al, 2011). While there are some results about the applicability of these techniques for the O(10km) scale, it is still not assessed how to use them for the O(1km) scale. From the COSMO-DE-EPS experience it is clear

that underdispersion severely affects the ensemble for surface variables, if only few physics parameters are perturbed. The SPPT scheme of ECMWF has been implemented in the COSMO code, to test its capability of representing model error in the LETKF ensemble. This code can be tested also for the ensemble forecasting set-ups, though it is argued that this approach may lead to serious unbalances in the model. Also, the scheme has been originally developed for the IFS model at coarser resolution and should be adapted for use at the O(1km) scale. On top of this, the SKEB scheme has been implemented in the COSMO model, opening the possibility of testing this approach for providing model perturbations to the convection-permitting ensembles. Finally, DWD has started the development of a new approach for model perturbation, aiming at simulating the model error as a continuous stochastic process with the same statistically properties as the empirically determined error of model tendencies.

3.1 Tests with the SPPT scheme

3.1.1 Tests at MCH

At MeteoSwiss, the SPPT scheme has been tested for the ensemble prediction system COSMO-E with 21 members for the Alpine area (see Fig. 1) and a mesh-size of 2.2 km and 60 model levels. The implementation of the SPPT in the COSMO code has been done by Lucio Torrisi and has been used in our first study to find an appropriate SPPT setup for the convection-resolving resolution as well as to understand the impact of the scheme on spread and error of temperature and humidity in COSMO-E. The main findings are:

- larger random numbers produce larger spread and faster spread growth
- larger correlation-lengths in space and time for the random numbers lead to substantially larger spread
- the spread increase due to SPPT decreases with increasing height above the surface

Details about this first study are given in Maurer et al. (2014).

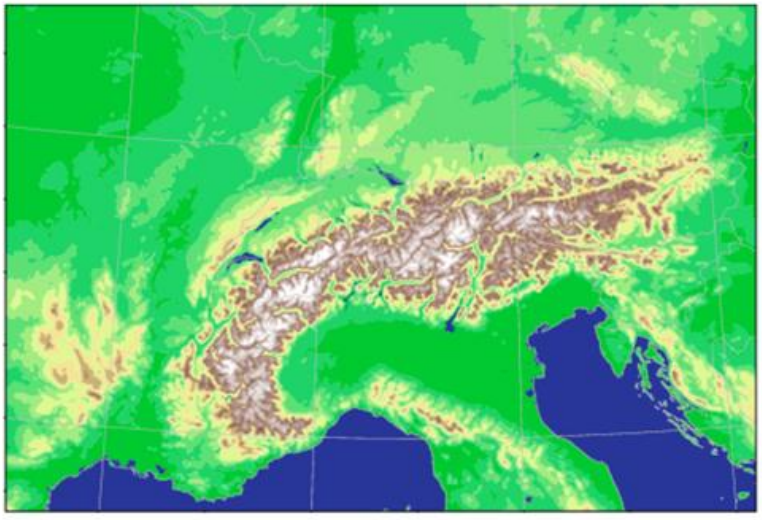

Figure 1: COSMO-E model domain for the experiments with orography.

In the course of the study, the SPPT implementation in COSMO has been reviewed and improved. In particular, perturbing the tendencies of the Coriolis force has been removed

as well as a few technical changes has been done to support single precision and to ensure the same results with different compilers. The revised SPPT code has been integrated into the official COSMO version 5.1. Further experiments for a summer period confirm these results and demonstrate that turning off the SPPT tapering below 850 hPa does not cause model stability problems and significantly increases the spread in the planetary boundary layer. Furthermore, deterministic forecasts for a summer and winter month in 2012 show no significant quality degradation with SPPT, even for rather strong stochastic perturbations of physical tendencies. Therefore, an aggressive SPPT parameter setting has been chosen for COSMO-E with:

- itype_vtaper_rn=2
- itype_qxpert_rn=1
- itype_qxlim_rn=0
- hinc_rn=6
- dlat_rn/dlon_rn=5.0
- stdv_rn=1.0
- range_rn=0.9
- lgauss_rn=.TRUE.
- lhorint_rn/ltimeint_rn =.TRUE.

This setup is used for further experiments to investigate the spread-error relationship in detail. To this end, 00 UTC COSMO-E forecasts are run for every second day from 26 July to 25 August 2012 for a summer period and from 3 December to 31 December 2012 for a winter period. Initial conditions including perturbations (if used) are taken from an early KENDA assimilation cycle in test mode which has been implemented at MeteoSwiss, while IFS-ENS control and members 1-20 are used to drive the COSMO-E forecasts at the lateral boundaries.The experiments are run with COSMO v5.0 including local modifications and with single precision (Rüdisühli et al., 2014). According to Jolliffe et al. (2011) the standard deviation of the ensemble mean error (STDE) needs to match the root mean ensemble variance (RMEV) for a reliable forecast.This is further discussed in Maurer et al. (2014). Fig. 2 shows RMEV (spread) and STDE (error) with respect to analysis for experiments without initial condition perturbations for temperature at the lowest model level,which is about 10m above surface. For summer, RMEV is clearly smaller than STDE in the first 4 days (i.e. roughly up to lead-time +96h) without SPPT and SPPT reduces the gap between RMEV and STDE to a large extend mainly by augmenting the daily cycle of RMEV. For the winter period, RMEV is clearly smaller than STDE in the first 3 days (i.e. roughly up to lead-time +72h) and the increase in RMEV due to the SPPT is much smaller. In the middle and upper troposphere the RMEV matches the STDE quite well except for the first day,also for the experiments with initial condition perturbations (not shown).

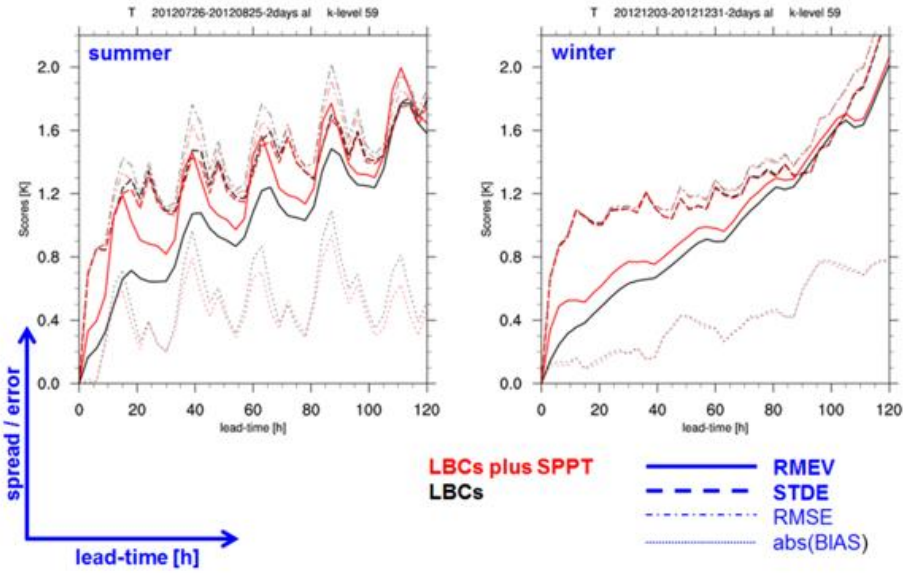

Figure 2: Root-mean ensemble variance (RMEV; bold solid), standard deviation of ensemble mean error against analysis (STDE; bold dashed), root mean square error of ensemble mean (RMSE; dashed-dotted) and the absolute value of the bias (dotted) for temperature as a function of forecast lead-time on the lowest model level at about 10m above surface averaged over the model domain for a summer (left) and winter (right) period without initial condition perturbations and with two different setups: boundary condition perturbations plus SPPT (red) and boundary condition perturbations only (black).

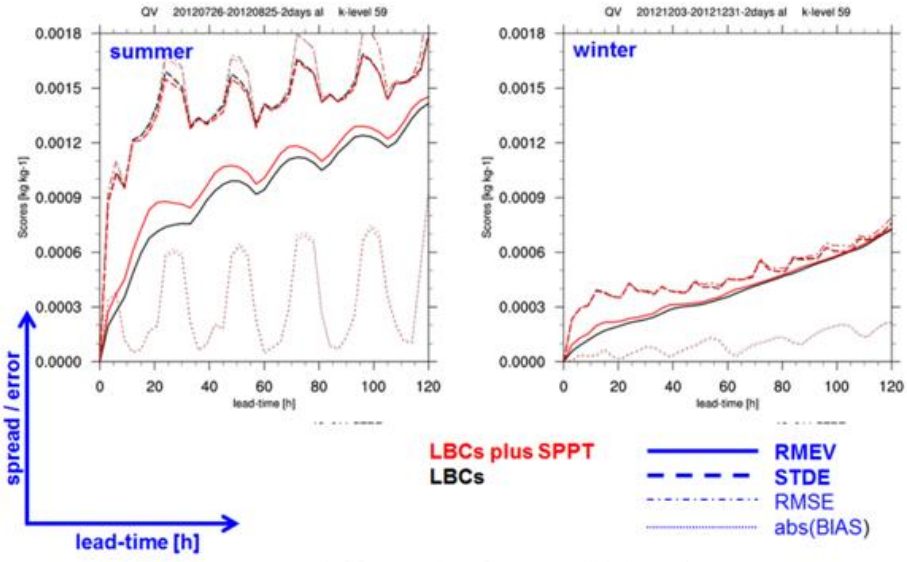

Figure 3: As Fig. 2 but for specific humidity.

Similar results are found for wind speed (not shown) but the underdispersiveness in winter with SPPT is clearly smaller than without. In contrast, the underspersiveness for specific humidity is much larger and SPPT does only slightly reduce the large gap between RMEV and STDE both in summer and winter (see Fig. 3). In the following, the vertical structure of the impact of SPPT is discussed for the summer period. Fig. 4 shows the RMEV, STDE, BIAS and RMSE differences for temperature between the summer experiments with and without SPPT for all model levels as a function of lead-time. The impact for temperature has an obvious daily cycle and is significant up to about level 42, i.e. up to about 2500m

above surface. Interestingly, SPPT does not only increase spread, it also decreases BIAS and STDE slightly (and thus RMSE as well). Similar results are found for wind speed and specific humidity in terms of RMEV, but the impact of SPPT clearly decreases with increasing lead-time (not shown).

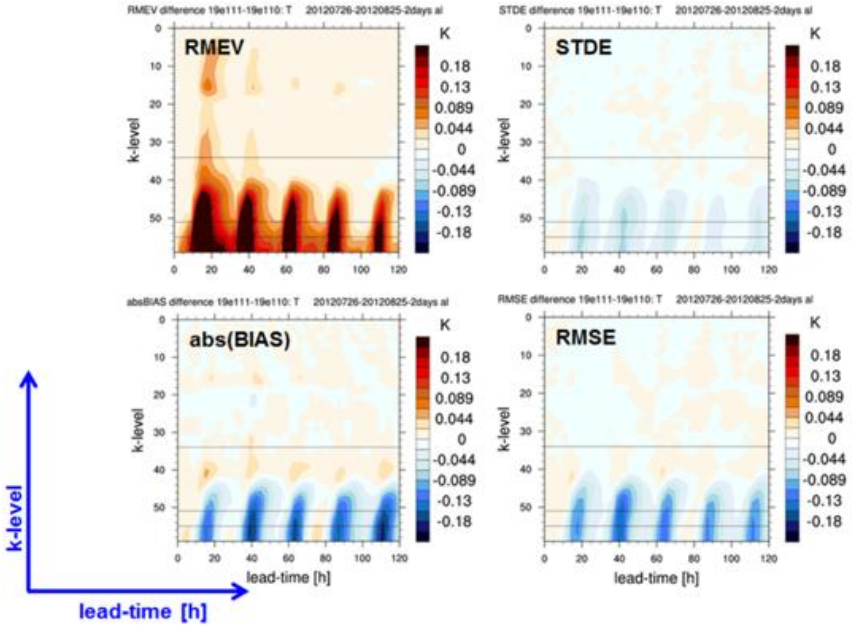

Figure 4: Difference between experiments with and without SPPT for RMEV (top left), STDE (top right), abs(BIAS) (bottom left), and RMSE (bottom right) for temperature on all model levels as a function of forecast lead-time for the summer period. The experiments use initial and lateral boundary condition perturbations.

In order to better understand the impact of SPPT, the tendency contributions from the different parametrizations are investigated. In the COSMO-E setup, the following parametrizations contribute to the sum of the temperature tendencies which is then perturbed by SPPT: turbulence, microphysics, shallow convection, and radiation. Fig. 5 shows the contribution of the different parametrizations on all model levels as a function of lead-time for a summer and winter day. It points out that for the summer day the tendencies from the turbulence scheme are at least an order of magnitude larger than the other ones. The tendencies show a daily cycle with values largest near-surface. This explains well the daily cycle of the SPPT impact on near-surface temperature in the summer period. For the winter day, the tendencies from the turbulence and radiation scheme are naturally smaller which explains the smaller impact of SPPT in winter. For the chosen day, they are of the same order of magnitude as the microphysics tendencies.

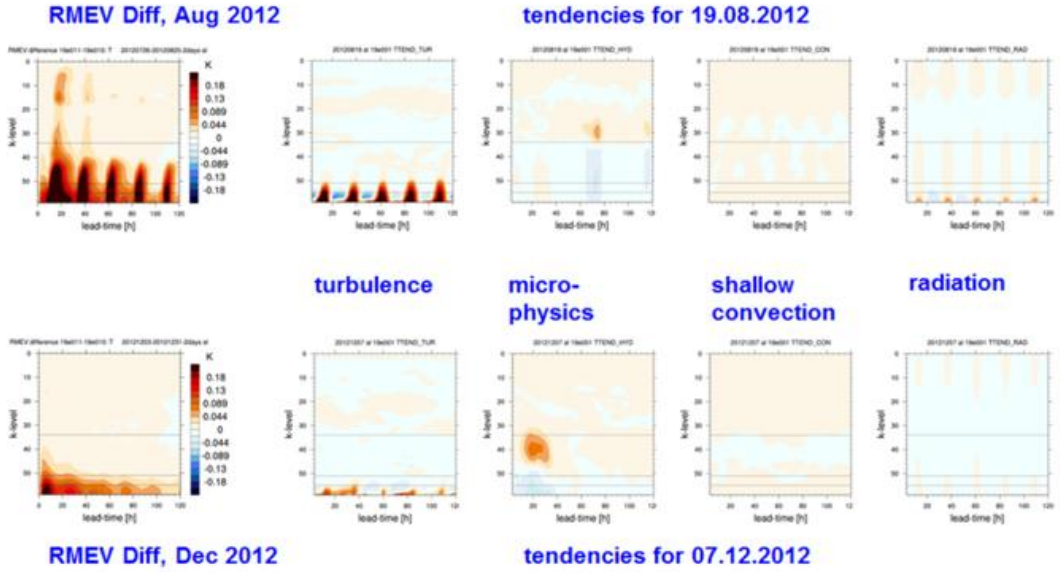

Figure 5: RMEV for temperature for the summer (top left) and winter (bottom left) period and temperature tendencies of the turbulence, microphysics, shallow convection and radiation scheme on all model levels as a function of lead-time for a summer (top) and winter (bottom) day. The sum of these temperature tendencies is perturbed by SPPT.

A further study has investigated the impact of an overlaid second smaller-scale spatial SPPT pattern and the impact of soil moisture perturbations. Both experiments show a positive impact for a summer case by further increasing the spread. However, they have only limited impact in winter when additional spread would be most helpful since then SPPT is less effective in representing model errors. In summary, the COSMO-E experiments show, primarily in summer, a significant improvement of RMEV, STDE, and BIAS due to SPPT in the lower troposphere for the entire forecast range, but they still lack spread in the first 3 days, in particular for humidity. In the middle and upper troposphere the experiments generally show a satisfactory spread-error relation, with the poorest results again for humidity which shows rather too little spread also at upper levels. The tendencies from the turbulence scheme generally show the largest physics tendencies and hence contribute strongest to the SPPT impact.

3.1.2 Tests at RHM

The goal of the RHM research was to assess the effect of stochastic perturbation of physical tendencies with different parameter settings in COSMO-Ru2-EPS (Montani et al., 2014). The ensemble consisted of 10 members, run with the COSMO model with a horizontal resolution of 2.2 km and 50 levels in vertical. The integration domain was the Sochi area. The initial and boundary conditions were provided by COSMO-S14-EPS (Montani et al., 2013). The period from 1 to 28 February 2014 was considered. The forecast length was 48h.The operational forecasts issued twice a day (00 and 12 UTC) during the Sochi Olympic Games 2014 were used as a reference experiment named noSPPT hereafter. The reference runs were carried out with COSMO model version 4.22. A set of experiments with COSMO-Ru2-EPS (the same EPS setting and period as in the reference experiment but model version 5.01) with different SPPT settings was held. The list of experiments and the corresponding SPPT settings are given in Table 1. In all experiments the distribution of random numbers was Gaussian (lgauss_rn=.true., default); a 5 deg x 5 deg coarse grid was used for random numbers (dlat_rn=dlon_rn=5); the random number field was changed every 6 hours (hinc_rn=6,

default); the tapering was prescribed by default near the surface and in the stratosphere (itypevtaperrn=1), and only one random number pattern with its correlation scales was applied (npattern_rn=1, default). The following SPPT parameters were varied:

- the standard deviation of the Gaussian distribution of random numbers stdv_rn;
- the upper limit imposed to the absolute value of random numbers range_rn;
- the parameters showing whether the random numbers are interpolated in space lhorint_rn and time ltimeint_rn;
- the parameter itype_qxpert_rn, showing which hydrometeor tendencies are perturbed;
- the parameter itype_qxlim_rn, determining the type of reduction/removal of the perturbation in case of negative or supersaturated values of specific water vapor content or negative other water-content related characteristics.

All SPPT runs completed successfully with no numerical instabilities. Both case study evaluation and probabilistic verification of monthly series of forecasts were carried out. The results of experiments SPPTtest and noSPPT were compared for the two cases: the tropospheric föhn event on February 7, 2014 and the heavy precipitation event on February 18, 2014. It was found that the SPPT effect on 2m T ensemble spread depends on orography (see Fig. 6). With SPPT the spread strongly increased over high mountains, moderately grew over low regions (including sea), and decreased over areas of medium heights. The strongest increase in the ensemble spread over high domains can be considered as a positive effect of SPPT introduction because the temperature forecasts above 1500 m were poor during the föhn (thus higher spread corresponded to less skilful forecast).

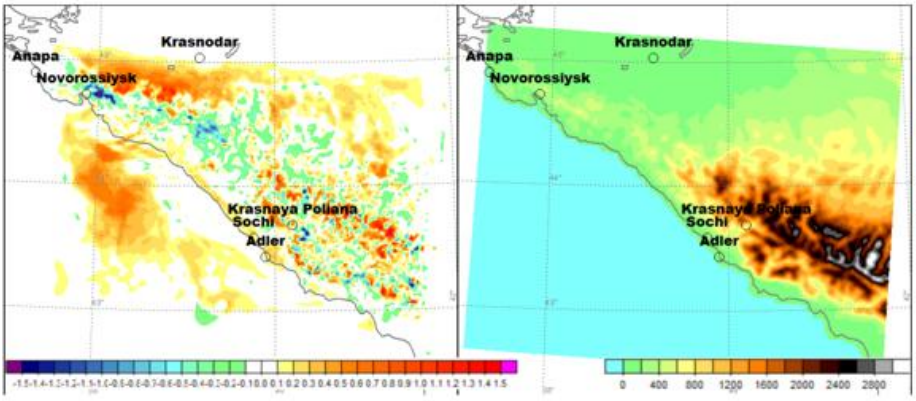

Figure 6: Left panel: difference of 2m temperature ensemble spread in experiments with and without SPPT (SPPTtest minus noSPPT). 30-h forecast starting at 00 UTC on February 6, 2014. Right panel: model orography.

For the case of heavy precipitation on February 18, 2014, the system with SPPT was more skilful in predicting the rain start. Also, it gave less false heavy rain areas and more correct peaks. However, the location of maximum precipitation was better predicted in the noSPPT experiment.

Perturbed parameters	**Experiment name and SPPT settings**						
	noSPPT	**SPPTtest**	**SPPTphys**	**SPPTintphys**	**SPPT_W**	**SPPT_W + phys**	**SPPT_W + intphys**
stdv_rn	N\A	0.4			1.0		
range_rn		0.8			0.9		
lhorint_rn		.FALSE. (no interpolation of perturbations)		.TRUE. (interpolated perturbations)	.FALSE. (no interpolation of perturbations)		.TRUE. (interpolated perturbations)
ltimeint_rn							
itype_qxpert_rn		0 (q_v only)	2 ($q_v, q_c, q_i, q_r, q_s, q_g$)				
itype_qxlim_rn		0 (no limitations imposed)	1 (do not perturb tt T- and tt q_v tendencies if new q_v are negative or supersaturated)		0 (no limitations imposed)	1 (do not perturb tt T- and tt q_v tendencies if new q_v are negative or supersaturated)	

Table 1: List of experiments with COSMO-Ru2-EPS and corresponding SPPT settings.

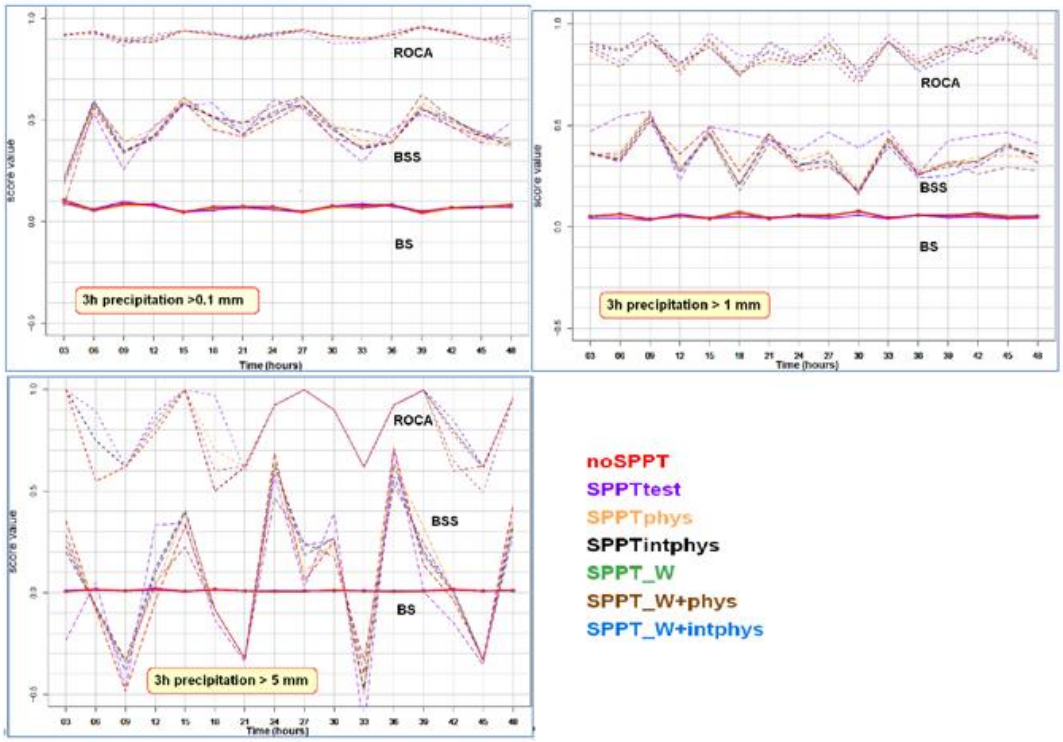

Figure 7: Verification of precipitation forecasts for various SPPT parameter settings.

The probabilistic verification was performed for the monthly (February 2014) series of COSMO-Ru2-EPS forecasts (56 in total, with no regard for the initial forecast time). The Brier score (BS), the Brier skill score (BSS) and the area under the ROC curve (ROCA) were computed for 3-hour total precipitation sum, 2-m air temperature, and 10-m wind speed. The verification was against observations at 31 meteorological stations in the Sochi region (http://frost2014.meteoinfo.ru). R-based utilities developed and kindly provided by A. Muravev were applied. Some positive effect of using SPPT was found for precipitation forecasts, especially for the event "3-h precipitation is greater than 1 mm". Though the application of different SPPT settings resulted in very close scores, SPPTtest was undoubtedly the best for the thresholds of 1 mm/3h and 5 mm/3h (Fig. 7). As for the 2-m temperature forecasts, SPPT did not improve their skill (Fig. 8). The experiment noSPPT was the best especially for high thresholds. SPPTtest, which demonstrated the best precipitation forecasts, was the worst in terms of 2-m temperature forecasts. Generally, the probabilistic scores for temperature differ more between the experiments than for precipitation. However, no sensitivity was found to interpolation of random numbers (parameters lhorint_rn, ltimeint_rn) and to the method applied to avoid problems with negative or supersaturated water vapor values (parameter itype_qxlim_rn). The verification results demonstrated the advantage of perturbing all hydrometeor tendencies and using wider distributions of random numbers.

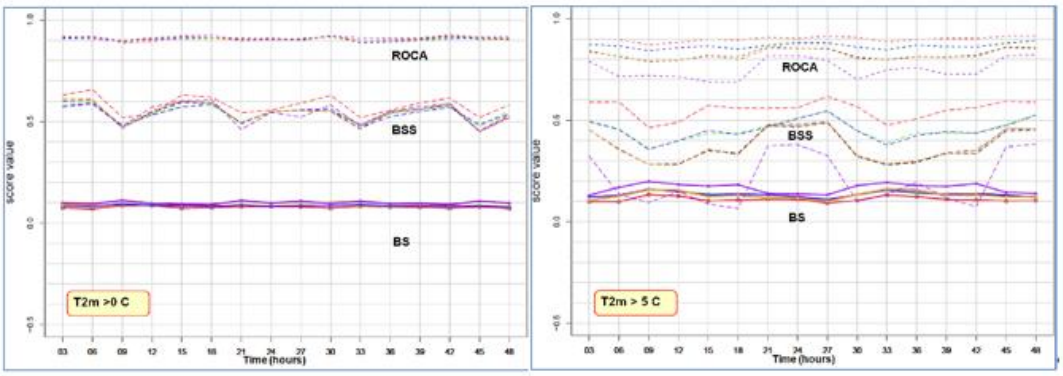

Figure 8: The same as Fig. 3 but for 2-m temperature.

The introduction of SPPT not only affected the probabilistic scores but also led to temperature biases that vary depending on the SPPT settings. Fig. 9 shows the monthly-averaged errors of the ensemble mean for different experiments at the Krasnaya Polyana station.

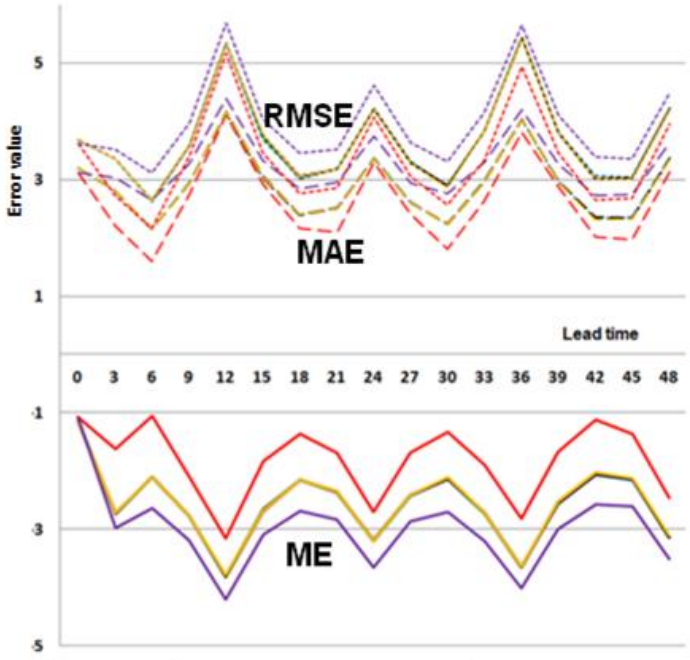

Figure 9: Mean error (ME, solid), mean absolute error (MAE, long-dashed), root-mean-square error (RMSE, dashed) for 2m T ensemble mean forecasts at Krasnaya Poliana station. Experiment as in Fig. 7.

The plot confirms the superiority of experiments with higher standard deviation of random number distribution and perturbation of all hydrometeor tendencies. High sensitivity of 2m T forecast skill to SPPT settings indicates that they could be improved as a result of SPPT tuning. Though SPPT seems to introduce biases to 2m T forecasts, it can improve the temperature distribution. The forecast histogram for experiment with SPPT in Fig. 10 looks more like the observation histogram than that for the experiment without SPPT.

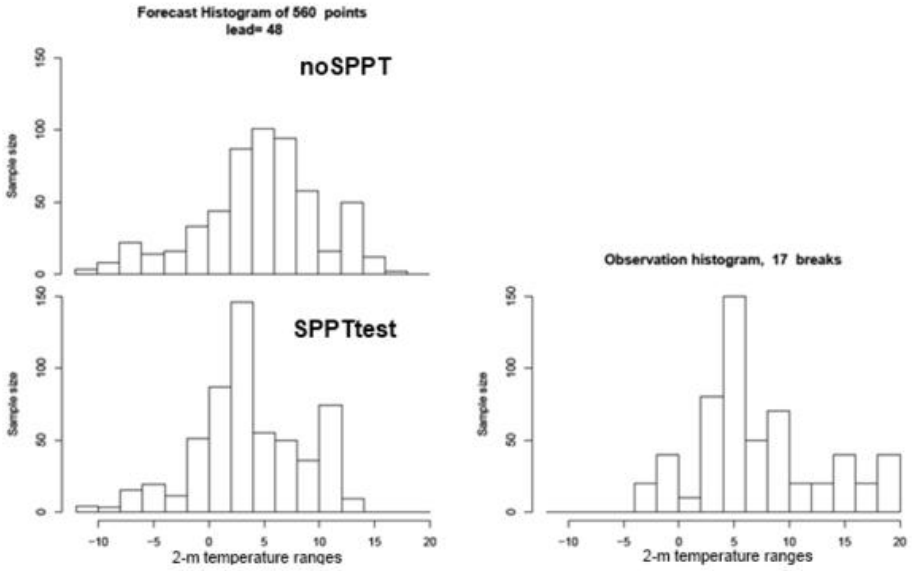

Figure 10: 2m T distribution histograms for noSPPT and SPPTtest 48-h forecasts and for observations at Krasnaya Polyana. February 1-28, 2014.

Wind speed forecast scores were rather poor both with and without SPPT. SPPT settings did not make significant difference.

Conclusions

Case studies in the Sochi mountainous area with COSMO-Ru2-EPS demonstrated that SPPT could be useful for precipitation forecasts, slightly improving the description of rain localization and start. The SPPT-related spread of 2m T ensemble forecasts correlates with the model orography. SPPT additional spread amplifies the coincidence between high-spread areas and the areas of less skilful forecast. The probabilistic verification of monthly series of COSMO-Ru2-EPS forecasts (56 in total) demonstrated a positive effect of using SPPT for precipitation forecasts, especially for the event "3-h precipitation is greater than 1 mm". Variations in the SPPT settings did not influence the results for precipitation much. SPPT worsens the 2m T forecasts, introducing temperature biases and deteriorating probabilistic scores. The verification showed rather large differences between the skills of experiments with various SPPT settings. At the same time, the eyeball analysis showed that the predicted temperature distribution became more realistic when physical tendencies were perturbed. Therefore, SPPT did not add value to temperature forecasts, but can sometimes improve the representation of distribution. It is possible to improve the 2m T forecast by varying the SPPT settings. For example, in most cases perturbations of all hydrometeor tendencies lead to better results than perturbations of specific water content tendency only. Also the increase of the range of standard deviation for the Gaussian distribution of random numbers and of the upper limit imposed to the absolute value of random numbers positively contributed to the results.

3.1.3 Tests at ARPA-SIMC

At ARPA-SIMC the SPPT scheme has been tested both in the COSMO-LEPS ensemble and in the COSMO-IT-EPS ensemble.

COSMO-LEPS

In the framework of the experimentation carried out in the PP, COSMO-LEPS was run for

Variables	2-m temperature, 10-m wind speed, 12-h cumulated precipitation
Period	22/11/2014 - 31/01/2015, starting at 12UTC
Verification period	35-55N, 0-20E (about 1000 synop reports/day)
Thresholds (for precipitation only)	1, 5, 10, 15, 25, 50 mm/12h
Method	Nearest grid point
Systems	OPER-CLEPS (v5.0) and SPPT-CLEPS (v5.1)

Table 2: Main features of the verification configuration.

about 70 days with SPPT switched on (SPPT-CLEPS) and its performance was compared to the operational set-up (OPER-CLEPS) for a number of surface variables. The verification network is provided by the synop reports which fall inside a domain covering Central and Southern Europe. On average, about 1000 observations are available for verification at each forecast range (Fig. 11).

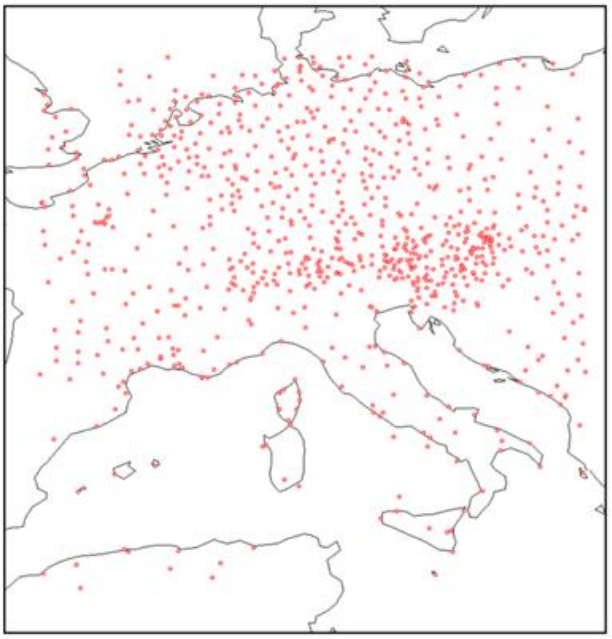

Figure 11: The verification domain used for inter-comparison between OPER-CLEPS and SPPT-CLEPS.

Table 2 summarises the main features of the experimentation.

As for the verification of temperature and wind-speed, the attention is focussed on the spread/skill relation of the two systems. As reported in Fig. 12, SPPT-CLEPS (blue lines) presents a larger spread than OPER-CLEPS for all forecast ranges. This is especially true for wind-speed and less evident for temperature. On the other hand, the impact on the forecast skill of the ensemble mean is negligible. In either cases, there is still a lack of spread in the short range, although the use of SPPT partly mitigates the underdispersion problem of COSMO-LEPS.

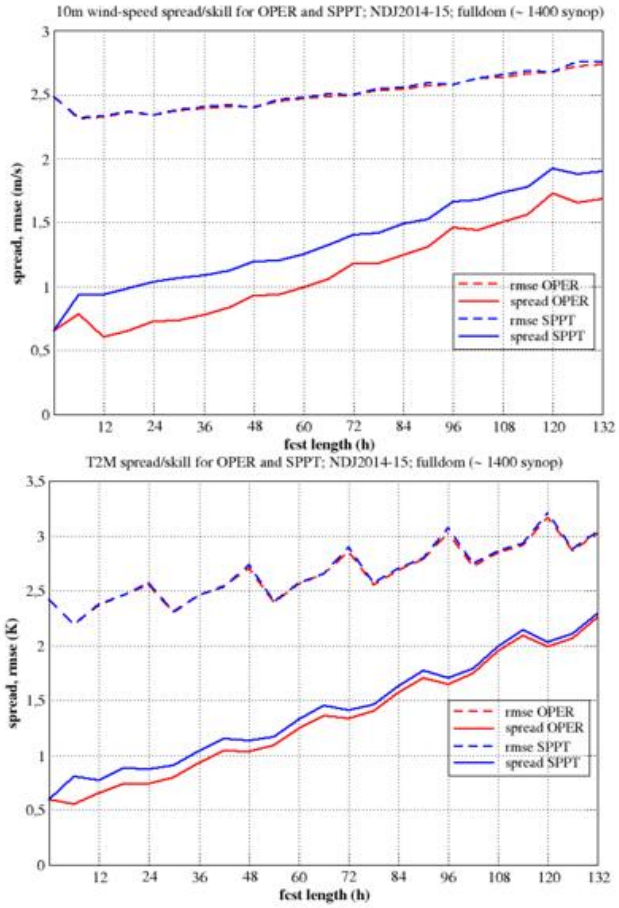

Figure 12: Spread/skill relation of OPER-CLEPS (red) and SPPT-CLEPS (blue) in terms of 2-m temperature (top panel) and 10-m wind speed (bottom panel) as a function of the forecast range. The rmse of the ensemble mean (spread) is reported as dashed (solid) line.

As for precipitation, the attention is focussed on the probabilistic prediction of 12-hour cumulated precipitation. In particular, the attention is focussed on the predictive skill of both systems for 2 types of events: 12-hour precipitation exceeding 1 mm and 10 mm. The left (right) panel of Figure 13 reports the values of the ROC area as a function of the forecast range for the 1mm (10 mm) threshold.

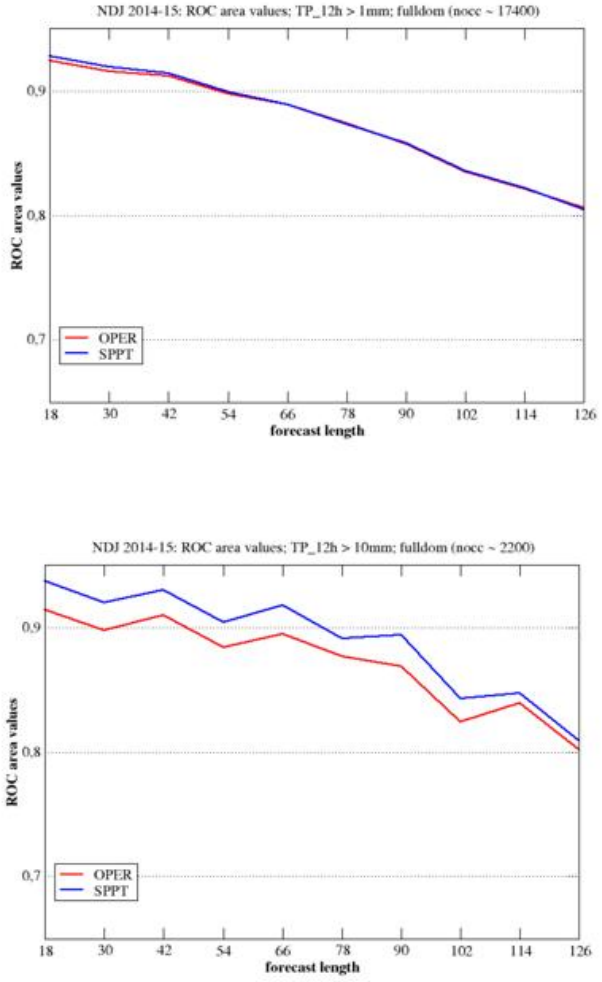

Figure 13: Roc area values for OPER-CLEPS (red) and SPPT-CLEPS (blue) as a function of the forecast range for the events: total precipitation over 12-hour exceeding 1 mm (top panel) and 10 mm (bottom panel).

It can be noticed that for the lower threshold, with about 17400 occurrences over the verifcation period of Table 2, the performance of OPER-CLEPS and SPPT-CLEPS is almost identical. On the other hand, for the higher threshold (about 2200 occurrences), some positive impact of using SPPT can be noticed. Therefore, on the basis of these encouraging results, it is planned to carry on the experimentation and assess the benefits of using SPPT also during summer months. In addition to that, it is also envisaged to study the possibility to run SPPT-CLEPS in single-precision mode, thus saving about 30% of computing resources and enabling the implementation of a larger-size COSMO-LEPS.

COSMO-IT-EPS

The COSMO-IT-EPS ensemble is an experimental convection-permitting ensemble running over Italy over selected cases/periods, aiming at the definition of an ensemble set-up to be operationally implemented as part of the Italian modelling chain. The COSMO model is run at 2.8 km of horizontal resolution, with 50 vertical levels, on an Italian domain. The ensemble has 16 members, which receive Initial and Boundary Conditions from the members of COSMO-LEPS. The aim of this work was to study the role of the physics perturbations focusing on severe rainfall events occurred in Italy. Three experimental ensemble set-ups

were run:

- no model perturbation (downscaling)
- perturbation of few physics parameters (PP)
- stochastic perturbation of physics tendencies (SPPT)

Two main rainfall events occurred in Italy in autumn 2014 were selected:

- Genova event, 9 October 2014
- Parma event, 13 October 2014

For the Genova event, the 6h accumulated precipitation estimated by radar during the 9th of October are shown in the first row of Fig. 14, while in the second row is shown the precipitation forecasted over the same time periods by the COSMO-I2 operational deterministic run.

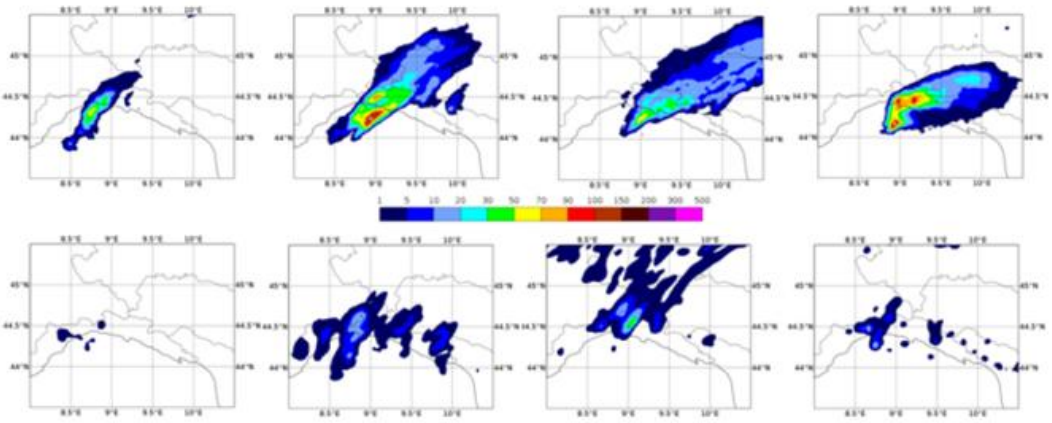

Figure 14: 6h accumulated precipitation during the 9th of October as estimated by radar (top row) and as forecasted by the COSMO-I2 operational deterministic run (bottom row).

For the Parma event, the precipitation accumulated over 24 hours, as measured by raingauges is shown in the left panel of Fig. 15, while in the right panel is shown the precipitation forecasted by the deterministic COSMO-2I model. The areas of maximum observed precipitation are highlighted in both plots by coloured ellipses.

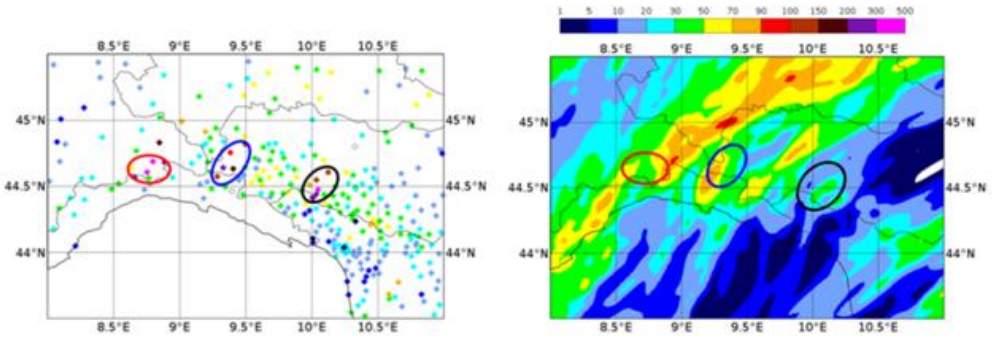

Figure 15: 24h accumulated precipitation during the 13th of October as measured by raingauges (left panel) and as forecasted by the COSMO-I2 operational deterministic run (right panel).

For the Genova event the behaviour of the 3 experimental suites is shown in the following figures, focussing on the 6h where the heaviest precipitation was observed, between 18 and 24 UTC of the 9th of October. In each figure, the precipitation forecasted by each ensemble member is shown, as well as the radar estimate in the uppermost right panel. In general, the ensemble members are able to forecast intense precipitation in the selected 6h period, but they tend to shift the structure toward the west (Fig. 16). The addition of parameter perturbations (PP, Fig. 17) permits to increase the diversity between the members and the introduction of the SPPT perturbation (Fig. 18) brings on top an enhancement of the precipitation forecasted by some members.

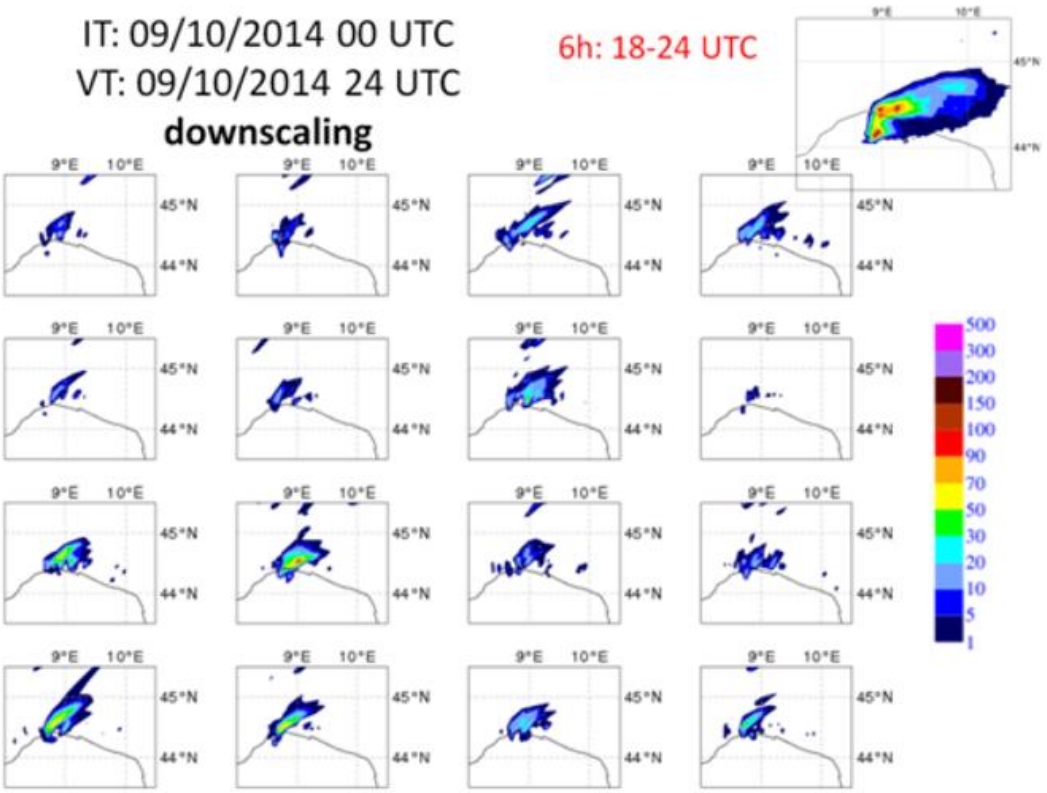

Figure 16: In the panels is shown the precipitation forecasted by each member of the downscaling ensemble accumulated over the 6 hours between 18 and 24 UTC of the 9th of October. The radar estimate for the same period is also shown in the uppermost right panel.

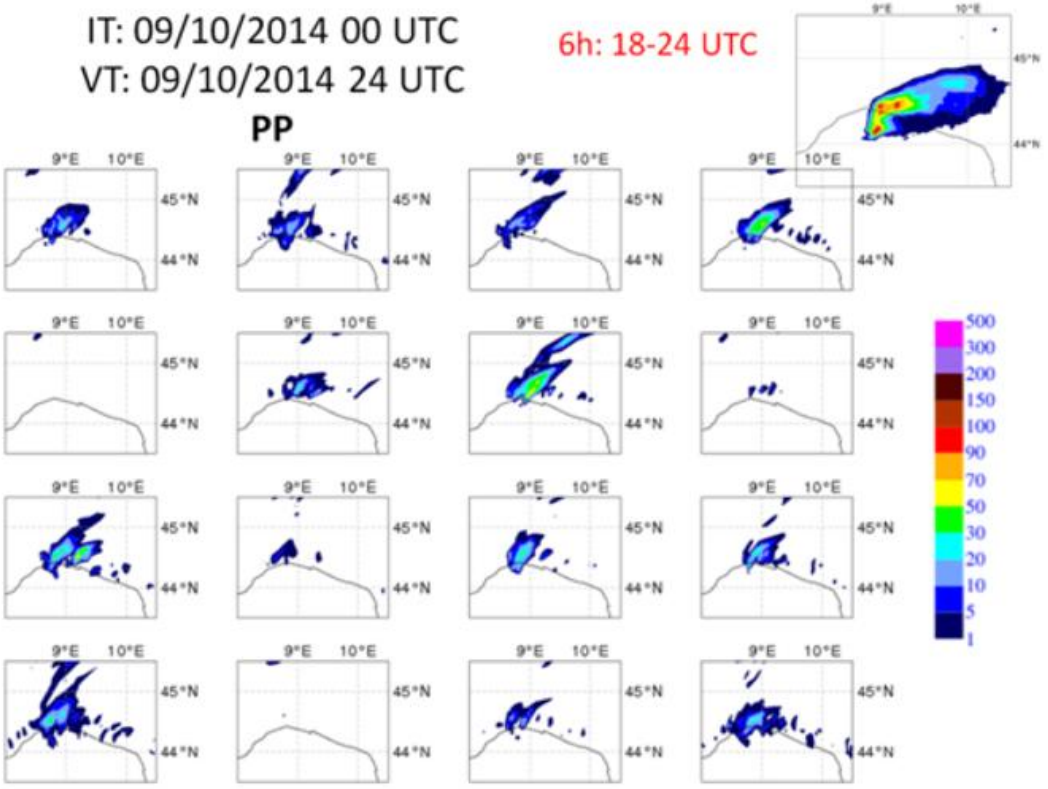

Figure 17: Same as Fig. 16 but for the PP ensemble.

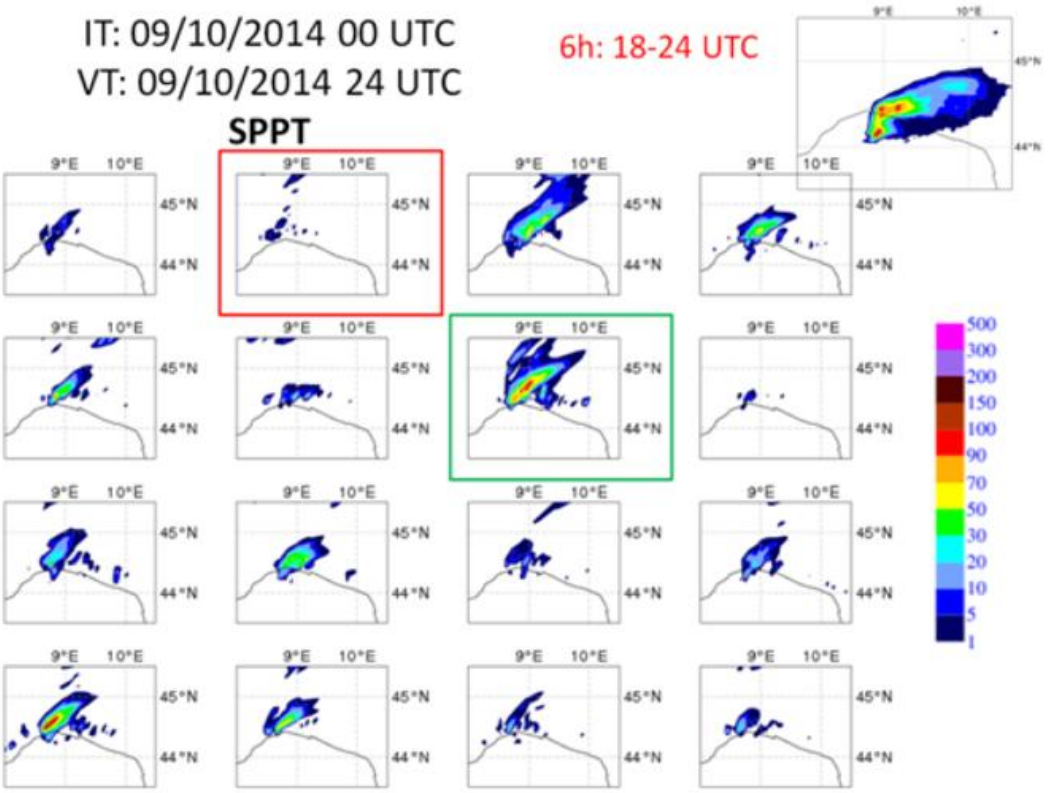

Figure 18: Same as Fig. 16 but for the SPPT ensemble.

The different role of the 2 perturbations in modifying the ensemble forecast for this case

is highlighted by considering the maps of ensemble mean and ensemble spread for the accumulated precipitation (Fig. 19). The PP ensemble (middle panel) forecasts an area of precipitation broader and more extended to the east than the downscaling ensemble (left panel), partly addressing the localisation error highlighted above, while the SPPT (right panel) mainly enhance the precipitation intensity, and adds spread particularly in the area where the precipitation peak was already forecasted by the downscaling ensemble.

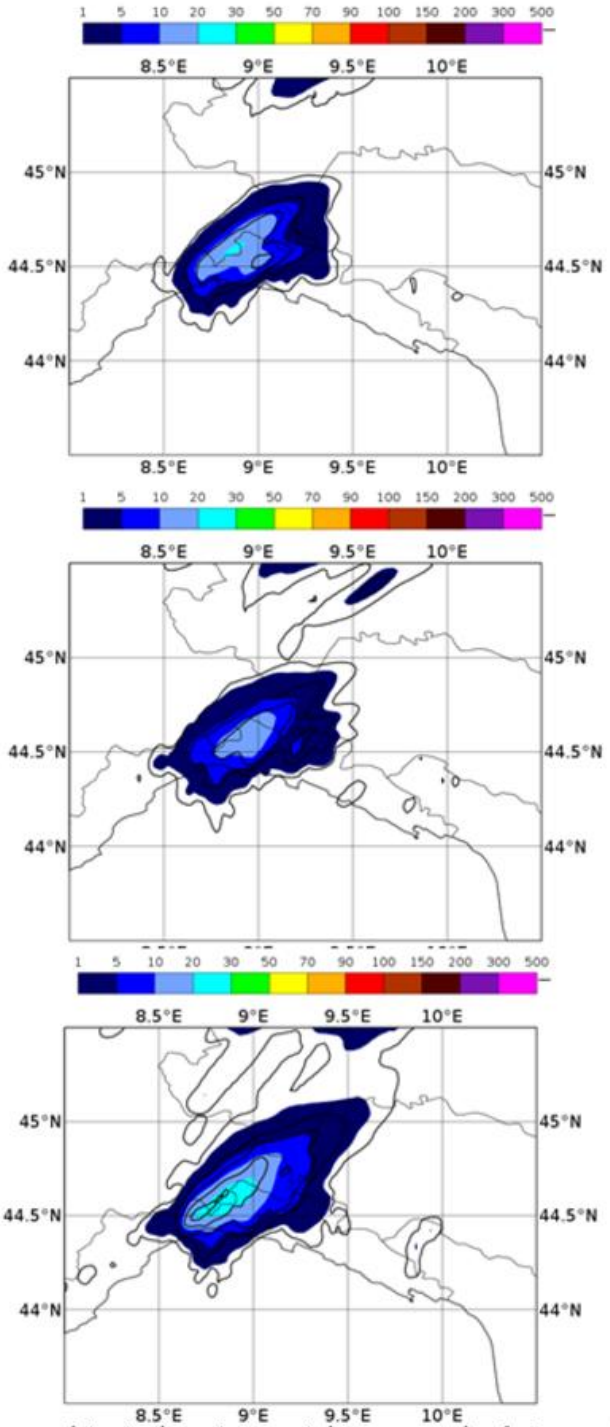

Figure 19: Ensemble mean (shaded) and spread (contouring) of the precipitation forecasted by the downscaling (left panel), PP (middle panel) and SPPT (right panel) ensemble, accumulated over the 6 hours between 18 and 24 UTC of the 9th of October.

Considering the Parma case, the precipitation forecasted over the 24h by 4 selected mem-

bers is shown in Fig. 20, for the downscaling ensemble (left column, labelled no physics perturbation in the Figure) and for the SPPT ensemble (right column). Also from this case is evident that SPPT tends to forecast more intense precipitation but does not address the issue of the localisation of the structures. Conclusions from these runs were drawn, by noticing that for the two cases the 2.8 km ensemble is able to provide scenarios different from the deterministic run, with few good members. The error in the localisation of the rainfall pattern is addressed by some model perturbations, but initial and boundary conditions seem to play a major role. Finally, SPPT-perturbed runs have a tendency towards more intense precipitation.

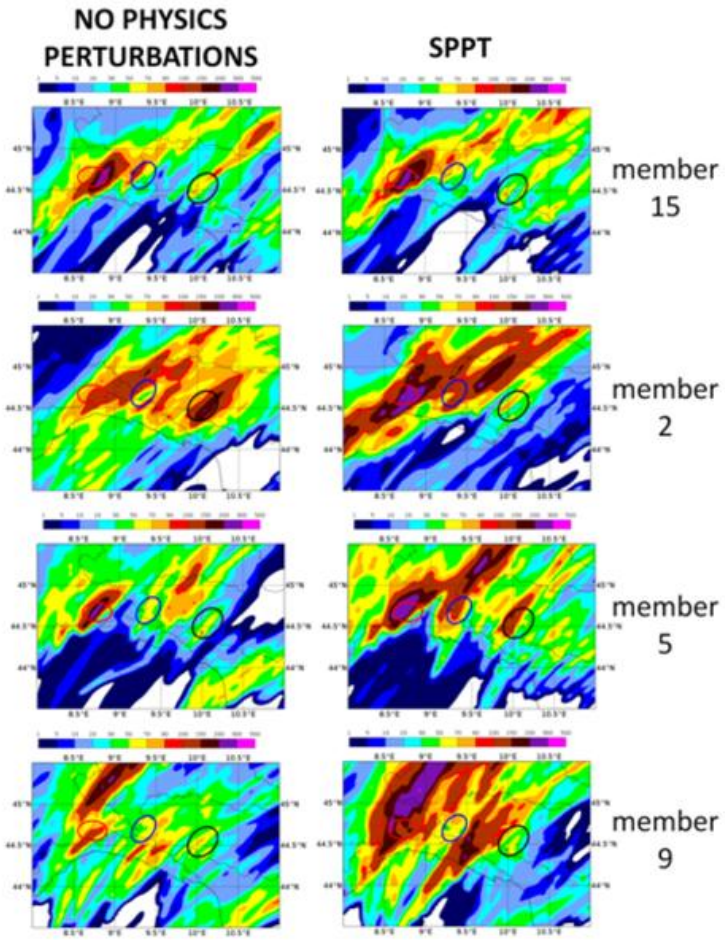

Figure 20: Precipitation forecasted by 4 members of the downscaling (left column) and SPPT (right column) ensembles, accumulated over 24 hours on the the 13th of October.

3.2 Test of the SKEB scheme in the 2.2 km ensemble at MCH

SKEB has not been further tested in COSMO, since the code is far from being ready for operational use due to performance issues. On the other hand, the generated perturbations are similar to those of the random pattern generator developed by RHM which has been implemented in COSMO with no performance problems. Hence, further work in this direction should preferably use this random pattern generator.

3.3 Information about improvements and a new strategy for model perturbations at DWD

At DWD, the research in model perturbations has been focussed on two aspects. On the one hand, the operationally used approach of fixed, non-stochastic perturbations of physics parameters has been extended and methodical modifications have been tested. On the other hand a prototype of a new model perturbation strategy with stochastic components has been developed and tested (model for the model error). The current set-up has been improved by including more parameters in the perturbation set up, i.e. the perturbation of minimum diffusion coefficients for heat and momentum has been added in the operational set-up in January 2014. Moreover, successful tests have been carried out for more perturbed parameters which have been selected with special focus on renewable energy applications. In general, adding more perturbed parameters led to a slight increase in ensemble spread with neutral or slightly positive impact on the root mean squared error of the ensemble mean. As a further methodical modification, which additionally helps to effectively perturb more parameters, a randomized selection of the perturbed values has been developed and first tests have been carried out. While there are still 2 -3 pre-defined different values for the parameters to be perturbed, there is a random approach how these perturbations are distributed within the 20 members. Under the condition that each parameter is perturbed in 50% of the members, a random selection of members which are actually perturbed is done for each parameter at each forecast start time. The selected perturbations stay fixed over the forecast range. Thus, the new method is not stochastic with respect to parameter values but used to distribute pre-defined values effectively among members and the EPS differs in this respect between forecast starts. Again, an increase of spread without degradation of skill (RMSE) has been observed. These refinements of the method became operational in November 2016. The research, which is intended to lead to a new perturbation strategy in upcoming years, is based on the assumption, that the temporal evolution of the model error itself can be described by an equation taking into account temporal and spatial coherence and a white noise stochastic component. The parameters of this model for the model error are estimated from past data and are considered to be weather-dependent. A prototype of this method has been implemented, tested and refined. Considerable resources will be denoted to further research on scientific and technical issues of this new strategy during the next years with the aim of operational implementation. Information on the advances concerning model perturbations has been provided to COSMO at the General Meetings and during the WG7 Meetings.

4 Soil/surface perturbations

The sensitivity of moist atmospheric processes to soil conditions has been demonstrated in numerous studies (Hacker 2010 and references therein). Although the physical representation of soil moisture in land surface schemes is known to have an influence on the quality of atmospheric predictions, the parametrization of the processes of soil moisture physics is not straightforward and the uncertainty in the parameters are little researched (Cloke et al, 2012). Some techniques have been proposed in the recent years: Cloke et al (2012) proposes a simple method, perturbation of 2 soil scheme parameters, in the ECMWF seasonal forecasting system; Sutton et al (2006) studied the impact of using two different soil moisture fields, estimated by 2 different LSM but with the same data and atmospheric forcing, showing that short-term precipitation is sensitive to the soil moisture, especially for a high-resolution run; a non-cycling surface breeding method has been proposed by Wang et al (2010), where short-range surface forecasts driven by perturbed atmospheric forcing are used for generating the

perturbation to surface ICs. A simple method is applied by Hacker (2010), who constructs perturbations of the soil moisture field that represent random, spatial correlated errors, to quantify the response to soil moisture perturbations. He recognises that this method is not suited for reproducing the characteristics of the actual soil moisture uncertainty, which varies locally with the properties of the soil, vegetation and background moisture itself (Hacker, 2010). In order to partly account for soil moisture uncertainty, in the COSMO PP CONSENS a methodology for soil moisture perturbation based on Sutton and Hamill (2004) was developed by HNMS (COSMO Technical Report No. 22). The method was never tested in ensemble mode but it could be revived and tested on the new ensembles under development. Other methods can be tested, among those available in literature, or proposed, according to the need of the COSMO countries and on the available resources. At DWD a simple method was developed to derive initial condition soil moisture perturbations from differences between COSMO-EU und COSMO-DE soil moisture. A long period test is now planned. Within the COTEKINO PP, work on soil/surface perturbation has been carried out at IMWG and at Arpa Piemonte. First a sensitivity study have been carried out, indicating a great sensitivity of COSMO run at 2.8 km to the soil conditions, in particular soil moisture and few TERRA parameters. Secondly, a scientific investigation of the possible strategies to be followed has been performed, including literature review and assessment of the more suitable methods. Then, techniques for lower boundary perturbation have been developed in the two Centres and have been implemented on selected cases. This work is described in detail in the following subsections.

4.1 IMGW

4.1.1 Preliminary sensitivity tests

The first part of this work focused on the test of different set-ups (configurations), in terms of parameters and methods. Shallow convection scheme was chosen as a basic (and invariant) setup to subsequent studies, because of the grid resolution used in the simulations (convection-permitting). As it was described in the previous work (Duniec and Mazur 2014), the other physical parametrizations and numerical schemes selected for the test were as follows (see also Schättler et al. 2016, for details):

- The various formulations of the advection:
  - Leapfrog: 3-timelevel HE-VI (Horizontally Explicit - Vertically Implicit) Integration. This scheme is used as default in Poland for the 7km resolution operational model, as well as for COSMO-EU at DWD
  - Runge - Kutta: 2-timelevel HE-VI Integration (irunge_kutta=1). This scheme is used in COSMO-DE
  - Runge - Kutta: 2-timelevel HE-VI Integration (irunge_kutta=2) - variant scheme with Total Variation Diminishing
- Vertical turbulent diffusion:
  - 1-D diagnostic closure (used in combination with leapfrog scheme only)
  - 1-D TKE-based diagnostic closure (used in COSMO-EU and in COSMO-DE)
- Type of parametrization for transpiration by vegetation:
  - Bucket version

– BATS version

All the above gives a total of 9 basic (reference) set-ups. Then soil-related parameters to be evaluated in the sensitivity test were chosen as follows:

- c_soil (with relation to c_lnd) - surface-area index of evaporating fraction from 0 to c_lnd (surface-area index of gridpoints over land, default 1.0),
- crsmin - minimum value of stomatal resistance (used in connection with BATS version only) from 50 to 200 (default 150.0),
- pat_len - length scale of subscale surface parameters over land from 0 to 10000 (default 500 m)

all the above are in the TUNING namelist. In addition:

- cz_bot_w_so - depth of bottom of last hydrological active soil layer, from 0.0 to last soil level depth (default 2.0 meters), in the PHYCTL namelist.

The general assumption for the preliminary assessment was to choose three to four values from a given parameter range, including minimum and maximum ones. Output fields selected for comparison were:

- Soil - soil temperature at 0 cm down (surface temp.).
- T2m - air temperature at 2m above ground level.
- Water - water + ice content of soil layers 1cm down the surface.
- U10m - zonal wind component, 10m above ground level.
- V10m - meridional wind component, 10m above ground level.

Statistical characteristics selected for the sensitivity analysis are here listed included the standard scores (BIAS, RMSE) as well as other measures here listed:

- the point-to-point difference field with centre of mass of field of differences is defined in Eq. 1 t_x being the value of the field at point r_x, average difference and RMS of difference (over entire domain)
- the maximum difference of values (MDV) defined in Eq. 2 where r and c are reference and changes, respectively
- the normalized difference of values NDV (Eq. 3) with $< T_x >$ defined in Eq. 4
- the R (Pearson) correlation coefficient (over entire domain) defined in Eq. 5

$$\overrightarrow{r_d} = \frac{\sum_{\overrightarrow{r_x}} t_x \cdot \overrightarrow{r_x}}{\sum_{\overrightarrow{r_x}} t_x} \tag{1}$$

$$MDV = max[|t_r(i,j) - t_c(i,j)|] \cdot sign[t_r(i,j) - t_c(i,j)] \tag{2}$$

$$NDV = \frac{\langle T_c \rangle - \langle T_r \rangle}{\langle T_r \rangle} \cdot 100\% \tag{3}$$

$$\langle T_x \rangle = \frac{\sum_{i=1}^{i_{max}} \sum_{i=j}^{j_{max}} t_x(i,j)}{i_{max} \cdot j_{max}} \tag{4}$$

$$R = \frac{\sum_{i=1}^{i_{max}} \sum_{j=1}^{j_{max}} (t_c(i,j) - \langle T_c \rangle) \cdot (t_r(i,j) - \langle T_r \rangle)}{\sqrt{\sum_{i=1}^{i_{max}} \sum_{i=j}^{j_{max}} (t_c(i,j) - \langle T_c \rangle)^2} \sqrt{\sum_{i=1}^{i_{max}} \sum_{j=1}^{j_{max}} (t_r(i,j) - \langle T_r \rangle)^2}} \tag{5}$$

As a case study basis eleven different synoptic situations were chosen (for Poland area); six of them were tested also in the framework of the COLOBOC Priority Project, and five new ones:

- 2009.02.01 (00 UTC) - low temperature, the ground was frozen solid
- 2009.02.22 (12 UTC) - sunny/fair day
- 2009.10.16 (00 UTC, 06 UTC) - ground covered with snow
- 2009.11.04 (12 UTC) - windy day with precipitation
- 2009.11.21 (06 UTC) - foggy day
- 2012.02.03 (00 UTC) - very cold day with air temperature below -20°C, ground frozen solid after two weeks of low air temperatures
- 2012.05.18 (00 UTC) - sunny/fair day, ground temperatures below 0°C
- 2012.07.01 (00 UTC) - sunny/fair/hot day
- 2012.12.14 (12 UTC) - again, very cold day with air temperature below -10°C
- 2012.12.16 (12 UTC) - right after previous, some warming in the air (higher temperature)

As a consequence of the results of these tests, the following conclusions were drawn (Duniec and Mazur, *ibidem*):

- No significant differences (sensitivities) with changes ofnumerical schemes (HE-VI, RK1 and/or RK2) were observed. Therefore, authors suggested to focus in the subsequent work on the COSMO operational configuration (i.e., 3-order standard Runge-Kutta scheme, 2-timelevel HE-VI integration)
- cz_bot_w_so has a noteworthy impact on values of water and ice content down to 1458 cm below ground level
- Parameter c_soil has a noteworthy impact on values of air temperature at 2m, dew point temperature and relative humidity at 2m, wind speed and direction at 10m and surface specific humidity
- For the other parameters no significant impact of the tested values against the reference ones was found.

Consequently, extended sensitivity tests were carried out with the following assumptions:

- CP-scale and model resolution forced the use of shallow convection scheme
- 3-order standard Runge-Kutta scheme was selected as a basic numerical scheme
- Different synoptic situations, i.e. the eleven cases listed above, were used to establish a relation between the stochastic variation of c_soil/cz_bot_w_so parameters and the skill of the ensemble members

The following figures (Figs. 21-28) show selected results from the sensitivity tests. Results are described in terms of the spatial distribution of the "spread" - i.e. standard deviation of the ensemble members vs. control (deterministic) run - for the selected parameter and presented as the "spread" (from left to right) of temperature (a), dew point (b), wind speed (c) and precipitation (d).

- c_soil sensitivity test results:

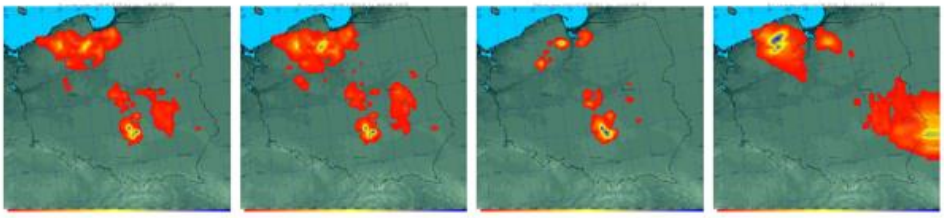

Figure 21: Winter case (December 14th, 2012). a, b, c, d from left to right respectively.

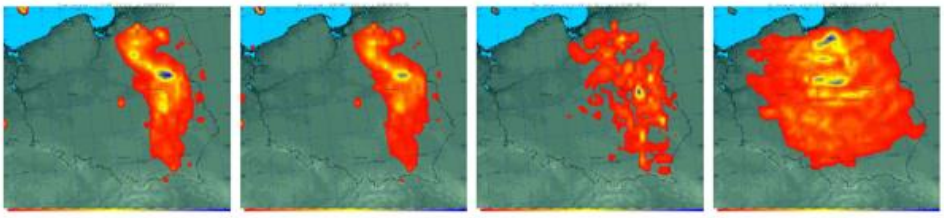

Figure 22: Spring case (February 22nd, 2009). a, b, c, d from left to right respectively.

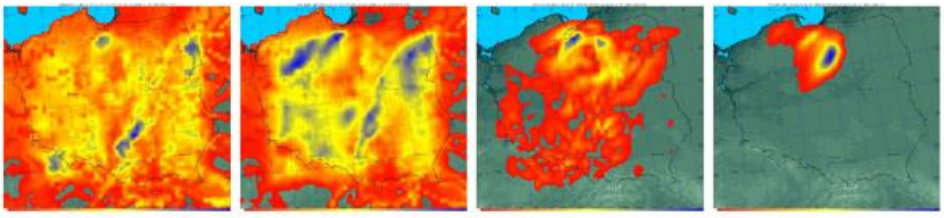

Figure 23: Summer case (July 1st, 2012). a, b, c, d from left to right respectively.

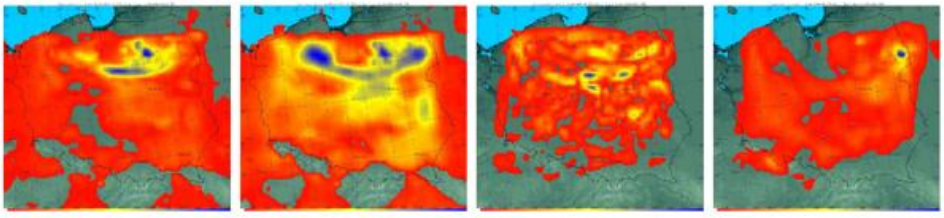

Figure 24: Autumn case (October 16th, 2009). a, b, c, d from left to right respectively.

- cz_bot_w_so sensitivity test results:

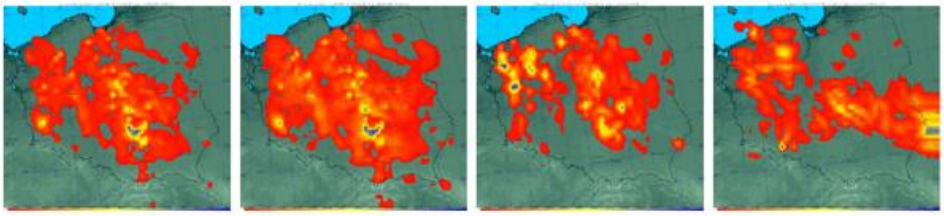

Figure 25: Winter case (December 14th, 2012). a, b, c, d from left to right respectively.

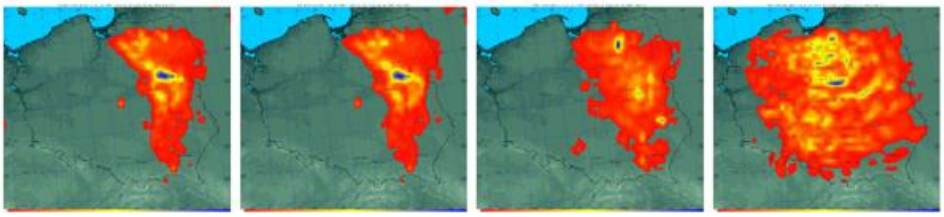

Figure 26: Spring case (February 22nd, 2009). a, b, c, d from left to right respectively.

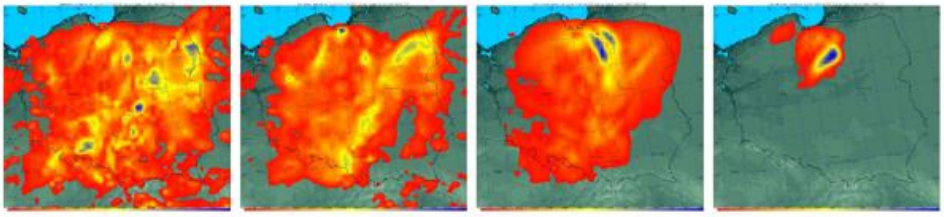

Figure 27: Summer case (July 1st, 2012). a, b, c, d from left to right respectively.

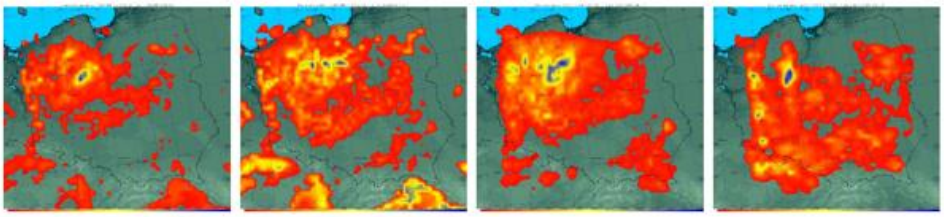

Figure 28: Autumn case (October 16th, 2009). a, b, c, d from left to right respectively.

It should be stressed that changes of cz_bot_w_so had a noteworthy impact on values of "deep soil" parameters, like water/ice and water content, temperature of soil layers down to 1458 cm (not shown). This influence varied from 10 to 25 percent of original (reference) value, and seemed to enlarge with increase of cz_bot_w_so. Impact on values of lower-atmosphere parameters like air temperature, dew point, precipitation amount or wind speed is regarded as negligible. Moreover, this parameter - which is of integer type, from 1 to 7 - seemed to be not very useful for the preparation of an ensemble. On the opposite, changes of c_soil seem to induce significant changes of values of air temperature, dew point temperature and relative humidity at 2m, wind speed/direction at 10m and surface specific humidity forecast against reference ones. Being a floating-point number it may be equal to any value in its range of variability (ie. from 0 to 2.0), so c_soil is (potentially) a much better candidate as a perturbation for an ensemble. Thus, all selected cases were studied in detail regarding changes of c_soil parameter (Mazur and Duniec, 2014a). The maximum "spread" (standard deviation of values against reference one) - is as big as 2°C(for temperature or dew point)

or 1.5 m/s (for wind-speed). Mean difference (over the entire domain) between maximum and minimum values was about 0.1°Cand 0.07 m/s, respectively. This order of changes pertained mostly to "warm" cases (late spring, summer, early fall), since the soil is at this time much more "subtle" to "stimuli" from a boundary layer. Thus, all the changes seemed to be much more visible during the warm season as above defined. Impact on values of soil parameters like water/ice and water content, or soil layers temperature is rather irrelevant. In the framework of the COTEKINO Priority Project it was planned to study the possibility to prepare a suitable ensemble in two different ways. The first one was a random setting of the value of c_soil globally and uniformly over the entire domain, which is easier to perform with no need for modification of the source code. The second approach proposed was a more "stochastic" one, consisting of a modification of the source code to perturb the values of c_soil from gridpoint to gridpoint over the domain in a random way. Subsequent activities were focused to build ensemble(s) in both ways and to compare results of these approaches. Having results of this approach as a first step (see Duniec and Mazur, 2014; Mazur and Duniec, 2014b), in the second phase further sensitivity tests were performed. This allowed for detailed selection of various configurations and for assessing methods of perturbation of important soil parameters.

4.1.2 Extensive test-cases and sensitivity tests

Effective ensemble members could be prepared using two methods:

- Set a unique random value of c_soil, globally on the whole domain. Easier to perform, by changing the namelists instead of modifying the model code
- An alternative approach - distribute the random values of the c_soil from point to point over the entire model domain by modifying the source code

The results are described in terms of spatial distribution of forecast "spread" - i.e. the standard deviation against mean value. As a case study basis, eleven events were chosen, covering four season and a diversity of synoptic situations. In Figs. 29 and 30 results of an application of the above mentioned point-to-point method for preparation of an ensemble, are presented.

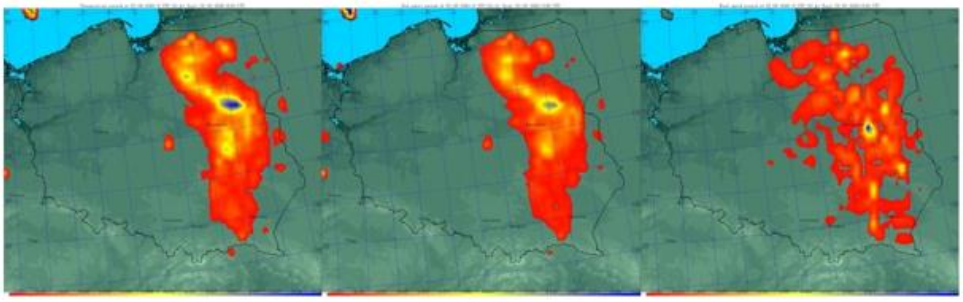

Figure 29: Spread of selected meteorological field from a c_soil based ensemble; winter case (February 22nd, 2009). Temperature (left), max spread value - 0.2°C, dew point temperature (middle), max spread value - 0.2°C, wind speed (right), max spread value - 0.1m/s.

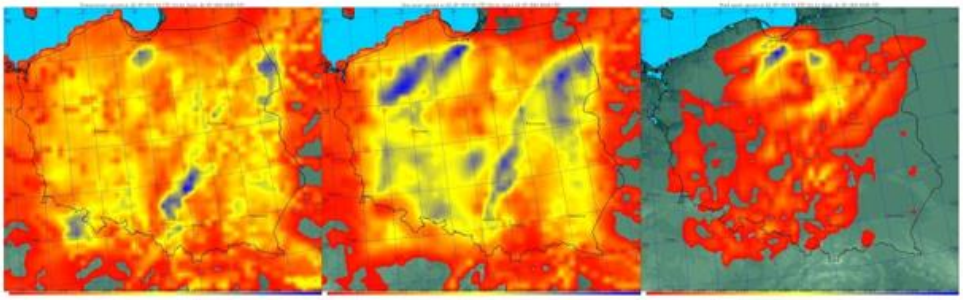

Figure 30: Spread of selected meteorological field over a c_soil based ensemble; summer case (July 1st, 2012). Temperature (left), max spread value - 0.7°C, dew point temperature (middle), max spread value - 0.9°C, wind speed (right), max spread value - 1.0m/s.

In Figs. 31-36 results of the comparison of ensemble forecasts with measurements at meteorological stations (seashore station Leba, midland station in Warsaw and Poznan, and the mountain station Zakopane) are shown for selected (winter and summer) cases.

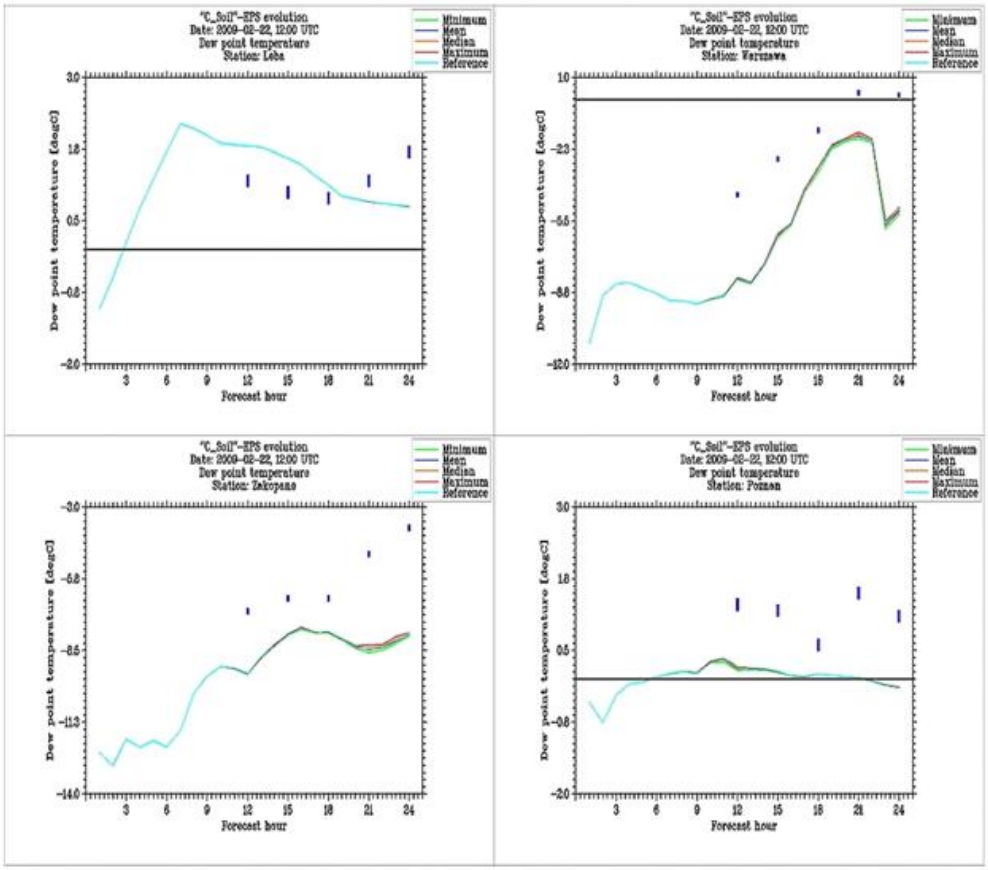

Figure 31: Ensemble forecast with c_soil, for the winter case, February 22nd, 2009. "Spaghetti-plots" against values measured at meteorological stations (vertical bars). Dew point temperature forecast at the following stations: upper left - Leba, upper right - Warsaw, lower left - Poznan , lower right - Zakopane.

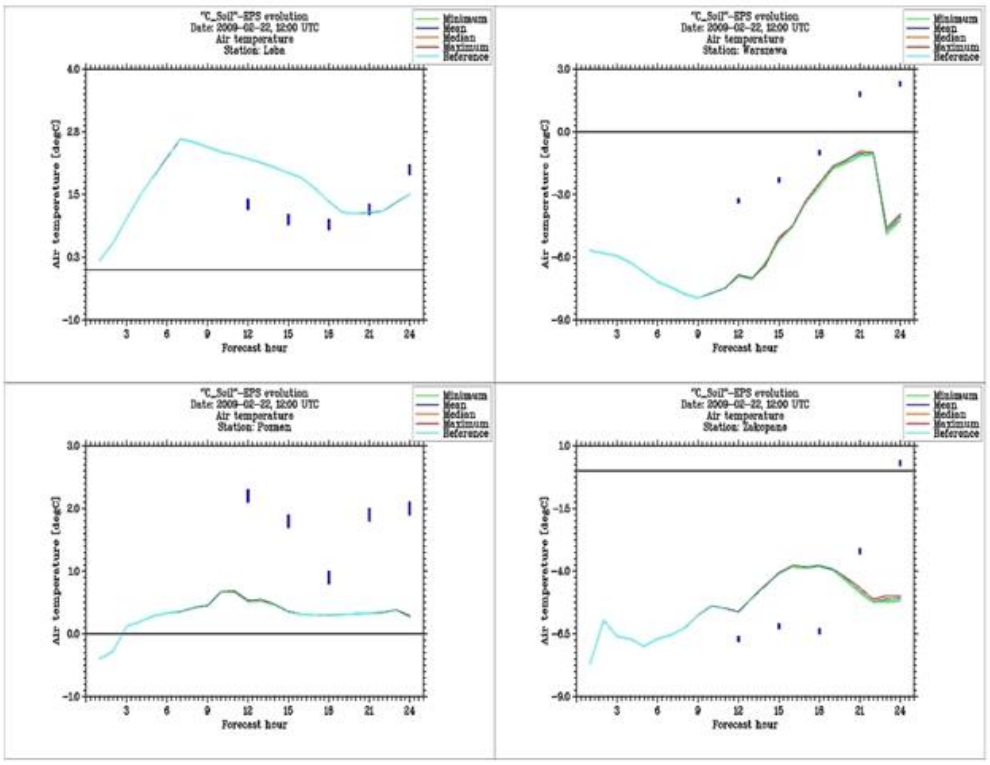

Figure 32: As above, but for air temperature forecast.

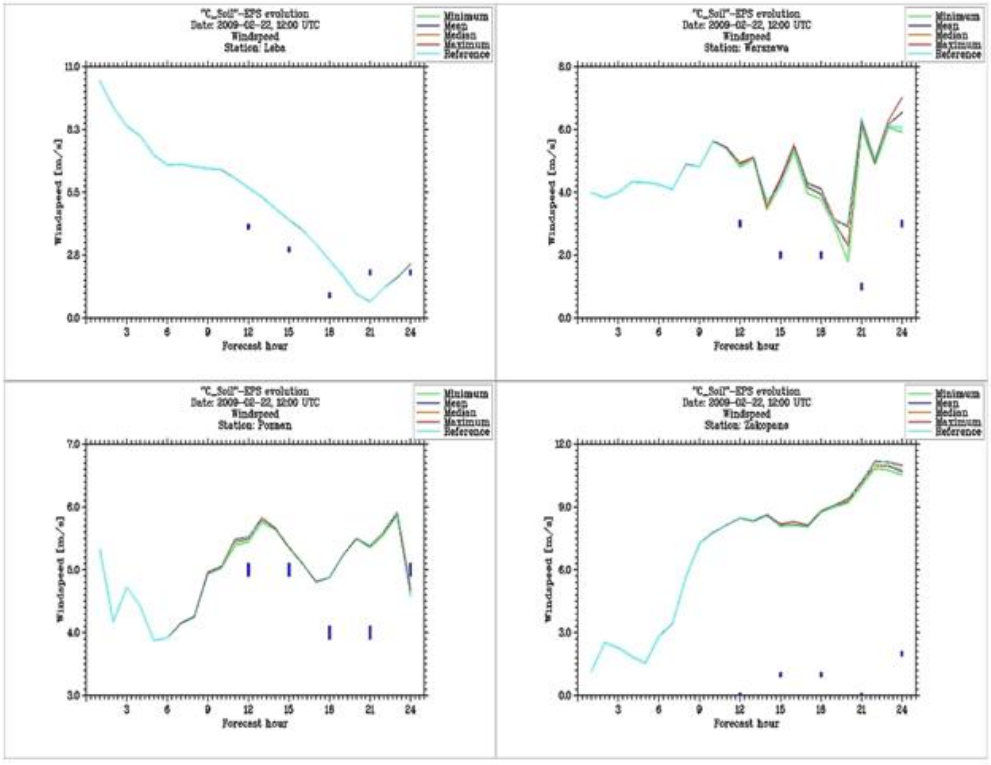

Figure 33: As above, but for wind speed forecast.

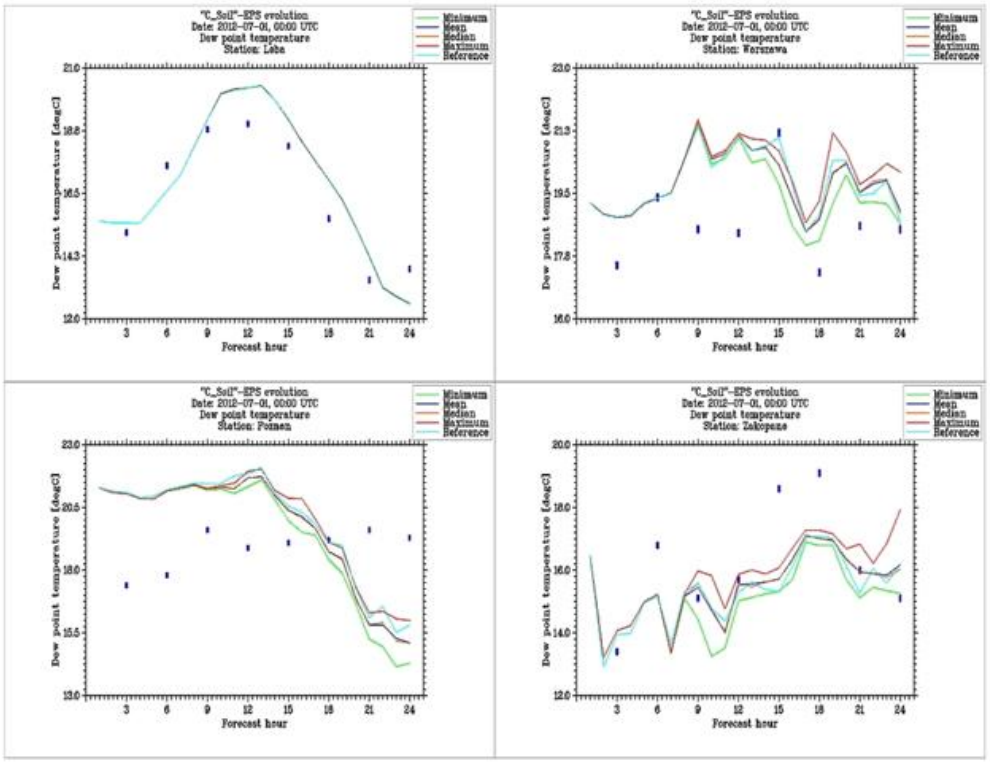

Figure 34: Ensemble forecast with c_soil, summer case, July 1st, 2012. "Spaghetti-plots" against values measured at meteorological stations. Dew point forecast at stations: upper left - Leba, upper right - Warsaw, lower left - Poznan, lower right - Zakopane.

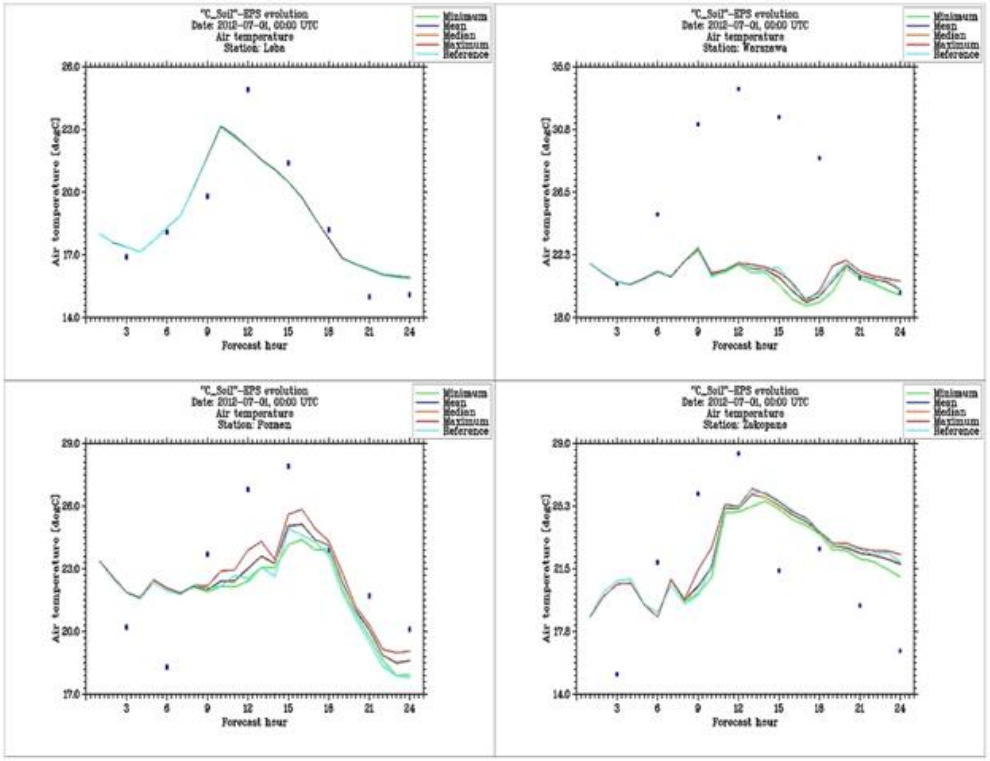

Figure 35: As above, but for air temperature forecast.

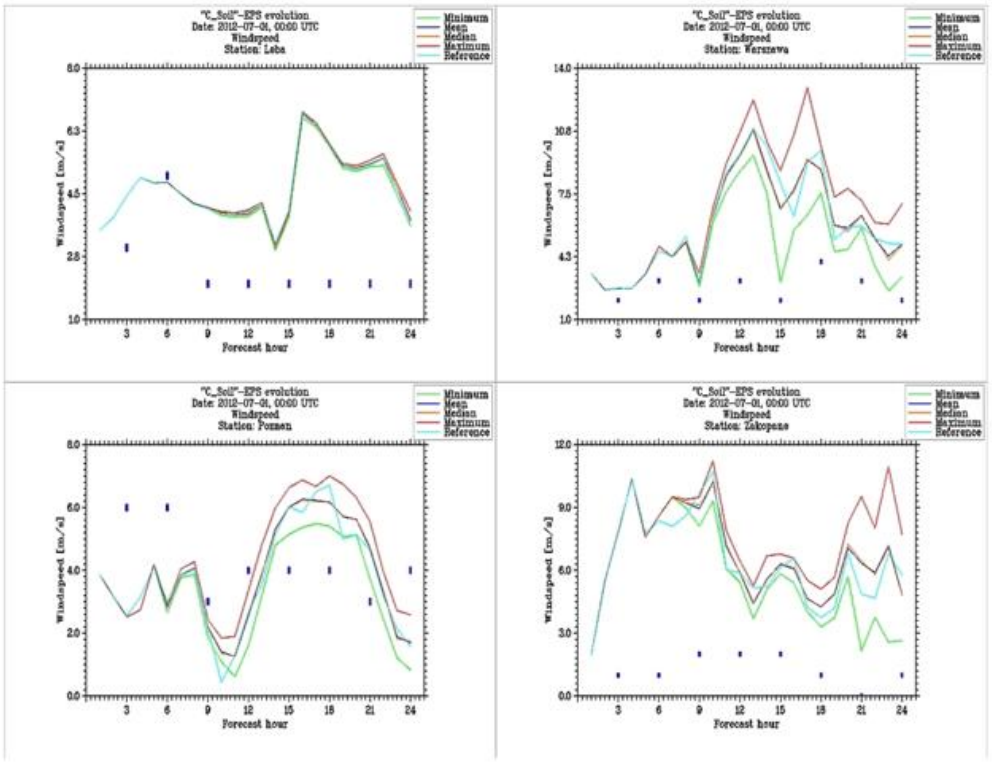

Figure 36: As above, but for wind speed forecast.

The next part of this study was to combine changes in the soil processes parametrization (Duniec and Mazur, 2014, developed by IMGW in the framework of WG3b activities) with the preparation of soil-based ensemble forecasts. After replacing the Dickinson equation with the temperature-dependent Darcy equation (see the above mentioned paper for detailed explanation), further improvements in forecasts can be seen. A quantitative effect of two different soil processes parametrization on a forecast quality was shown in Figs. 37-38. A comparison of these two forecasts was carried out by computation of a "distance" of a real value, measured at SYNOP stations, from an interval defined by the forecast spread, computed as the difference between minimum and maximum values over the ensemble. If the measured value was located inside the interval, this "distance" was identified as equal to zero. In the figures areas with "warm" colours (from yellow to red) represent an improvement of forecast (i.e., decrease of the "distance" of forecast spread from real values) caused by change of parametrization, whereas areas with "cold" colours (from blue to green) - represent a decrease of the forecast accuracy, both measured in [°C] in case of air temperature/dew point temperature, or [m/s] in case of wind speed. An overall improvement, defined by the sum of these "distances" calculated for all SYNOP stations and for every considered element, is presented in the Table 3.

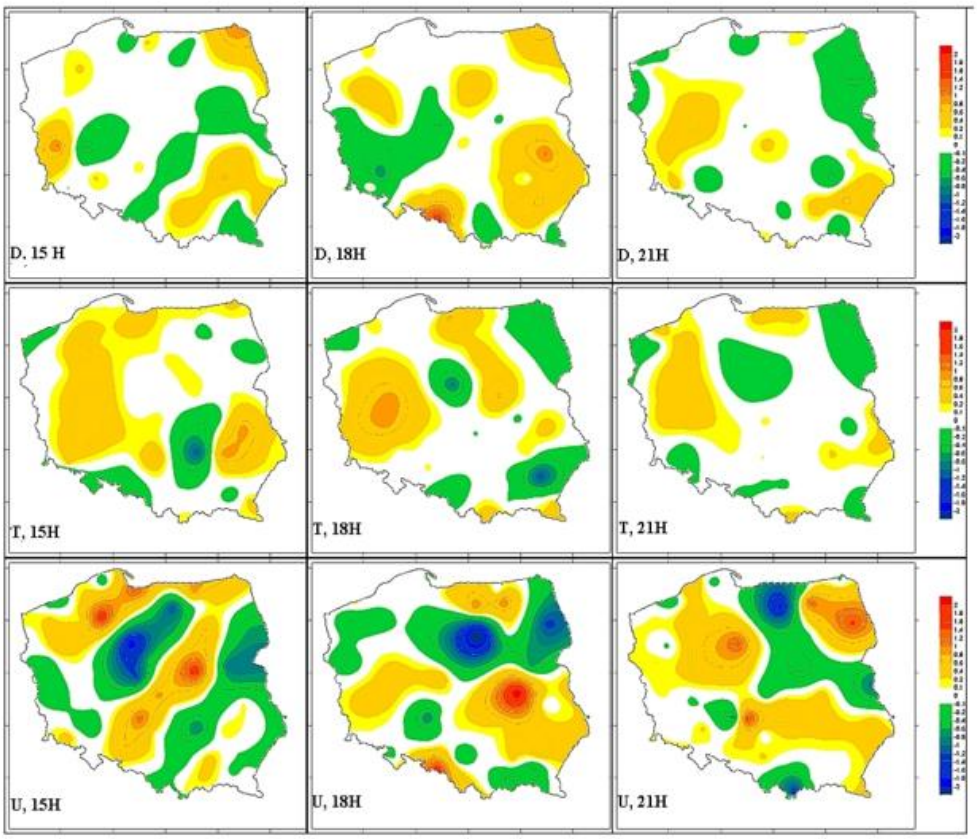

Figure 37: Comparison of "regular" c_soil-based ensemble forecast with the one combined with altered soil processes parametrization. Summer case, July 1st, 2012. Upper row - prediction of dew point temperature for 15th, 18th, and 21st hour of forecast, middle row - temperature forecast. lower row - wind speed forecast, similarly. Areas with "warm" colours represent improvement of forecast, areas with "cold" colours - worsening of forecast (see further explanation in text) due to change of soil processes parametrization. Scale units: °C in case of air temperature or of dew point temperature, or m/s in case of wind speed, all from -2.0 to 2.0.

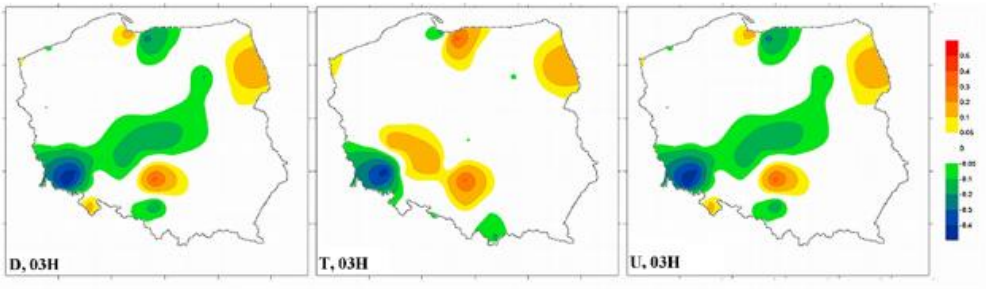

Figure 38: Comparison of "regular" c_soil-based ensemble forecast with the one combined with altered soil processes parametrization. Summer case, July 1st, 2012. Prediction of dew point temperature, air temperature and wind speed (from left to right) for 3rd hour of forecast. Areas with "warm" colours represent improvement of forecast, areas with "cold" colours - worsening of forecast due to change of soil processes parametrization. Scale units: °C in case of air temperature or of dew point temperature, or m/s in case of wind speed, all from -0.5 to 0.5.

It should also be stated, however, that this improvement can hardly be seen in the beginning of the forecast(s). It seems that the soil parametrization need some "spin-up" time to have a significant impact on the quality of an ensemble forecast of the atmospheric state.

hour of forecast	dew point (°C)	air temperature (°C)	wind speed (m/s)
3	-0.152	-0.071	-0.150
6	0.036	0.149	-0.201
9	-0.013	-0.181	0.143
12	-0.168	0.154	-0.115
15	1.714	4.205	2.016
18	4.701	2.460	1.720
21	1.103	1.969	2.751

Table 3: Indicator of overall improvement/worsening due to combination of ensemble preparations with changes of soil processes parametrization (for details see explanations in text).

In case of dew point and air temperature, significant improvement can be especially seen in the western, north-western and south-eastern part of Poland. In case of wind speed forecasts, the "area of improvement" was moving with forecast hour, in general, from west to east. This could be related to distribution of soil types (mainly areas with sand and loam) in Poland as adopted in the COSMO model (see Doms et al., 2011). Tests proved that small perturbations of selected parameter(s) were sufficient to induce significant changes in the forecast of the state of the atmosphere and to provide valid members in the ensemble. However, perturbations have had almost negligible impact in the areas with land fraction much less than one and during the cold season (perhaps due to the specific soil conditions, e.g. frozen ground). A detailed (seasonal/annual) performance analysis is needed for stochastic forecasts. Comparison of ensemble forecasts with observations at meteorological stations showed that, as in the case of deterministic forecasts, introduction of altered soil processes parametrization slightly improved the forecasts, mainly in the central/southern part of Poland, rather than closer to the sea or in mountain regions. All the results obtained from the tests allow to set-up an operationally running EPS at IMGW.

4.1.3 Test-bed and configuration for (quasi-)operational EPS, concept of time-lagged ICs/BCs

The first approach followed to establish an operational configuration has been carried out with BCs/ICs from COSMO-LEPS. Results were satisfactory from the point of view of the quality (i.e. skill) of the forecasts vs observations, however, time needed to prepare an operational forecast turned out to be unacceptably long, taking into account the downloading and pre-processing of BCs/ICs for the needs of EPS at IMGW. Thus, the idea of time-lagged initial and boundary conditions woke up. An explanation of the concept is presented below. At IMGW-NRI, the COSMO model runs in a deterministic mode using initial (IC) and boundary (BC) conditions from the ICON global model (previously from GME), as shown in Fig. 39. The non-hydrostatic ICON model runs at DWD using an icosahedral-hexagonal grid, with the highest spatial resolution over Europe equal to 13 km and a time span of at least 78 hours, four times per day. The ICON generates a set of IC/BCs for COSMO mesoscale model runs with a basic spatial resolution of 7 km and the domain covering the central part of Europe. This generates 78-hour forecasts. The COSMO model with 7 km horizontal resolution (COSMO-7 km) applies nudging-based data assimilation to correct global model forecasts, ingesting the most recent set of meteorological data acquired from the GTS/WMO network. Forecast results from the COSMO-7 km are further used as IC/BCs for a nested instance of a COSMO model with a higher resolution of 2.8 km and 36-hour forecasts. A set of the deterministic COSMO-2.8 km forecasts define the basis for the operational configuration

Model	Resolution min. (km)	Grid size (NxMxL)	Forecast length (h)
ICON (DWD, former: GME)	13	2949120 triangles	78
COSMO v5.01	7	415x460x40	36
COSMO v5.01	2.8	380x405x50	36

Table 4: Details of the configuration of deterministic models, status for year 2017.

of an ensemble forecasting system. More details of the configuration of deterministic models that run operationally at IMGW-NRI are presented in Table 4.

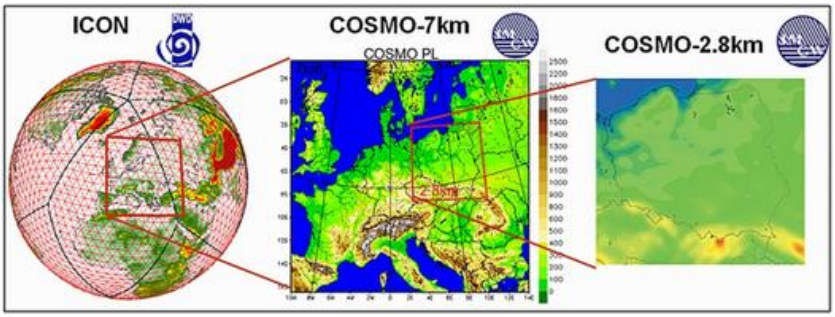

Figure 39: Operational configuration of deterministic COSMO-7 km model and 2.8 km resolution EPS runs at IMGW-NRI. From left to right - domain of ICON global model, domain of COSMO-7 km model running at IMGW-NRI, and a set of nested COSMO-2.8 km domains, forming a 20-members EPS.

In the recently developed EPS configuration, twenty ensemble members are run, based on the COSMO-2.8 km convection permitting (CP) forecasts. Every member of the ensemble applies perturbed lower boundary conditions, composed of a random noise of a specified amplitude added to perturbation of a parameter of the soil-model physical parametrization. The proper collection of adequate initial and boundary conditions (IC/BC) is a crucial issue. In the basic EPS configuration, the whole set of IC/BC was obtained from a single 78-hour deterministic run of the COSMO model with spatial resolution of 7 km. In order to increase the spread of the forecasts, we have further adopted the concept of time-lagged IC/BCs (see e.g. Lu et al., 2007; Chen et al., 2013), in which the set of deterministic CP forecasts is subdivided into groups starting at consecutive time windows: 00, 06, 12, and 18 UTC.

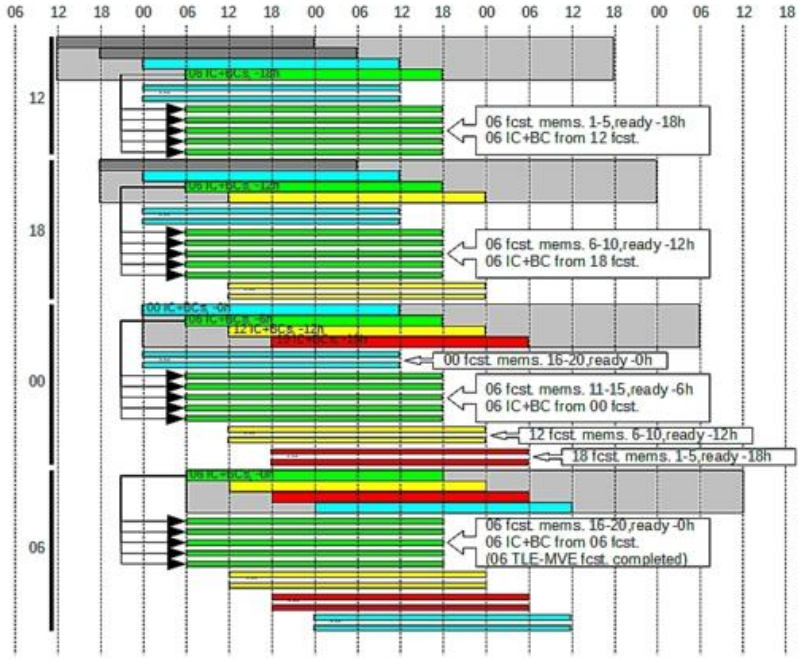

Figure 40: Operational setup of EPS based on Time-Lagged IC/BCs. X-axis - lead time (UTC), Y-axis - forecast individual initial time. The four different colours distinguish forecast nominal start time: blue - 00 UTC, green 06 UTC, yellow 12 UTC, and red 18 UTC.

In the final EPS configuration run operationally at IMGW-NRI, a set of twenty ensemble members is grouped into four bundles, each containing five elements as shown in Fig. 40. The uppermost group - members no. 01 to 05 - is finalized and ready for post-processing 18 hours before the nominal EPS start-up time in the current time window; the second group - members no. 06 to 10 - are gathered 12 hours before the current time window; the third group - members no. 11 to 15 - are prepared 6 hours before the current time window; and finally the lowermost group - members no. 16 to 20 - starts and is finalized in the current time window, completing the whole EPS forecast. The available forecast results (i.e., various meteorological fields) are ready for post-processing in order to provide selected statistics (ensemble mean, ensemble spread, probability of exceedance etc.) in graphical form, suitable for forecasting applications.

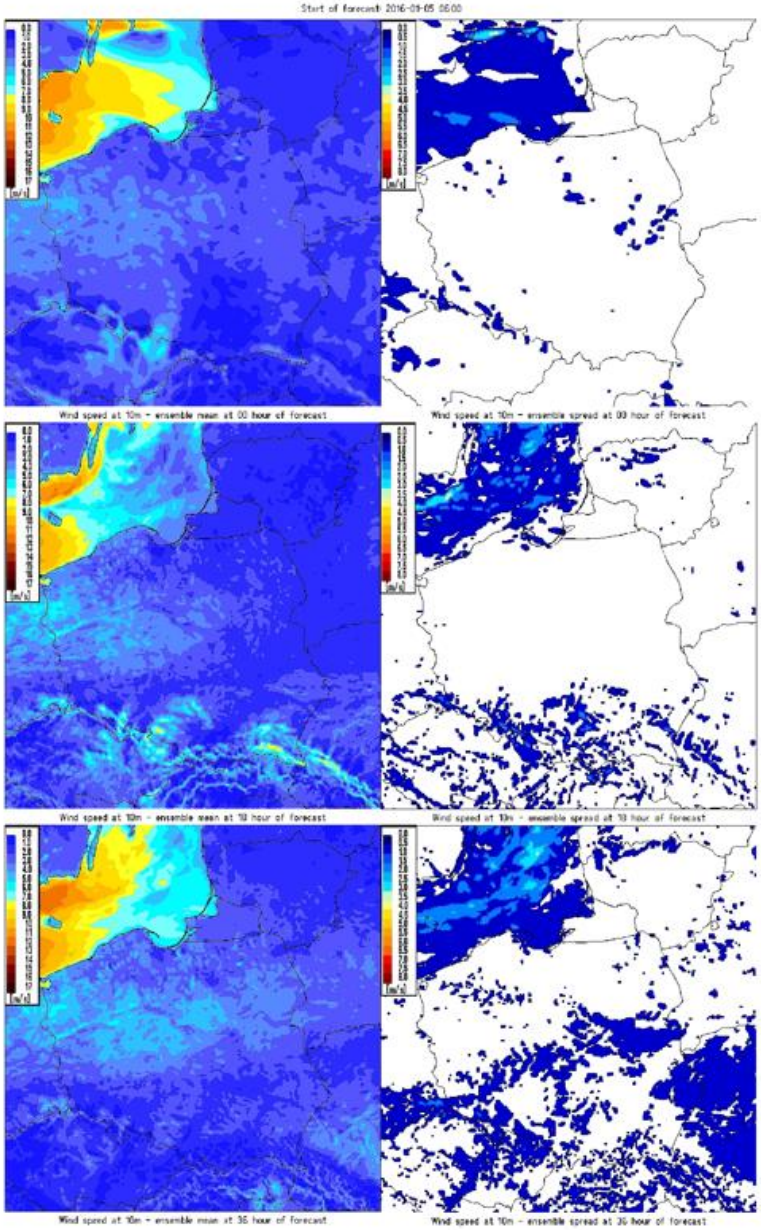

Figure 41: Ensemble mean (left) and ensemble spread (right) of wind speed at 10 m above ground level (m/s) at start (top), at 18th hour (middle) and at 36th hour (bottom) of forecast.

The EPS provides an estimate of the most probable and of alternative realisations of the event. The first two charts in Fig. 41 demonstrate examples of the ensemble mean and ensemble spread of selected meteorological fields (i.e., wind speed at 10 m above ground level). While ensemble spread has the general tendency for underestimation, it helps to objectively estimate the uncertainty of generated forecasts. The low values of the spread mean that forecasts converge toward a similar solution, leading to stronger anomalies. If the spread is large, the atmosphere is in a state where the small changes in the initial conditions may have a large effect on the forecast quality. In Fig. 42 an example of the probability of the exceedance of a selected threshold in the meteorological field is presented. This option is especially useful for calculating the probability of a predefined amount of precipitation (here: 1.5mm/3hours).

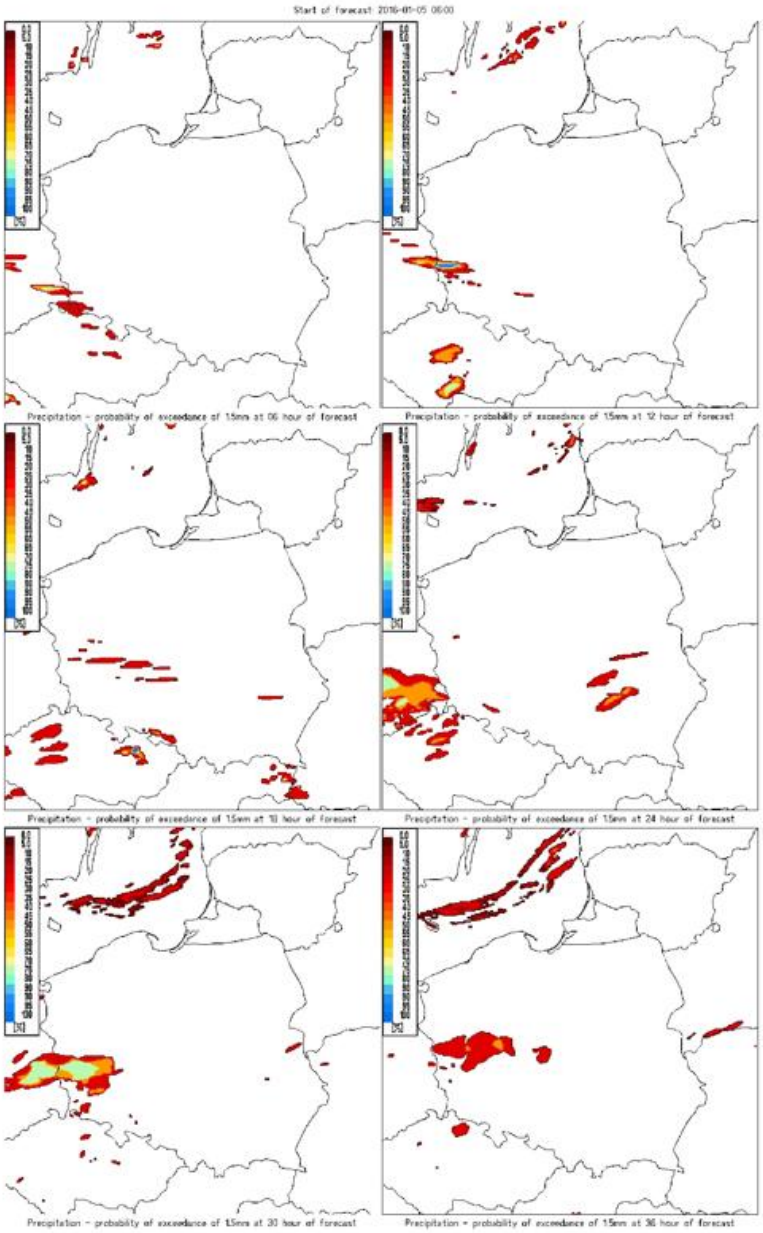

Figure 42: Probability (percentage) of exceedance of precipitation intensity of 1.5mm/3hours at 6th hour (top left), at 12th hour (top right), at 18th hour (mid. left), at 24th hour (mid. right), at 30th hour (bottom left) and at 36th hour (bottom right) of forecast.

In Fig. 43 an example of the so-called "spaghetti plots" is shown - the representation of a selected isopleth of a chosen meteorological field (here, the temperature at 2m above the ground) for every member in an ensemble. Since ensemble members generally diverge in time, these plots show many different model outputs. In the areas where the isopleth pattern is chaotic (i.e., resembling spaghetti) the confidence of the forecast is low. Spaghetti plots provide high confidence of a forecast in regions where members tend to coincide (i.e., contours follow a recognisable pattern through the sequence), and allows for identifying possible clustering of lines (e.g., bi-modal distributions). This particular chart shows an example of the amount of uncertainty in the forecast of air temperature. If there is a good agreement and the contours are close to one another (like in the presented case), then the confidence in the forecast can be high. The presented analysis (as the spread and other probabilistic statistics) derived from ensemble forecasts leads to an increase of confidence

in the forecast and may provide critical information that increases the awareness of a high impact event in advance.

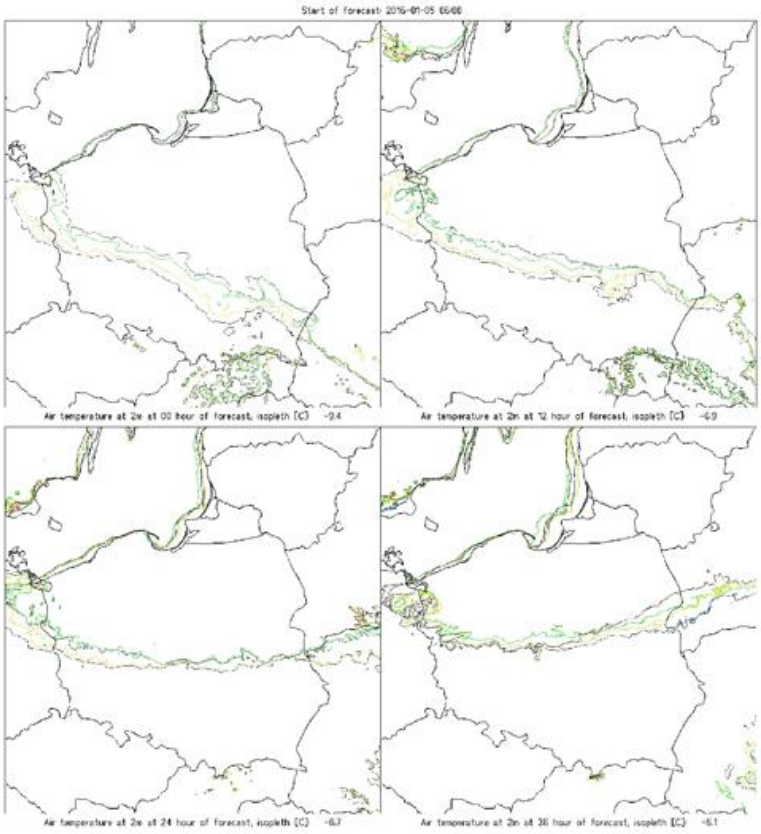

Figure 43: "Spaghetti plots" of air temperature (°C) at 2 m above ground level at the start (top left; isopleths -9.4°C), at the 12th hour (top right; -6.9°C), at the 18th hour (bottom left, -6.7°C) and at the 36th hour (bottom right; -6.1°C) of the forecast. Every coloured line represents the spatial distribution of isopleths for a single ensemble member.

The EPS results were compared with observations collected from 61 Polish SYNOP stations. In the following charts (Figs. 44-45) analysis of the model generated air temperature/dew point temperature forecast averaged for the whole day of 5-01-2016 are presented. In both cases, the EPS mean reproduces the main spatial features of the large-scale temperature distribution. The observed temperature is in a similar range (-20.7°C, -2.5°C) to the computed EPS mean (-20.8°C, -3.8°C).

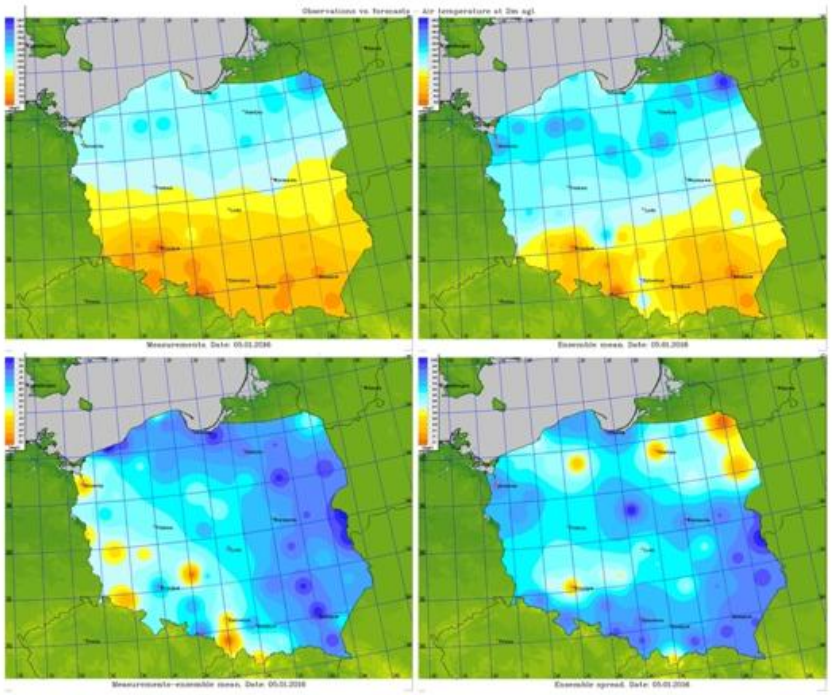

Figure 44: Comparison of the EPS derived temperature: ensemble mean (upper right), spread (lower right) with measurements (upper left), the absolute value of difference between measurement and ensemble mean (lower left).

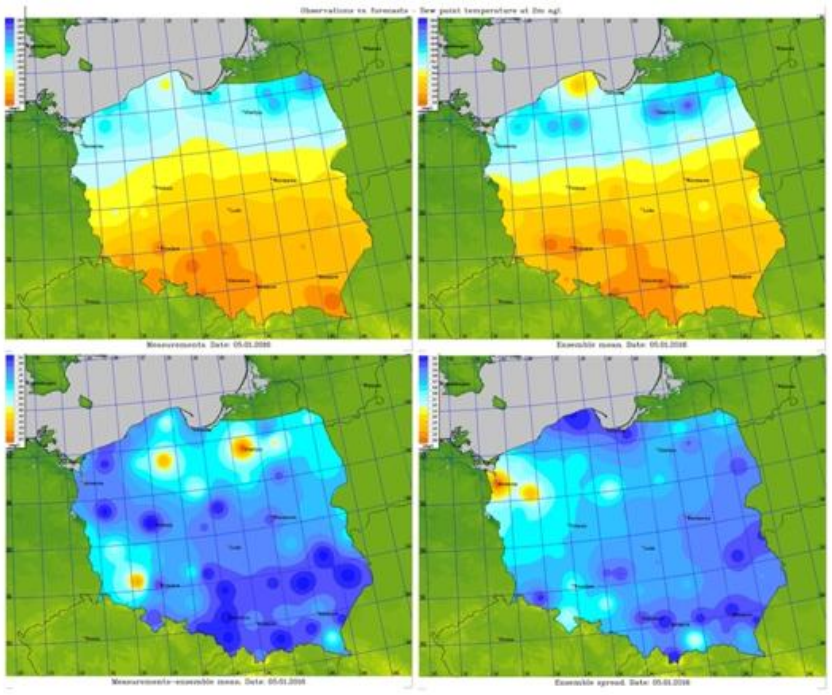

Figure 45: Same as Fig. 44 but for dew point temperature.

Similarly, the observed dew point temperature (Fig. 45) is in a similar range (-20.7°C, -2.0°C) than the EPS computed mean (-20.6°C, -1.6°C). In both cases, the model shows a bias when compared to observations with an absolute error of up to -6.1°Cfor temperature and -5.7°Cfor dew point temperature. For the temperature, larger error values (above 3°C) are well correlated with the air masses that came after the warm front crossing Poland during 5

January, 2016. Dew point temperature generally shows a small error - below 2°C- except in the north-eastern part of Poland, where we can observe a persistent lack of cloud coverage and in south-western areas, which may be correlated to a larger exceedance of precipitation intensity (see Fig. 42) that started in the afternoon hours of 5-01-2016 and developed further during the night and the morning hours of the following day. In summary, it should be stated, that our extensive tests conducted during the COTEKINO Priority Project proved that small perturbations of selected soil parameters were sufficient to induce significant changes in the forecast of the state of the atmosphere and to a provide valid members to the ensemble (Duniec and Mazur, 2014; Mazur and Duniec, 2014a). Changes of c_soil had a significant impact on values of air temperature, dew point temperature and relative humidity at 2m, wind speed/direction at 10m, and surface specific humidity (ibidem, see also Mazur and Duniec, 2015). The use of the concept of time-lagged initial and boundary conditions allowed us to obtain a valid ensemble and use it efficiently in an operational mode. Further work is intended to focus on "tuning" ensemble performance and to provide quantitative quality scores. For this purpose, a random number generator combined with perturbations of initial soil surface temperature and the dependence of the amplitude of perturbation on soil type will be implemented in the COSMO model. While the set of equally weighted time-lagged forecasts improves short-range forecasts, further progress may also be sought by adopting a regression approach to compute a set of weights for different time-lagged ensemble members. In this approach, the perturbation of the evaporating fraction in the soil has a significant impact on the forecast due to the increased stimulation of energy exchange between the surface and atmosphere. The maximum spread for the temperature is most likely of about 1.1°C, with increased value covering the entire northern and western parts of Poland. For the dew point temperature, we observe a higher spread of the amplitude up to 2.0°C, localized only in the north-western corner of the country. More advanced analysis of the EPS scores and of the correlation between EPS error and spread will be further provided in the context of specific applications. The examples of the probability of the occurrence of dry spells or of rainfall occurrence and distribution are both important in agriculture in assessing the influence of EPS forecasts on irrigation, crop growth or drought occurrence. For synoptic forecasters, the risk of the likelihood of a phenomena and its potential impact will have to be properly estimated to provide the objective basis for a decision to issue a warning. Overall, this phase of project task was focused on:

1. initiatory, quasi-operational implementation of EPS (BCs/ICs from a deterministic 7km runs of COSMO-PL)
2. Post-processing of results general charts/maps of mean/spread/max-min difference, spaghetti-charts of selected meteo elements
3. concept of time-lagged BCs/ICs - idea, technical aspects, details
4. time-lagged BCs/ICs - extended tests of the setup, case study results, quasi-operational implementation.

The work done in the framework of point 1 (and tests with ICs/BCs from COSMO-LEPS) has been presented at the COSMO User Seminars 2015. Further activities, related to points 2-3 have been presented at the COSMO General Meeting 2015, with particular emphasis on the comparison of the results of point 1 with those of points 3 and 4. A contribution has been also published in the COSMO Newsletters No. 14 and 15 as well as in the MHWM (Duniec and Mazur, 2014; Mazur and Duniec, 2015; Duniec et al., 2017).

4.2 ARPA Piemonte

The goal of this Task was to implement a soil perturbation technique in a high resolution ensemble system based on the Italian version of the limited area model COSMO at a resolution of 2.8 km taking into account soil surface uncertainties. To do this, we performed first a sensitivity test to assess the behaviour of the COSMO model to different lower boundary initial conditions. In fact, even if the sensitivity of the atmospheric moist processes to different soil condition initializations has been demonstrated in several studies, it cannot be generalized to a completely different modelling system. After that, we tried to find the best setting of a soil perturbation technique to be implemented in a high resolution ensemble system based on the Italian version of the limited area model COSMO at a resolution of 2.8 km taking into account soil surface uncertainties.

4.2.1 Sensitivity of COSMO model to different lower boundary initial conditions.

Different models with different spatial resolutions have been chosen to ensure a good variability among the soil moisture fields used to initialize COSMO model for the sensitivity test. A good variability in the ICs of soil moisture fields increases the chance to obtain a good spread among the ensemble members. The sensitivity test has been performed considering case studies taking into account summer and winter conditions, in order to evaluate the potential differences in sensitivity of the COSMO model in different seasons. For the model runs, COSMO model version 5.0 was used, with a horizontal resolution of 0.025 degrees (about 2.8 km), driven by ECMWF reanalysis at 0.125 degrees. The domain of integration is centered on Italy, with 45 vertical levels, 14 of which below 850 hPa. The variables that we opted to analyze for each case study to assess the changing spread due to different initializations were: 2 meters temperature and dew point, 10 meters wind speed (module), vertical velocity (w) at an altitude of about 1000 m, total precipitation, cloud cover, soil temperature and moisture. The spatial average of the spread for all the atmospheric and soil variables considered (Fig. 46), reveals a considerable spread increase for summer (red line), spring (orange line) and autumn (green line) cases, whereas in the winter one (blue line) the increase is less appreciable. Moreover, the diurnal cycle of some variables is evident (temperature, wind speed, and cloudiness), more pronounced in summer and spring conditions and almost absent in the winter stable case. The summer case, showing the highest values in spread and the most pronounced diurnal cycle, is also the one with the lowest initial mean spread. These results can be justified by the fact that during spring and summer seasons the fluxes, namely the exchanges of moisture and energy between soil and atmosphere, are stronger compared to autumn or winter conditions, especially during daytime. For this mechanism, variations in soil moisture may deeply affect the boundary layer and influence atmospheric processes leading to a considerable variability among COSMO runs.

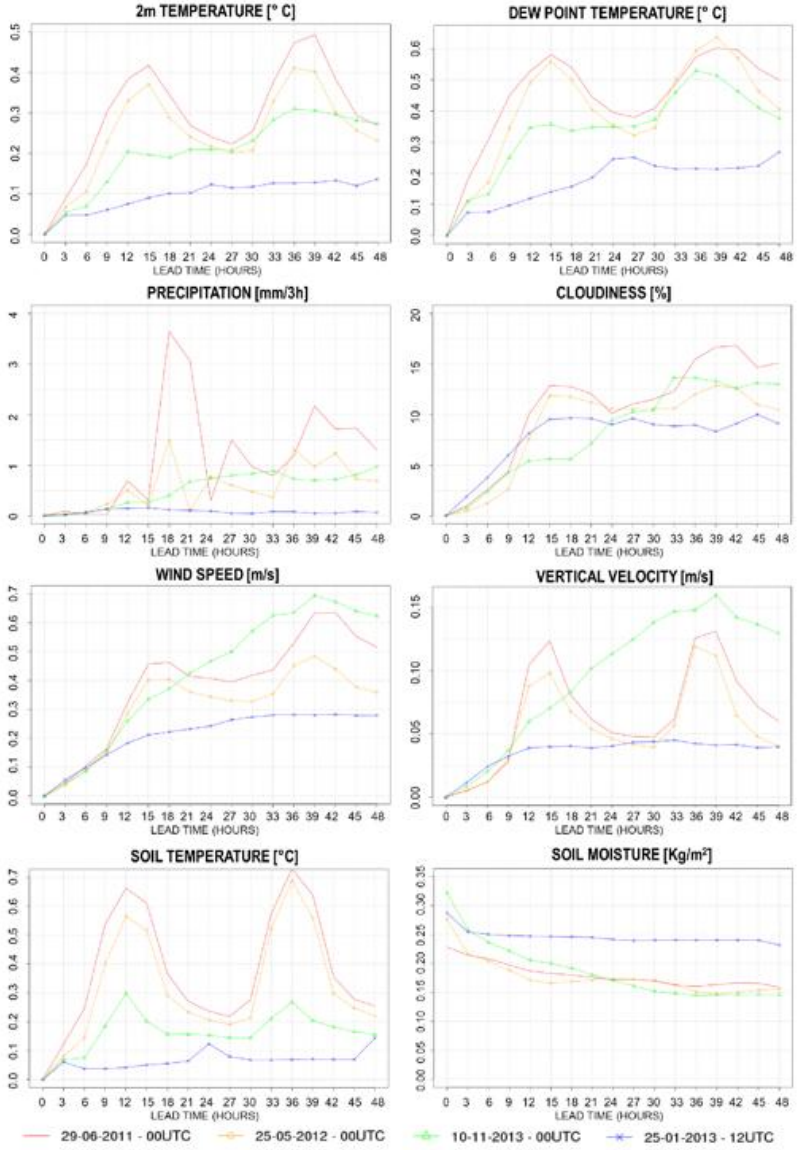

Figure 46: Spread of the variables indicated in panels averaged over the domain as a function of lead time.

This assumption is also confirmed by the behaviour of the soil moisture spread of the first soil layer (bottom right panel). For the winter stable case study, soil moisture spread remains nearly constant, because of the small fluxes leading to a limited exchange of moisture between soil and atmosphere. In other cases, where the fluxes are stronger, the initial spread in soil moisture tends to decrease, especially in the first day of the run. As regard the precipitation spread (left column, second row), the highest values are reached in summer case study with strong synoptic forcing, when events of heavy rainfall occurred. In general, for this variable and for all cases considered, a diurnal cycle is less evident or absent. In fact, for the two convective cases (spring and summer, respectively orange and red lines), thunderstorm events also occurred in the late evening and in the night time, where the cold front or an upper level trough interested some regions of the domain. Hence, in these convective cases, the highest spread generation occurs concurrently with convective phenomena. On the contrary, in the autumn case (green line), less convective precipitation leads to a more uniform spread increase. For the winter case (blue line), no spread appears because of stable synoptic

conditions. Moreover, the soil moisture spread remains nearly constant during the run, as already noticed. To explain this results we have to consider first that a strong inversion layer inhibits the moisture and heat transfer between soil and atmosphere and hence the variability from soil to the surface variable. Second, if the lower boundary layer is already close to the saturation, variations in the soil moisture content probably have a weak effect in the fog formation at the surface. These two points could explain why the influence of soil moisture perturbation in the surface variable is weak for winter case studies. As regard the wind speed and the vertical velocity (third row), the different behavior in spread between spring and summer case studies and the autumn one can be noticed. Considering the convective case studies analysed and as far as precipitation is concerned, we noticed that the areas of large spread are approximately also the regions where the convective phenomena took place (Fig. 47).

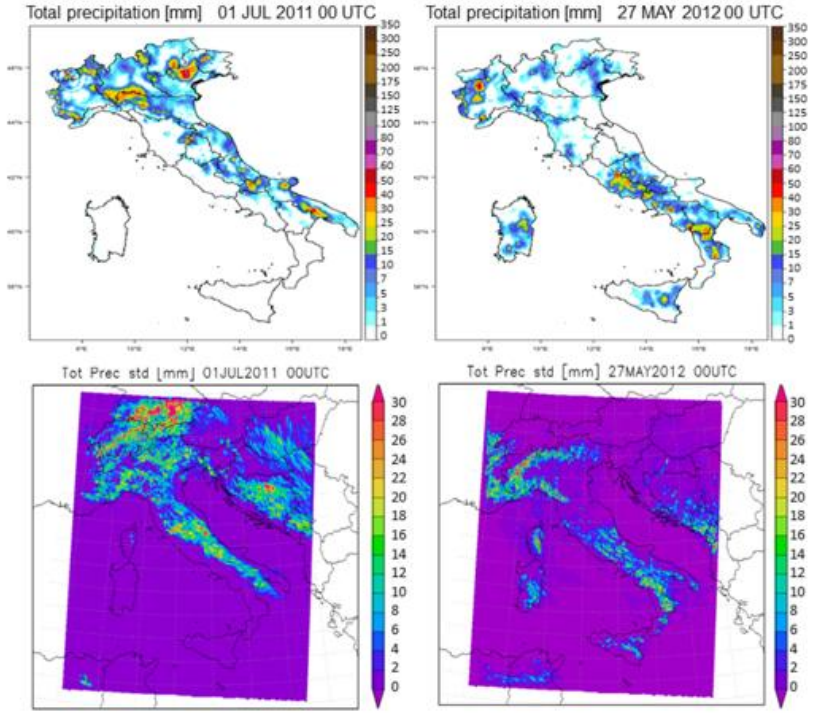

Figure 47: Total precipitation accumulated over 24 h (top row) and spread for this variable for the summer (left) and spring (right) cases.

This result indicates that the introduction of soil perturbation can add some skill to the ensemble system. Similar conclusion can be inferred considering the autumn case study, where the regions with the highest values of spread coincide with the regions of interesting weather (i.e. katabatic wind). In the winter case study, the spread increase is too weak and no noticeable signal can be detected. We investigated also if the different ICs of the soil have a contribution in the spread diffusion in the upper levels of the atmosphere. The spread of the main prognostic variables on longitudinal and latitudinal cross sections of the domain (Fig. 48), demonstrates that the soil moisture content change at the beginning of the simulations have a contribution in generating spread not only near the surface but even in the upper level of the atmosphere. In particular temperature spread is affected by the soil perturbation up to 850 hPa prognostic level, while the contribution to wind speed and water content spread propagates to higher levels affecting also the highest levels of the model integration. The speed of propagation of the spread in the upper atmosphere depends on the case study considered, because the phenomena involved in this study take place with

different time scales. The case studies associated with convective phenomena are the ones with the fastest spread propagation in the atmosphere. In the other cases, the propagation is slower and the spread diffuses less deeply in the upper levels of atmosphere.

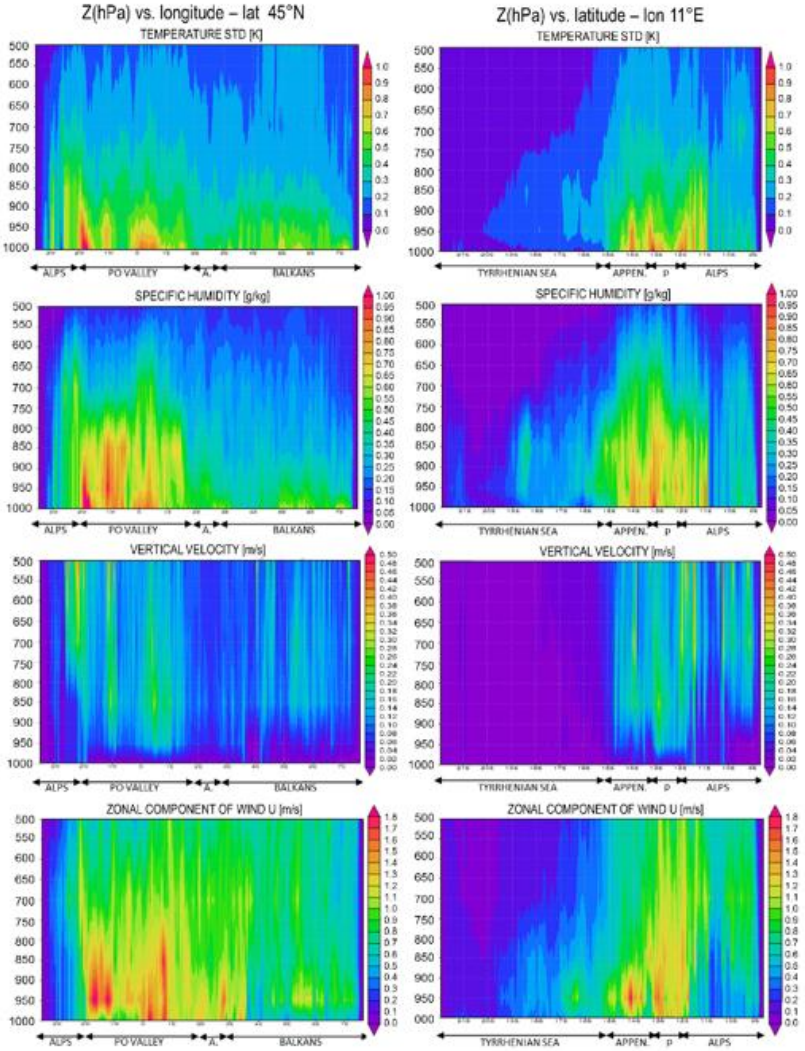

Figure 48: Spread of the main prognostic variables on longitudinal (left column) and latitudinal (right column) cross sections of the domain.

The results showed us that the model is very sensitive to soil moisture changes. This perturbation reflects in an increase of the spread of the main near-surface prognostic variables as well as upper in the atmosphere. The strength of the signal is higher in the case of convective case studies and weaker for the other cases. Moreover, in most of the analysed cases, it can be noticed that areas with large spread coincide with areas where "interesting" weather was observed, indicating that the soil moisture perturbation could potentially add some skill in the ensemble system. Considering the promising result of this study, we started the next phase of the priority project: test a perturbation technique in a full-fledged ensemble prediction system with ICs of soil and atmosphere as well as atmospheric BCs perturbed. Results of the sensitivity test are more extensively described in Bonanno and Loglisci (2014).

4.2.2 Implementing a soil perturbation technique in a high resolution ensemble system.

A first step to reach this goal was to choose between two available perturbation techniques. The first one (SHP hereafter, Spherical Harmonics Perturbation), proposed by Lavaysse et al. (2013), is based on perturbation of spectral coefficients in the expansion in spherical harmonics (in the horizontal) and Fourier harmonics (in the vertical). The second one (SPG hereafter, Stochastic Pattern Generator) is based on expansions in Fourier harmonics on a doubly periodic domain that contains the domain of interest (Tsyrulnikov and Gayfulin, 2016). This last SPG technique has been preferred because it gives a more irregular and noisy random field compared with the SHP technique. Moreover, SPG has the advantage of being less expensive from a computational point of view. Being SPG, with a specific setting, the selected technique to perturb soil field, we performed a sensitivity to initial soil moisture fields: the first coming from COSMO-EU (the operational run of DWD at the time of the experiments, with 7 km horizontal resolution over Europe), the second from the IFS model of ECMWF. This sensitivity test demonstrated that perturbing ECMWF initial soil moisture field gives a negative impact in terms of spread generation because of its highest values of soil moisture, close to saturation. To complete the sensitivity test, we tried to understand how sensitive the ensemble system is to the perturbation of other soil related external parameters such as LAI (Leaf Area Index), roughness length and vegetation cover. This last experiment revealed that the perturbations of external soil related parameters do not have a great impact on the generation of spread for 2-m temperature or soil moisture. The same results were obtained for other variables such as 2-m dew point, 10-m wind speed, precipitation, vertical velocity and soil temperature. Moreover, perturbing both the soil moisture and the external soil related parameters did not have a significant impact on the spread in the surface variables.

The selected perturbation method was, finally:

- SPG (Stochastic Pattern Generator), having the best numerical performances in terms of computational demands to compute the perturbed fields;
- Soil Moisture as the only field to be perturbed in the soil initial conditions, because perturbing other soil related external parameters and/or a combination of them do not produce enough spread compared to the one produced by soil moisture initial condition perturbation;
- Initial soil moisture field from the COSMOEU, because the use of ECMWF soil moisture analysis has a negative impact in terms of spread generation. Moreover, the use of COSMOEU soil moisture field guarantees, as an added value, that soil initial conditions come from the same modelling system.

The effects of an initial soil surface perturbation on surface prognostic variables have been analysed, but the soil initial perturbation have, indeed, an effect on the upper level atmosphere. In fact, latitude-height and longitude-height cross sections demonstrate how the soil moisture initial condition perturbation with SPG and the selected setting is able to propagate spread from the bottom layer to middle troposphere (Fig. 49).

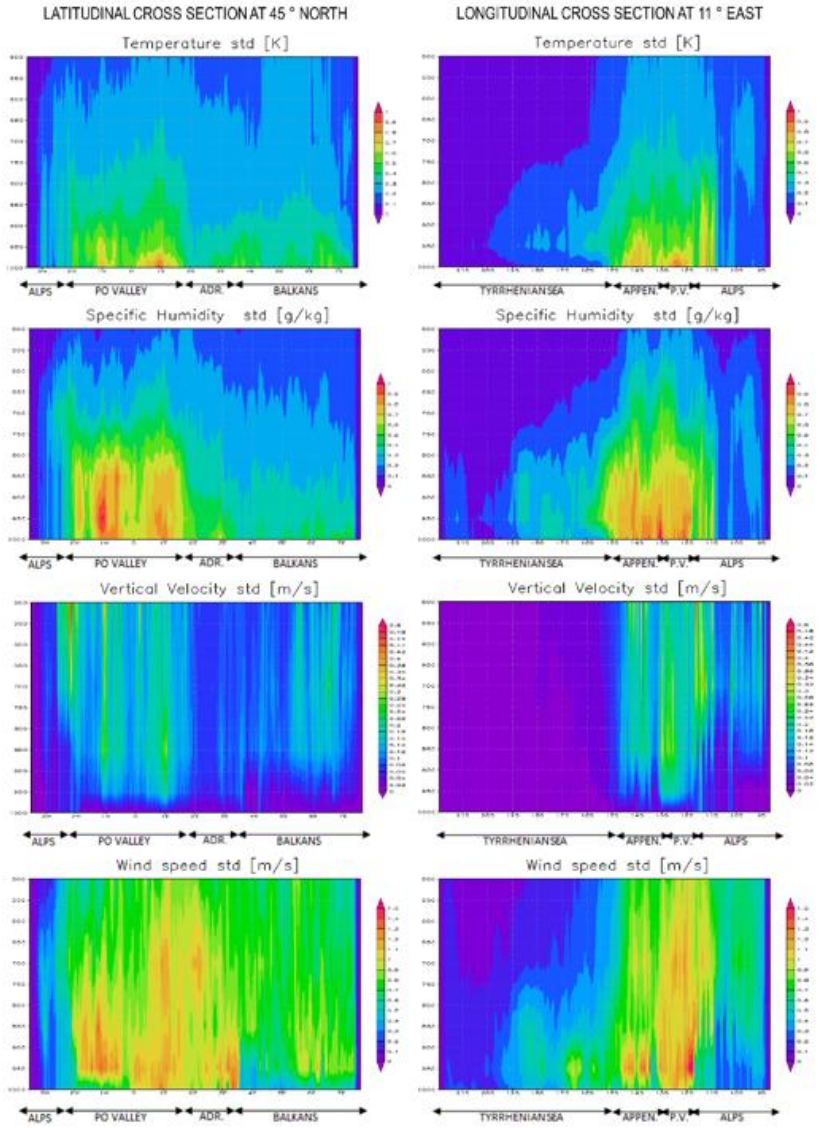

Figure 49: Spread of the main prognostic variables on longitudinal (left column) and latitudinal (right column) cross sections of the domain.

We finally compared the spread obtained with the selected soil perturbation technique with the one coming from an ensemble with perturbed atmospheric initial and boundary conditions, in this case COSMO-LEPS (Montani et al., 2011) (Fig. 50).

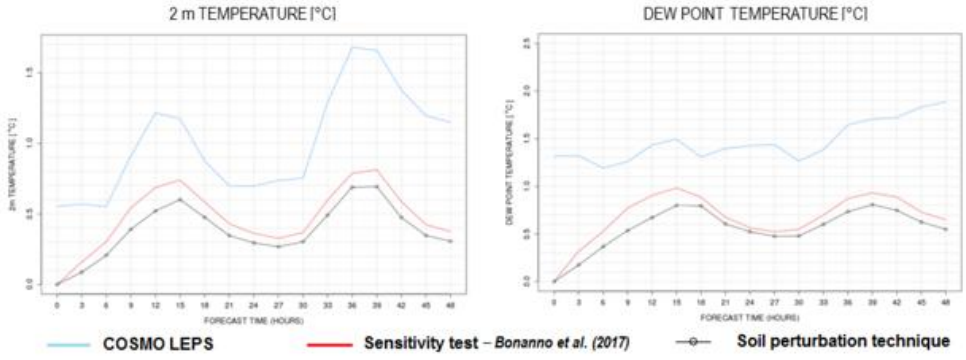

Figure 50: Spread of the variables indicated in panels averaged over the domain as a function of lead time, for the three systems COSMO-LEPS (blue line), a grouping of the runs performed in the sensitivity test (red line) and the ensemble generated by applying the soil perturbation technique based on SPG (black line).

Both systems produce comparable spreads as far as inland surface atmospheric variables are concerned. In fact, the main difference between the two EPSs is that COSMO-LEPS is able to produce spread also over the sea. Perturbing soil moisture initial condition has, naturally, a significant impact only for land areas. Over land the spread generated by the COSMO LEPS ensemble system is considerably higher than the one generated with the soil moisture perturbation. However, the latter is not negligible but gives a significant contribution, especially in the central hours of the day when the fluxes are higher. This fact led us to introduce the soil moisture perturbation into a full-fledged EPS expecting a positive contribution in term of spread generation. After this deep analysis, based on sensitivity of the model to soil uncertainties, we develop a perturbation technique able to generate randomly and numerically cheaply a perturbation of the soil moisture consistent with the model error of this important variable. This technique was successfully tested in a completely perturbed ensemble system based on the COSMO high resolution model, where perturbations act in the initial conditions of atmosphere and soil as well as in the boundary conditions of the atmosphere. Results have been published in COSMO Newsletter No. 15, Bonanno and Loglisci, 2015 and in a peer-reviewed paper (Bonanno and Loglisci, 2017).

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

For any comments and questions, please contact the editor:

1 Introduction

Convective indices describe characteristics of the thermodynamical state of the atmosphere with regard to convection and are widely used by forecasters to estimate the potential for convective precipitation. Some of the most popular indices include Convective Available Potential Energy (CAPE) and Convective INhibition (CIN). Most of these stability indices are related to the vertical structure of temperature, humidity and wind and can be calculated from radiosonde measurements or output of NWP models.

The following document describes the algorithms used in the COSMO model (Version 4.10) code to calculate a set of convective indices.

2 Parcel theory

A common way to assess the instability of the atmosphere is to apply the parcel method, which evaluates the buoyancy of an air parcel displaced a finite distance under a pseudo-adiabatic or reversible process. The advantages of using the parcel approach includes the ability to evaluate the stability of an unsaturated air mass to the displacement of the saturated parcel, the capability of measuring the total reservoir of potential energy for the convection of a parcel and the ability to assess *conditional instability*, which occurs, when a small displacement is stable but a sufficiently large one is not. The disadvantage of the parcel method is that it cannot account for the reaction of the environment to the parcel displacement. For a detailed description of the parcel theory we refer to [4].

3 Convective indices

3.1 CAPE and CIN

The potential energy PE estimates the available potential energy of the atmosphere. In the parcel theory framework it is calculated by integrating the buoyancy of a parcel lifted from a starting level z along the vertical parcel trajectory and ending at the equilibrium level z_{EL}. We define the potential energy PE of a parcel using the virtual temperature according to [3]

$$\mathrm{PE}(z) = g \cdot \int_z^{z_{\mathrm{EL}}} \frac{T_v^p - T_v^e}{T_v^e} dz \tag{1}$$

Here, g denotes gravitational acceleration, $T_v^{\{e,p\}}$ the virtual temperature $T_v = T(1 + \alpha q_v)$ of the environment and the parcel, respectively, q_v is the specific humidity and $\alpha = (R_v - R_d)/R_d \approx 0.608$. R_v and R_d denote the gas constants of water vapour and dry air, respectively. The ascent of the parcel is calculated dry adiabatically whenever the parcel is unsaturated (i.e. before reaching the condensation level) and pseudo-adiabatically when the parcel is saturated with respect to the environmental air. PE usually consists of a negative part accumulated below the level of free convection (LFC) z_{LFC}, commonly known as Convective INhibition (CIN)

$$\mathrm{CIN}(z) = -g \cdot \int_z^{z_{\mathrm{LFC}}} \frac{T_v^p - T_v^e}{T_v^e} dz \tag{2}$$

which is the energy that must be put into a parcel for its lifting until it gets positively buoyant and a positive part accumulated above the level of free convection, known as Convective

Available Potential Energy (CAPE)

$$\mathrm{CAPE}(z) = g \cdot \int_{z_{\mathrm{LFC}}}^{z_{\mathrm{EL}}} \frac{T_v^p - T_v^e}{T_v^e} dz \tag{3}$$

which is the energy released by the parcel once it is positively buoyant and rises without the addition of external energy. The relation PE(z) = CAPE(z) - CIN(z) holds.

Note that CAPE calculated with the parcel method is just an *upper bound* of the atmosphere's available potential energy due to the fact that the parcel cannot react with the environment (see [4]).

Since CAPE and CIN does not only depend on the thermodynamic structure of the sounding, but also on the parcel in question and on what thermodynamic process is applied in the parcel's displacement, there are many ways to calculate CAPE, which makes the comparison of different variants difficult. We adopted two CAPE and CIN methods which are widely used and robust in practice. They differ only by the definition of the starting parcel.

Implementation in COSMO and fieldextra The parcel ascent is performed using a parcel with given start temperature and humidity. It is then lifted dry adiabatically from model level to model level, preserving the potential temperature at the starting level

$$\theta = T\left(\frac{p_0}{p}\right)^{R_d/c_p} \tag{4}$$

until it reaches saturation at the lifted condensation level (LCL) z_{LCL}. Then it is further lifted pseudo-adiabatically, preserving the equivalent potential temperature at the lifting condensation level

$$\theta_e = T\left(\frac{p_0}{p}\right)^{R_d/c_p} \exp\left(\frac{L_v r_s}{c_p T}\right) \tag{5}$$

until it reaches the level of free convection z_{LFC} where $T^e = T^p$ and buoyancy gets positive. The parcel continues its ascent pseudo-adiabatically until it reaches the equilibrium level z_{EL}. $p_0 = 1000$ hPa, r_s is the saturation mixing ratio $r_s = R_d/R_v \cdot e_s/(p - e_s)$, e_s is the saturation water vapour pressure, c_p is the heat capacity at constant pressure of dry air and L_v is the latent heat of vapourization. All constants are defined as in the COSMO code and are listed in the Appendix for convenience. The main algorithm is as follows

- set start temperature, humidity and start level kstart for the ascent
- calculate potential temperature (θ) for start parcel
- loop over all levels
- if below LCL, perform dry ascent (θ const) to next level
- if at LCL, calculate equivalent potential temperature (θ_e)
- if above or at LCL, perform wet ascent (θ_e const) to next level
- calculate buoyancy $T_v^p - T_v^e$
- check for LFC (buoyancy changes from negative to positive)
- accumulate CAPE or CIN (dependent on sign of buoyancy)
- check for 500 hPa level and store $T_v^p - T_v^e$ (used for SI and SLI)
- end loop over all levels

Remarks

- The saturation water vapour pressure is approximated using Teten's formula (also used in the COSMO code)

$$e_s(T) = b_1 \exp\left(b_{2w}\frac{T - b_3}{T - b_{4w}}\right)$$

with b_1=610.78 Pa, b_{2w}=17.27, b_3=273.16 K and b_{4w}=35.86 K

- Since the temperature cannot be derived analytically from the equivalent potential temperature, it is calculated numerically using the Newton iteration method

$$\begin{aligned} T^{(k+1)} &= T^{(k)} - \frac{f(T^{(k)})}{f'(T^{(k)})} \\ f(T) &= T(\frac{p_0}{p})^{R_d/c_p}\exp(\frac{L_v r_s}{c_p T}) - \theta_e \end{aligned}$$

where k is the iteration index. There are usually less than 10 iterations needed for an accuracy of 0.003 K.

- Tests showed that very often a LFC is already found within the boundary layer even if significant capping inversions with a substantial amount of CIN are present above, implying that there are more than one LFC. Since CIN is defined as the part of PE below the LFC no CIN is present in these cases. To handle these situations in a meteorological meaningful way a check is done if the CIN within the capping inversion is larger than half (empirical value) the CAPE in the layer below. If this is the case, the LFC is set to the upper boundary of the CIN region (i.e. the second LFC) and CIN is defined as the CIN of the capping inversion.

- Since CIN is defined as the part of PE below the LFC, all contributions to CIN above the LFC are subtracted at the end of the ascent.

- In unstable situations (no LFC is present) or CAPE=0, CIN is set to "undefined value"

3.1.1 CAPE and CIN based on the most unstable parcel

The parcel with the largest CAPE value of all starting parcels within a certain layer above the earth's surface is chosen. By definition, the CAPE value of this parcel is an upper bound of all parcels starting within the given layer. This has the advantage that the CAPE value is independent of large vertical gradients of temperature and humidity often occurring in the surface layer. Therefore this variant of CAPE is a robust measure also during night when shallow surface-based inversions are present. CIN is calculated using the same starting parcel. For a graphical representation of an ascent using the most unstable parcel see Figure 1 (black line).

Implementation in COSMO and fieldextra To calculate the CAPE and CIN using the most unstable parcel (CAPE_MU and CIN_MU), an ascent is performed for each model level starting at the surface and ending at 300 hPa (adjustable parameter) above the surface. For each ascent the CAPE value is calculated and the parcel with the maximum value is taken as the starting parcel. CIN_MU is the CIN corresponding to this starting parcel. Since several ascents need to be performed for each grid point, these indices are computationally more expensive than the mean layer CAPE/CIN and the Showalter Index/Surface Lifted Index.

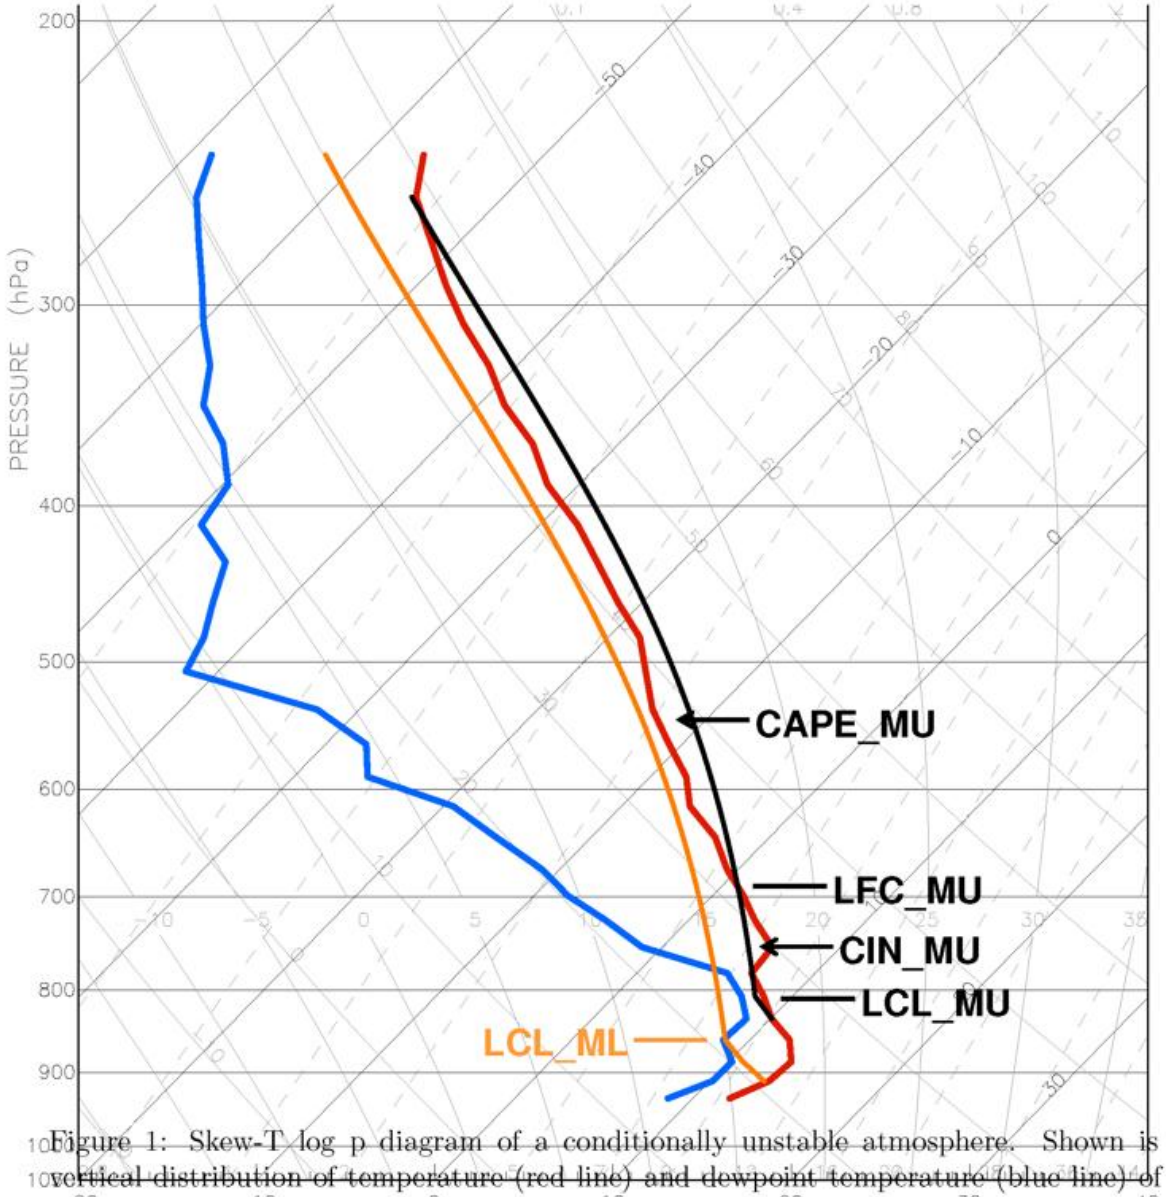

Figure 1: Skew-T log p diagram of a conditionally unstable atmosphere. Shown is the vertical distribution of temperature (red line) and dewpoint temperature (blue line) of the environment and two ascents using the parcel method starting from the most unstable parcel (black line) and a mean layer parcel (orange line). In the mean layer parcel ascent no level of free convection (LFC) is found, therefore CAPE_ML=0 and CIN_ML is undefined. In the most unstable parcel ascent a LFC (LFC_MU) is present, resulting in defined and non-negative CAPE_MU and CIN_MU. The lifting condensation levels are marked with LCL_MU and LCL_ML, respectively.

3.1.2 CAPE and CIN based on a mean layer parcel

In this case, the temperature and humidity of the starting parcel is calculated from that representative for a shallow surface layer (mean temperature and humidity of that layer). Like the CAPE/CIN using the most unstable parcel this results in a robust calculation without being too much dependent on the exact structure of the surface layer which may be not representative for the real atmosphere. CIN is calculated using the same string parcel. For a graphical representation of an ascent using the most unstable parcel see Figure 1 (orange line).

Implementation in COSMO and fieldextra To calculate the CAPE and CIN using a mean layer parcel (CAPE_ML and CIN_ML) a mean temperature and humidity from the lowest 50 hPa (adjustable parameter) above the surface are used for the "initialization" of the parcel. Only one ascent has to be performed per grid point.

3.1.3 CAPE_3KM on a mean layer parcel

CAPE_3KM is similar to the CAPE based on a mean layer parcel. The starting point for the parcel ascent is the same, whereas the ending point of the ascent is different. In case of CAPE based on a mean layer parcel, the ascent is performed until the equilibrium level z_{EL} is reached. For the CAPE_3KM the ascent is stopped at a height of 3 km above the ground. This particular CAPE is helpful for the forecasters. High values of CAPE_3KM tend to promote a stretching of the air columns and thus the development of tornadoes when high vorticity near the ground and high humidity occur simultaneously. Stretching is considered as significant when CAPE_3KM is greater than 150 J/kg (see [2]).

Implementation in COSMO and fieldextra The CAPE_3KM is computed exactly in the same way as the CAPE_ML excepting the fact that the ascent is stopped at 3 km above the ground.

3.2 Level of Free Convection

The Level of Free Convection LFC is the altitude at which the buoyancy is first positive, i.e. at which the lifted air parcel first becomes warmer than the surrounding air (see [4]). The PE of a lifted parcel is thus negative under the LFC (CIN) and we have to put some energy in the parcel in order to lift it. In opposite the PE of a lifted parcel is positive above the LFC (CAPE) and free convection occurs. The determination of the LFC is straightforward by computing the buoyancy at each level during the ascent and by searching the level at which the buoyancy sign changes.

Implementation in COSMO and fieldextra LFC is computed using a mean layer parcel (i.e. using mean values from the lowest 50 hPa above the surface as starting values for the parcel ascent).
The buoyancy is computed for each level:

$$Buo(k) = T_v^p(k) - T_v^e(k)$$

Then a sign change is searched: we test that $Buo(k) > 0$ and $Buo(k-1) < 0$. If it is the case k is the index corresponding to the LFC. The LFC is then computed as the height above the ground corresponding to this index k.

3.3 Lifting Condensation Level

Adiabatic expansion of moist air will always ultimately lead to saturation in the earth's atmosphere (see [4]). The LCL is the height at which a parcel, upon dry adiabatic lifting, will first achieve saturation (see [6]). It is often associated with the cloud base. At this point the parcel is just saturated with no cloud liquid water (see [12]). It is computed by comparing the current specific humidity with the specific humidity at saturation under the same conditions (pressure, temperature).

Implementation in COSMO and fieldextra We compute the LCL based on a mean layer parcel. We thus use a mean temperature and humidity from the lowest 50 hPa above the surface as starting values. Saturation humidity is computed for each level and the current specific humidity is compared to it. If the current specific humidity is greater or equal to the saturation value the LCL is found.

3.4 Showalter Index (SI)

The Showalter Index SI [9] is defined by the difference between the environmental temperature at 500 hPa and the 500 hPa temperature of an air parcel lifted dry adiabatically from 850 hPa to its condensation level and pseudo-adiabatically thereafter.

Implementation in COSMO and fieldextra For the calculation of the Showalter Index, an ascent is performed with a starting parcel at 850 hPa. SI is then equal to the temperature difference between the environment and the lifted parcel at 500 hPa. Only one ascent has to be performed per grid point. If the 850 hPa surface is below the topography, SI is set to "undefined value".

3.5 Surface Lifted Index (SLI)

The Surface Lifted Index SLI is defined by the difference between the environmental temperature at 500 hPa and the 500 hPa temperature of an air parcel lifted dry adiabatically from the surface to its condensation level and pseudo-adiabatically thereafter.

Implementation in COSMO and fieldextra For the calculation of the Surface Lifted Index, an ascent is performed with a starting parcel at the first model level. SLI is then equal to the temperature difference between the environment and the lifted parcel at 500 hPa. Only one ascent has to be performed per grid point.

3.6 $SWISS_{00}$ Index (SWISS00)

The $SWISS_{00}$ Index was especially designed for northern Switzerland during night conditions [5]. It is based on a combination of the Showalter Index, the wind shear between 3 and 6

km a.s.l. and the dewpoint depression on 600 hPa. This definition is similar to that of the SWEAT Index developed for the USA.

$$\mathrm{SWISS}_{00} = \mathrm{SI} + 0.4\mathrm{WSh}_{\text{3-6km}} + 0.1(T - T_d)_{\text{600hPa}}$$

where SI is the Showalter Index defined above and $\mathrm{WSh}_{\text{3-6km}}$ is the wind shear between 3 and 6 km.

Implementation in COSMO and fieldextra The SWISS_{00} Index is calculated as defined in section 3.6. The vertical wind shear is approximated by

$$\mathrm{WSh}_{\text{3-6km}} = \sqrt{u^2 + v^2}_{\text{6km}} - \sqrt{u^2 + v^2}_{\text{3km}}$$

3.7 SWISS_{12} Index (SWISS12)

The SWISS_{12} Index was especially designed for northern Switzerland during day conditions [5]. It is based on a combination of the Surface Lifted Index, the wind shear between ground and 3 km a.s.l. and the dewpoint depression on 650 hPa. This definition is similar to that of the SWEAT Index developed for the USA.

$$\mathrm{SWISS}_{12} = \mathrm{SLI} - 0.3\mathrm{WSh}_{\text{0-3km}} + 0.3(T - T_d)_{\text{650hPa}}$$

where SLI is the Surface Lifted Index defined above and $\mathrm{WSh}_{\text{0-3km}}$ is the wind shear between surface and 3 km.

Implementation in COSMO and fieldextra The SWISS_{12} Index is calculated as defined in section 3.7. The vertical wind shear is approximated by

$$\mathrm{WSh}_{\text{0-3km}} = \sqrt{u^2 + v^2}_{\text{3km}} - \sqrt{u^2 + v^2}_{\text{z(kdim)}}$$

z(kdim) is the height of the lowest model level.

3.8 Heat Index

The Heat Index (HI) is an index that combines air temperature and relative humidity in an attempt to determine the human-perceived equivalent temperature, how hot it feels, termed the felt air temperature. The human body normally cools itself by perspiration, or sweating, which evaporates and carries heat away from the body. However, when the relative humidity is high, the evaporation rate is reduced, so heat is removed from the body at a lower rate causing it to retain more heat than it would in dry air. Measurements have been taken based on subjective descriptions of how hot subjects feel for a given temperature and humidity, allowing an index to be made which create a correspondence between a temperature and humidity combination and a higher temperature in drier air.

The HI derives from a model comprising a collection of equations developed by Steadman [11]. It is the result of extensive bio-meteorological studies. The model is reduced by an iterative procedure to a relationship between temperature and relative humidity versus apparent temperature, Steadman developed a table based on this relationship.
The equation used commonly results from a multiple regression analysis performed on the data from Steadman's table [7] and is given by:

$$\begin{aligned} HI &= -42.379 + 2.0490T + 10.1433R - 0.2248TR - 6.8378 * 10^{-3}T^2 \\ &\quad - 5.4817 * 10^{-2}R^2 + 1.2287 * 10^{-3}T^2R + 8.5282 * 10^{-4}TR^2 - 1.99 * 10^{-6}T^2R^2 \end{aligned}$$

where T is the ambient dry bulb temperature (°F) and R is the relative humidity (%). This formula is only meaningful for temperatures above 80°F (corresponding to 26.7°C) and relative humidities above 40%.

The meaning of a Heat Index value can be summarized as follows:

Heat Index	Effects
<70°F	no effect for most of the people
71-79 °F	discomfort for half of the people
80-90°F	caution: fatigue is possible. Discomfort for all the people
91-105°F	extreme caution: sunstroke, heat cramps, heat exhaustion possible
106-130°F	danger: sunstroke, heat cramps, heat exhaustion likely
>130°F	extreme danger: heat strokes and sunstroke likely

Implementation in fieldextra The Heat Index is computed with the formula given in section 3.8 and for temperatures above 80°F (corresponds to 26.7°C) and relative humidities above 40%. For all other combinations of T and R the HI is flagged as undefined.

[7] does not mention at which height the temperature and the relative humidity should be considered. But this index attempts to determine the human-perceived equivalent temperature so the typical height is about 1.5-2 m. Thus, we choose to consider them at 2 meters height because of realism and simplicity. These outputs from the COSMO model are thus used:
- 2m temperature
- 2m relative humidity.

3.9 Bulk Richardson number and height of the planetary boundary layer (PBL)

The stability of the atmosphere plays a key role in the transport of air masses as well as in the transport of pollutants or humidity. The vertical transport is prevented in case of a stable stratified atmosphere whereas it is enhanced under unstable, or convective, conditions [12]. The dynamic stability is defined as the ability of an air mass to resist or recover from finite perturbations of a steady state. The perturbations are mechanically or thermally initiated [4].

The boundary layer is defined as the lowest part of the troposphere, whose behavior is directly influenced by the surface forcing with a response time of less than an hour [12]. This layer is turbulent, showing rapid fluctuations of the physical quantities, while the rest of the atmosphere (free atmosphere) is usually non turbulent or intermittently turbulent ([6]). Its thickness varies during the day cycle and during the year. It is generally thin at night and in the cool season and thicker during the day and in the warm season [12].

The characterization of the atmospheric stability and of the boundary layer height is crucial for a good comprehension of our atmosphere [8] and applications in air quality.

The following document describes the algorithms used in the COSMO model code to calculate the Bulk Richardson Number (BRN) and the height of the Planetary Boundary Layer (HPBL).

3.9.1 Bulk Richardson Number

The gradient Richardson Number is a dimensionless number relating the buoyant consumption term to the mechanical production term of the TKE budget equation [10].

$$Ri = \frac{(g/\theta_v)(\partial\theta_v/\partial z)}{(\partial u/\partial z)^2 + (\partial v/\partial z)^2} \tag{6}$$

Where θ_v is the virtual potential temperature in K, g is the acceleration due to gravity in m/s^2 , z is the height in m, u is the zonal wind in m/s and v is the meridional wind in m/s.

The Bulk Richardson Number BRN is an approximation of the gradient Richardson Number formed by approximating local gradients by finite difference across layers [12]. When approximating $\partial\theta_v/\partial z$ by $\Delta\theta_v/\Delta z$ and $\partial u/\partial z$ and $\partial v/\partial z$ by $\Delta u/\Delta z$ and $\Delta v/\Delta z$ respectively, we obtain the BRN:

$$BRN = \frac{g\Delta\theta_v\Delta z}{\theta_v[(\Delta u)^2 + (\Delta v)^2]} \tag{7}$$

We compute it between the ground and a height z:

$$BRN(z) = \frac{g(\theta_v(z) - \theta_{v_{ground}})(z - z_{ground})}{\theta_v(z)[(u(z) - u_{ground})^2 + (v - v_{ground})^2]} \tag{8}$$

Some authors [6] consider that $\theta_{v_{ground}} = \theta_v(z_{0,h})$ where $z_{0,h}$ is the energy roughness length [1]. In NWP models we consider however the surface values or the 2 meters values for the temperature related quantities and the 10 meters values for the winds.
According to [12], the bulk form of the Richardson Number, BRN, is used most frequently in meteorology because of the discrete nature of rawinsonde measurements and of numerical models.

[6] suggests this interpretation for the BRN:

BRN	Flow Type	Level of Turbulence due to Buoyancy	Level of Turbulence due to Shear
< 0, large	turbulent	large	small
< 0, small	turbulent	small	large
> 0, small	turbulent	none	large
> 0, large	laminar	none	small

Implementation in the COSMO model The BRN is computed according to equation (8). We consider no velocity at the ground, i.e. $u_{ground} = 0$ and $v_{ground} = 0$. The virtual

potential temperature at the denominator should be the mean virtual potential temperature for the whole layer. We thus have $\overline{\theta_v(z)} = [\sum_{k=1}^{n} \theta_v(k)]/(n+1)$, where n is the number of levels between the ground and the level k, instead of $\theta_v(z)$.
We thus obtain:

$$BRN(z) = \frac{g(\theta_v(z) - \theta_{v_{2m}})(z - z_{ground})}{\overline{\theta_v(z)}[u(z)^2 + v(z)^2]} \tag{9}$$

3.9.2 Height of the Planetary Boundary Layer

The height of the planetary boundary layer HPBL is a fundamental parameter characterizing the structure of the lowest troposphere [8]. It can be derived from profiles or parameterized. The second approach is used in NWP models. The parameterization is based on prognostic or diagnostic equations. The prognostic equations are more complicated and diagnostic methods are thus preferred.

The Bulk Richardson Number method is the standard way to derive HPBL from model outputs [8]. [10] considers it as a robust and fairly accurate method, which is particularly suited when the vertical resolution of the meteorological fields (temperature, winds) is limited.

This method consists in calculating the BRN and then in searching the height at which the BRN reaches a critical value, the critical Bulk Richardson Number. This level is the top of the boundary layer [10]. In the literature, one finds critical values between say 0.2 and 1. The method is however not very sensitive to this critical value. Values between 0.1 and 0.4 are generally admitted [10].
We have to notice that the diagnostic methods usually perform well under convective conditions, whereas their ability to predict the HPBL under stable conditions is poorer [8]. It can happen that the BRN profile never crosses the critical Bulk Richardson Number. In those cases it is thus impossible to find a HPBL with this method.

Implementation in the COSMO model There is no consensus in the literature about the critical Bulk Richardson Number. We decide to take into account the current stability conditions for the choice of the critical value. If the conditions are stable, we use a critical value $Ri_{B,cr}$ of 0.33 [14], whereas under convective conditions we use the value prescribed by [13] $Ri_{B,cr} = 0.22$.

The stability assessment is carried out in a simple way by computing the coefficient of the linear regression between the virtual potential temperature and the height in the 4 first model levels. If the coefficient is positive, the conditions are stable and if it is negative the conditions are known as convective. It is given by:

$$\beta = \frac{\sum_{i=1}^{4} z\theta_v - 1/4 \sum_{i=1}^{4} z \sum_{i=1}^{4} \theta_v}{\sum_{i=1}^{4} z^2 - 1/4 \sum_{i=1}^{4} z \sum_{i=1}^{4} z} \tag{10}$$

We then scan the levels starting at the bottom model level until a level satisfying this condition is reached: $BRN(z) > Ri_{B,cr}$. This level is the top of the PBL. If no such level is

found a missing value is returned.

We currently have not set some minimal and maximal threshold heights. It could be however useful when using this HPBL for certain applications (dispersion models for example).

3.10 Supercell Detection Index

The **Supercell Detection Index (SDI)** was devised by Wicker et al. [15] to help forecasters to detect the mesocyclone of a supercell from high resolution forecast models. At each horizontal grid point (i,j), the first Supercell Detection Index SDI_1 is defined as the product

$$\mathrm{SDI}_{1,ij} := \rho_{ij}\overline{\zeta_{ij}} \tag{11}$$

of the velocity-vorticity correlation

$$\rho_{ij} := \frac{< w'\zeta' >}{(< w'^2 >_{ij} < \zeta'^2 >_{ij})^{1/2}}$$

and the vertically averaged vorticity

$$\zeta_{ij} := (\nabla \times \mathbf{v})_{\mathbf{z}}.$$

Here, $< \ldots >$ denotes the average, taken over a sliding 3D slab of extensions 20 km * 20 km * [1.5 ... 5.5] km, and the overbar on ζ denotes a vertical average, taken in the height range [1.5 ... 5.5] km.
In contrast to other quantities that are used to predict tornados, like for instance the Storm Relative Environmental Helicity (SREH), or the near surface wind shear, the SDI_1 directly attempts at detecting the stream shape of a supercell in the model. That is the reason, why the SDI_1 can only be applied if the model resolution is sufficiently high. Hence it cannot be used for COSMO-7, since the resolution there is too low. The following threshold values of the SDI_1 for the detection of supercells are given in [15]:

$\lvert\mathrm{SDI}_1\rvert = 0.0003$ 1/s:	minimal threshold for supercells
$\lvert\mathrm{SDI}_1\rvert > 0.003$ 1/s:	significant signal for supercells

For regions of updraft, the product of correlation and vorticity is positive, and thus $\mathrm{SDI}_1 > 0$ holds true. For regions of downdraft $\mathrm{SDI}_1 < 0$.
Since the up- and downdrafts for supercells are coupled to each other, one is, however, rather interested in using the sign information to detect the sense of rotation of the supercells. Wicker et al. [15] thus define the second Supercell Detection Index SDI_2 at grid point (i,j) as

$$\mathrm{SDI}_{2,ij} := \begin{cases} \rho_{ij}|\overline{\zeta_{ij}}| & : \quad w > 0 \\ 0 & : \quad w \leq 0 \end{cases} \tag{12}$$

Thus it holds that $\mathrm{SDI}_2 > 0$ for regions of cyclonic updrafts, and $\mathrm{SDI}_2 < 0$ for regions of anticyclonic updrafts.
In practice, evaluation of the SDI_2 should be sufficient. The threshold values given for SDI_1 are of course also valid for SDI_2.

Implementation in the COSMO model Within COSMO, the Supercell Detection Indices SDI_1 and SDI_2 have been implemented by Axel Seifert (DWD) according to (11) and (12), respectively.

A Table of Constants

Name	Description	Value	Unit
g	Acceleration due to gravity	9.80665	m s^{-2}
R_d	Gas constant of dry air	287.05	$JK^{-1}kg^{-1}$
R_v	Gas constant of water vapour	461.51	$JK^{-1}kg^{-1}$
c_p	Specific heat of dry air at constant pressure	1005	$JK^{-1}kg^{-1}$
L_v	Latent heat of vapourization	$2.501 \cdot 10^6$	Jkg^{-1}

Table 1: Table of constants

B Grib parameters of indices

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW) and Romania (NMA). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction

Nonhydrostatic models using terrain-following coordinates, such as the Penn State-NCAR Mesoscale Model "MM5" (Dudhia, 1993) or the Lokal-Modell "LM" (Steppeler et al., 2002) are not well suited for predictions of flow near mountains in the environment of a stratified atmosphere. Numerical errors can be induced around steep slopes, due to numrical errors in connection with the terrain following coordinate transformation. The stratified atmosphere generates artificial forces, caused by numerical errors. These can produce artificial circulations which destroy clouds in the vicinity of mountains. For example, in the model LM, the condition that such numerical forces remain reasonably small is $\delta h < dz$, with δz being the layer thickness and δh the change of orography between one gridpoint and the next. This condition is violated in most operational models, even for larger scale operational hydrostatic applications. With fine meshes the model orography tends to be steeper than for coarser meshes. Therefore the circulations driven by numerical errors can be substantial (Sundqvist, 1976).

For models using the terrain following coordinate, such as MM5 or LM, a spatially homogeneous reference profile is introduced, in order to reduce this effect. If this reference profile is rather near to the real state of the atmosphere in the model, the error mentioned is absent, and nearly perfect simulations of gravitational waves can be done. This is the situation investigated in this paper. As in addition rather smooth grid representations of the mountain are used, the terrain following coordinate can be supposed to simulate these tests very well. For operational applications on large areas it will not be possible to choose a horizontally homogeneous atmospheric reference state in the way indicated. Therefore operational applications will always suffer from numerically generated artificial forces near mountains.

A method to reduce this error has been proposed by Mesinger (1988). This method reduces the coordinate deformation by having the model layers not following the mountains, but rather ending at mountains. The lower boundary is treated under the assumption that it is represented by a step function. While this coordinate has the expected advantages in low wind situations, it has disadvantages concerning the flow around smooth topography. In particular, Gallus and Klemp (2000) reported a failure to produce proper mountain induced gravitational waves. As opposed to this, the test case proposed by Gallus and Klemp (2000) is simulated properly using the terrain following coordinate. Another z-coordinate approach was proposed by Tripoli (private communication). It has been presented at the Third International Workshop on Non-Hydrostatic Modelling in Offenbach, 1999, and does not suffer from the problems mentioned above. A short report on the workshop is given by Saito (2001). The method by Tripoli is based on posing lower boundary values for the velocity components using assumptions on the vorticity. In the present paper a different method is used to obtain the approximation near the lower boundary. The free slip boundary condition is used and numerically evaluated using the finite volume approximation.

With simple equations a sufficient convergence condition is met when the domain boundary is a continuous spline. Such a condition is present in the z-coordinate atmospheric model described here, being based on the shaved element method, used in computational fluid dynamics and oceanography (Adcroft, 1997). A cartesian structured grid corresponding to the case without orography is assumed and the topography is assumed to be represented by a bilinear spline with nodes at the gridpoints with half values of the x-axis. There are three types of grid squares: those which are completely under the earth, those completely above the topography and those which are cut by the topography function. The first two classes of elements can be treated in an obvious way. The volumes which are cut by the orography are treated by the finite volume method.

Without further approximations this method may require very small time steps, since the elements cut from a volume may be rather small. One solution would be to use a semi-implicit discretization (Thomas et al., 2000). Here we use the time splitting method, as introduced by Klemp and Wilhelmson (1978b). This has been shown by Saito (1998) to have good operational efficiency with the model LM. The problem of a restrictive CFL criterion with small cut off elements is solved by using the thin wall aproximation, which is common in oceanography. An atmospheric use of this method was tested by Bonaventura (2000). The derivation of this method from the shaved element approach requires in addition to the vertical walls also the use of horizontal walls as opposed to Bonaventura (2000), who uses vertical walls only. Test integrations using this method in two space dimensions will be given in Section 3. The test problems proposed by Gallus and Klemp (2000) are simulated properly by the z-coordinate version of LM.

The present paper gives an extensive description of the z-coordinate, as implemented in the LM. THe tests involving an idealized bell shaped mountain are described. They perform well and the z-coordinate LM is now ready for further development towards operational implementation.

2 Basic Numerical Concept

2.1 Equations of Motion

The following numerical model simulates a 3d atmospheric flow in z-coordinates. Since the z-surfaces are horizontal, the governing equations are formulated in an orthogonal coordinate system on a sphere. The underlying mathematical structure consists of the full compressible Euler equations. The model takes gravity, coriolis force and metric terms into account, Reynolds stresses and viscosity are neglected. Physical processes like cloud physics, radiation and boundary layer physics are not included. The current version is suitable for idealized experiments in fluid flows and is the starting point to develop a weather forecast model in a z-coordinate system. The equations are the same as for the operational LM (Doms and Schaettler 2001) with the simplifications mentioned above. The equations read:

$$\frac{\partial u}{\partial t} = -\vec{v}\cdot\nabla u + \frac{uv}{a}\tan\varphi + fv - \frac{1}{\rho a\cos\varphi}\frac{\partial p}{\partial\lambda} \tag{1}$$

$$\frac{\partial v}{\partial t} = -\vec{v}\cdot\nabla v - \frac{u^2}{a}\tan\varphi - fu - \frac{1}{\rho a}\frac{\partial p}{\partial\varphi} \tag{2}$$

$$\frac{\partial w}{\partial t} = -\vec{v}\cdot\nabla w - \frac{1}{\rho}\frac{\partial p}{\partial z} - g \tag{3}$$

$$\frac{\partial p}{\partial t} = -\vec{v}\cdot\nabla p - \frac{c_p}{c_v}pD_3 \tag{4}$$

$$\frac{\partial T}{\partial t} = -\vec{v}\cdot\nabla T - \frac{1}{\rho c_v}pD_3 \tag{5}$$

The advection operator is definied by

$$\vec{v}\cdot\nabla = \frac{1}{a\cos\varphi}\left(u\frac{\partial}{\partial\lambda} + v\cos\varphi\frac{\partial}{\partial\varphi}\right) + w\frac{\partial}{\partial z} \tag{6}$$

and the threedimensional wind divergence by

$$D_3 = \frac{1}{a\cos\varphi}\left[\frac{\partial u}{\partial\lambda} + \frac{\partial}{\partial\varphi}(v\cos\varphi)\right] + \frac{\partial w}{\partial z} \tag{7}$$

The vertical acceleration due to the pressure gradient and gravity in (1.3) is expanded as

$$-\frac{1}{\rho}\frac{\partial p}{\partial z} - g = g\frac{\rho_0}{\rho}\left(\frac{T-T_0}{T} - \frac{T_0}{T}\frac{p'}{p_0}\right) - \frac{1}{\rho}\frac{\partial p'}{\partial z} \tag{8}$$

p' is the predicted pressure perturbation. p is the total pressure calculated as the sum of base-state pressure and predicted pressure perturbation:

$$p = p_0 + p' \tag{9}$$

The full set of model equations become

$$\frac{\partial u}{\partial t} = -\vec{v}\cdot\nabla u + \frac{uv}{a}\tan\varphi + fv - \frac{1}{\rho a\cos\varphi}\frac{\partial p'}{\partial\lambda} \tag{10}$$

$$\frac{\partial v}{\partial t} = -\vec{v}\cdot\nabla v - \frac{u^2}{a}\tan\varphi - fu - \frac{1}{\rho a}\frac{\partial p'}{\partial\varphi} \tag{11}$$

$$\frac{\partial w}{\partial t} = -\vec{v}\cdot\nabla w + g\frac{\rho_0}{\rho}\left[\frac{T-T_0}{T} - \frac{T_0}{T}\frac{p'}{p_0}\right] - \frac{1}{\rho}\frac{\partial p'}{\partial z} \tag{12}$$

$$\frac{\partial p'}{\partial t} = -\vec{v}\cdot\nabla p' + g\rho_0 w - \frac{c_p}{c_v}pD_3 \tag{13}$$

$$\frac{\partial T}{\partial t} = -\vec{v}\cdot\nabla T - \frac{1}{\rho c_v}pD_3 \tag{14}$$

The governing nonhydrostatic equations describe a compressible model atmosphere, thus meteorological unimportant sound waves are also part of the solution. According to the Courant Friedrich Levy criterion the fastest signal velocity, i.e. the sound velocity, determines the integration time step. In order to keep numerical efficiency, the mode-splitting time-integration method proposed be Klemp and Wilhelmson (1978) is applied. In practice the mode splitting time integration scheme in symbolic form can be written as:

$$\frac{\partial\psi}{\partial t} = s_\psi + f_\psi \tag{15}$$

Where ψ denotes a prognostic model variable, f_ψ the forcing terms due to the slow modes and s_ψ the source terms which are related to the acoustic and gravity wave mode (fast mode).

The full set of model equations can then be split:

a) slow tendencies

$$f_u = -\vec{v}\cdot\nabla u + \frac{uv}{a}\tan\varphi + fv \tag{16}$$

$$f_v = -\vec{v}\cdot\nabla v - \frac{u^2}{a}\tan\varphi - fu \tag{17}$$

$$f_w = -\vec{v}\cdot\nabla w \tag{18}$$

$$f_{p'} = -\vec{v}\cdot\nabla p' \tag{19}$$

$$f_T = -\vec{v}\cdot\nabla T \tag{20}$$

b) fast tendencies:

$$s_u = -\frac{1}{\rho a \cos\varphi}\frac{\partial p'}{\partial \lambda} \tag{21}$$

$$s_v = -\frac{1}{\rho a}\frac{\partial p'}{\partial \varphi} \tag{22}$$

$$s_w = -\frac{1}{\rho}\frac{\partial p'}{\partial z} + g\frac{\rho_0}{\rho}\left[\frac{T-T_0}{T} - \frac{T_0}{T}\frac{p'}{p_0}\right] \tag{23}$$

$$s_{p'} = g\rho_0 w - \frac{c_p}{c_v} pD_3 \tag{24}$$

$$s_T = -\frac{1}{\rho c_v} pD_3 \tag{25}$$

The f_ψ -terms denote the tendencies due to the slow modes. These terms are kept constant during the subcycle procedure. The equations for w' p' and T are coupled and solved implicitly.

Currently the model still runs with the originally introduced $\Delta\,(p_0)_k$ (thickness of layer k expressed by Δp_0) which is present in the entire programm code. So the vertical derivative is written as:

$$\frac{\partial}{\partial z} = -\frac{g\rho_0}{\Delta p_0}\frac{\partial}{\partial \zeta} \tag{26}$$

2.2 Volume Elements and Grid Design

The Arakawa C-Grid of the LM is used in the current model. Fig. 2.1 illustrates the staggering of the dependent model variables.

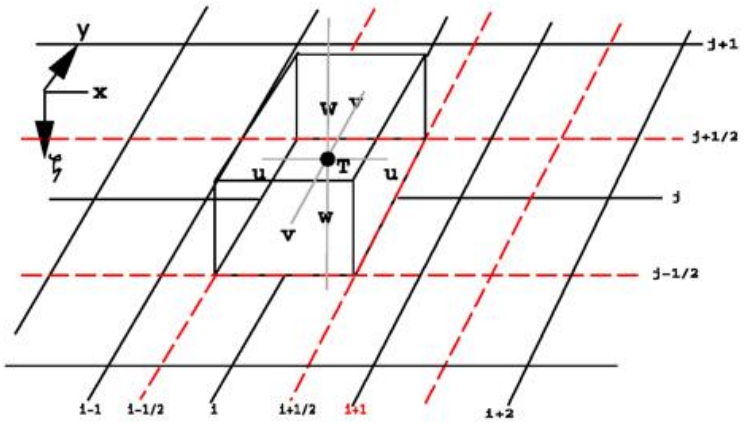

FIGURE 2.1: The three dimensional grid box.

Note, that the ζ -coordinate in the vertical is still used with $\Delta\zeta = 1$. Eq. (1.26) is applied to gain $\frac{\partial}{\partial z}(...)$.

The orography is definied at the corner points $(i + 1/2, j + 1/2)$ of a grid element (see Fig. 2.2).

Fig. 2.3 illustrates, how the surface of the orography intersects a column of volume elements.

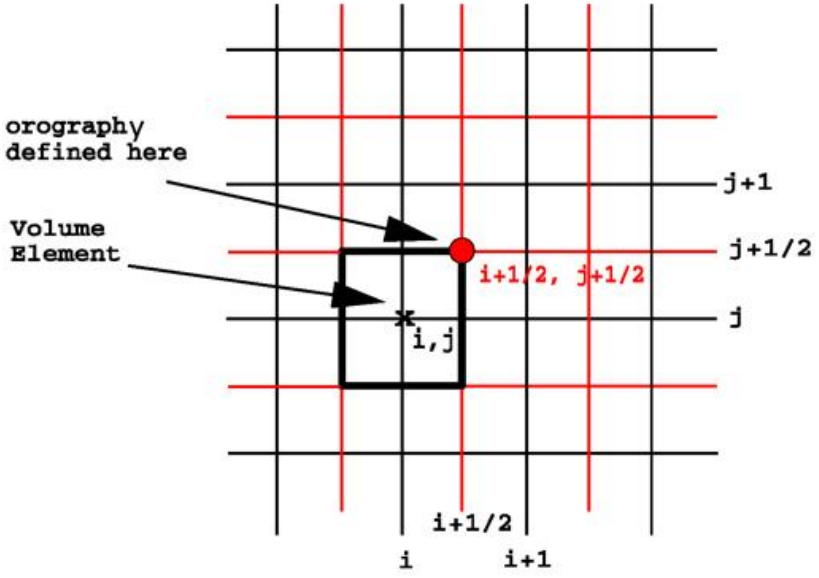

FIGURE 2.2: The horizontal grid and the definition of orography.

Fig. 2.4 illustrates for a bell shaped mountain, how the mountain's surface intersects the volume element. In the LM with terrain-following coordinates the horizontal pressure gradient is gained by applying the transformation formula which takes the vertical pressure difference along the sloped surface into account. Since the current model is formulated in z-coordinates, we have no metric term in the expression for (see Doms and Schättler, 2001) $\frac{\partial p}{\partial x}$ is not longer present. Instead a significant difference in the calculation of the spatial derivatives between the current model and the LM appears. As shown in Fig. 1.4 the volume element located at i, j, k is cut by the mountain's surface. In the advection term of equation (1.16),

$$-\vec{v} \cdot \nabla u = \underbrace{-u\frac{\partial u}{\partial x}}_{1} - v\frac{\partial u}{\partial y} - w\frac{\partial u}{\partial z} \tag{27}$$

the three terms have to be determined at position $i + 1/2, j, k$. For term 1 this is done in the following way, using the centered difference approximation

$$-u\frac{\partial u}{\partial x} = \overline{-\overline{u}^{x}\frac{\partial u}{\partial x}}^{x} = -\frac{1/2}{\Delta x}\left(u_{i,j,k}\Delta u_{i,j,k} + u_{i+1,j,k}\Delta u_{i+1,j,k}\right) \tag{28}$$

$$\text{with } u_{i,j,k} = \frac{1}{2}\left(u_{i-1/2,j,k} + u_{i+1/2,j,k}\right) \tag{29}$$

$$\Delta u_{i,j,k} = u_{i+1/2,j,k} - u_{i-1/2,j,k} \tag{30}$$

$$\Delta u_{i+1/j,k} = u_{i+11/2,j,k} - u_{i+1/2,j,k} \tag{31}$$

The velocity $u_{i-1/2,j,k}$ required in (1.29) and (1.30) which is denoted in Fig. 2.4 with u^*, is unknown, as it is underneath the mountain.

Fig. 2.5 gives a horizontal cross section through the grid. All values within the dashed area (see Fig. 2.5) lie underneath the mountain's surface. The solid line represents the

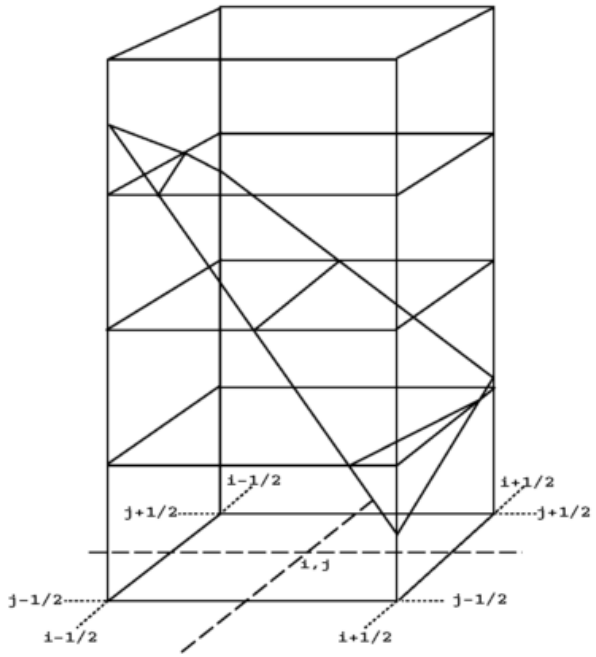

FIGURE 2.3: A column and the cells cut by a bilinear function representing the orography.

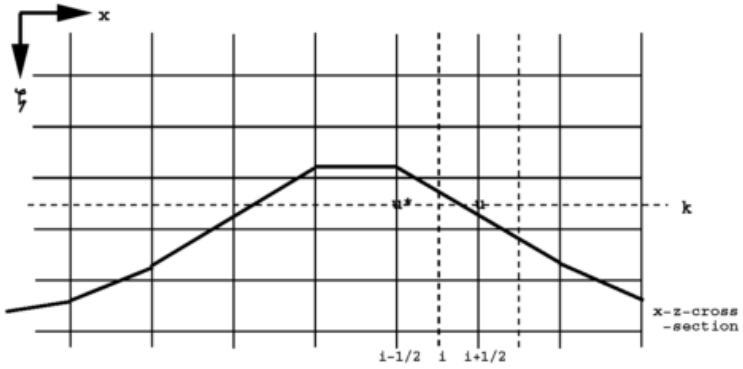

FIGURE 2.4: A vertical cross section through the grid and the boundary value u^* under the mountain.

intersection curve of the mountain's surface and a z-plane. Applying the formula

$$-v\frac{\partial u}{\partial y} = \overline{-\overline{v}^x \frac{\partial u}{\partial y}}^y = -\frac{1/2}{\Delta y}\left(v_{i+1/2,j+1/2,,k}\Delta u_{i+1/2,j+1/2,k} + v_{i+1/2,j-1/2,k}\Delta u_{i+1/2,j-1/2,k}\right) \quad (32)$$

with

$$v_{i+1/2,j-1/2,k} = \frac{1}{2}\left(\underline{v_{i,j-1/2,k}} + v_{i+1,j-1/2,k}\right) \quad (33)$$

and

$$\Delta u_{i+1/2,j-1/2,k} = u_{i+1/2,j,k} - \underline{u_{i+1/2,j-1,k}} \quad (34)$$

$v_{i,j-1/2,k}$ and $u_{i+1/2,j-1,k}$ are unknown quantities under the mountain. Our goal is, to determine a realistic value for $-u\frac{\partial u}{\partial x}$ and $-v\frac{\partial u}{\partial y}$ at point $i+1/2, j, k$. In order to do that the star values are computed.

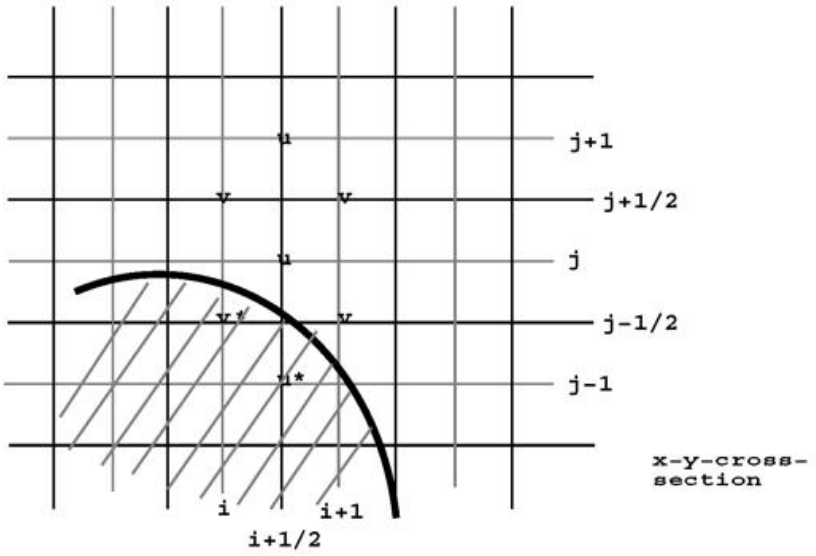

FIGURE 2.5: A horizontal cross section through the grid with boundary values in the horizontal

Please note, the star values are not computed in order to gain realistic values under the mountain. These quantities are artificial. The star values are just preliminary values, so called help values which are necessary to compute a realistic derivative at a point which lies very close at the boundary. In the horizontal plane (Fig. 2.5) the star quantities are those, which have at least one neighbour in the same plane positioned in the free atmosphere.

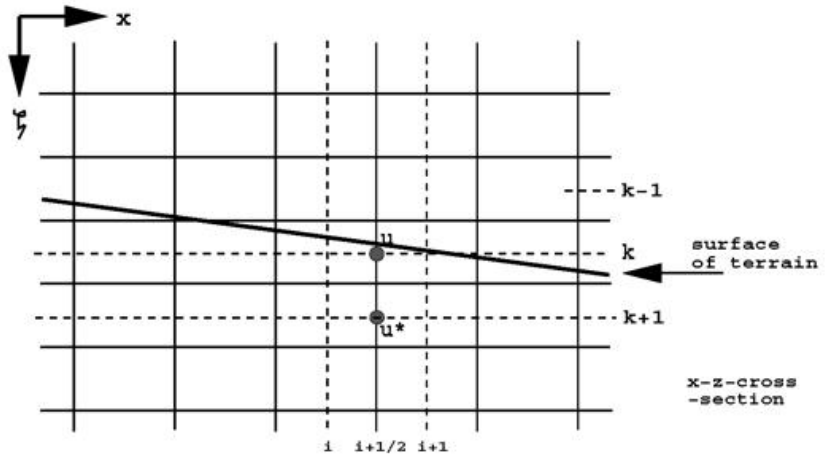

FIGURE 2.6: Boundary values u^* under flat terrain.

In many cases the surface of the terrain is flat (see Fig. 2.6). A star value under the surface is necessary for the correct evaluation of the vertical derivative. As illustrated in Fig. 2.6 u^* at $i+1/2, j, k+1$ is required for $\left.\frac{\partial u}{\partial \zeta}\right|_{i+1/2,j,k+1/2}$.

2.3 Computation of Sub-Surface Values of Meteorological Fields

The situation is represented in Fig. 2.7 where u^* as a help quantity has to be evaluated. In the current model a three point formula is applied.

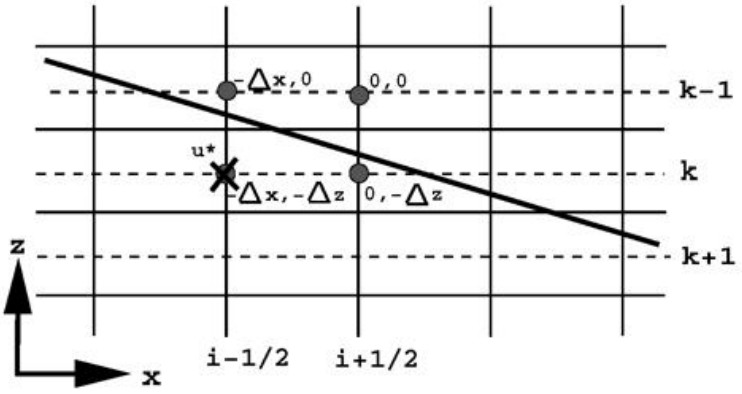

FIGURE 2.7: The interpolation of sub-surface boundary values $u^*$from surrounding values u.

Since the curvature of the spatial distribution of u is not taken into account the three points have to be chosen very close to the boundary. The method to yield u^* is based on the formula for a plane in a 3-dimensional space.

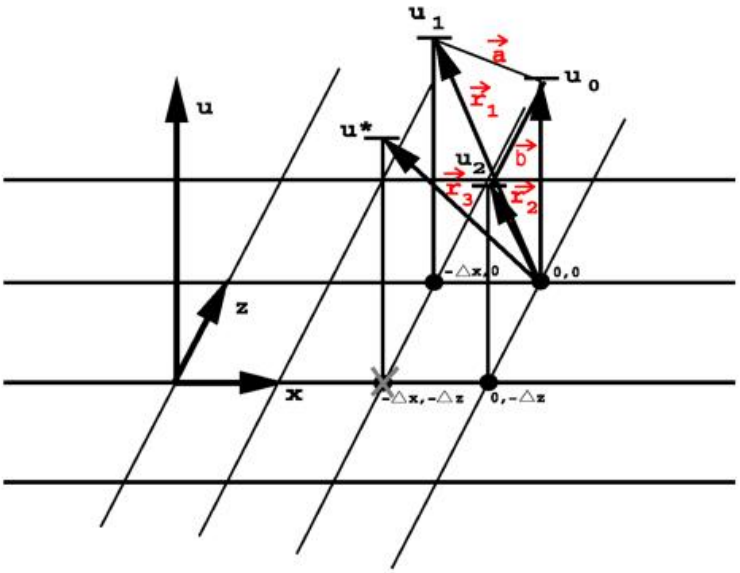

FIGURE 2.8: The plane used for the interpolation of u^*.

The plane is stretched by the vectors $\vec{a}$ and $\vec{b}$ in Fig. 2.8. The origin of the relative coordinate system is detoned with 0,0. The vectors $\vec{r_0}, \vec{r_1}, \vec{r_2}$ and $\vec{r_3}$ are the position vectors pointing to u_0, u_1, u_2 and u^*, they read:

$$\vec{r_0} = \begin{pmatrix} 0 \\ 0 \\ u_0 \end{pmatrix} ; \vec{r_1} = \begin{pmatrix} -\Delta x \\ 0 \\ u_1 \end{pmatrix} ; \vec{r_2} = \begin{pmatrix} 0 \\ -\Delta z \\ u_2 \end{pmatrix} ; \vec{r_3} = \begin{pmatrix} -\Delta x \\ -\Delta z \\ u_* \end{pmatrix} \tag{35}$$

The general formula of a plane in parameter representation is:

$$\vec{r} = \vec{r_0} + \lambda\vec{a} + \mu\vec{b} \tag{36}$$

where λ and μ are the parameters and $\vec{r}$ is a vector pointing to a point in the plane which

is stretched by $\vec{a}$ and $\vec{b}$. $\vec{a} = \vec{r_1} - \vec{r_0}$; $\vec{b} = \vec{r_2} - \vec{r_0}$ from (1.35) follows:

$$\vec{a} = \begin{pmatrix} -\Delta x \\ 0 \\ u_1 - u_0 \end{pmatrix} \quad ; \quad \vec{b} = \begin{pmatrix} 0 \\ -\Delta z \\ u_2 - u_0 \end{pmatrix} \tag{37}$$

The demand is: u^* is located within the plane. Thus, vector $\vec{r}$ in (1.36) can be replaced by $\vec{r_3}$:

$$\begin{pmatrix} -\Delta x \\ -\Delta z \\ u^* \end{pmatrix} = \begin{pmatrix} 0 \\ 0 \\ u_0 \end{pmatrix} + \lambda^* \begin{pmatrix} -\Delta x \\ 0 \\ u_1 - u_0 \end{pmatrix} + \mu^* \begin{pmatrix} 0 \\ -\Delta z \\ u_2 - u_0 \end{pmatrix} \tag{38}$$

The first two components of the vector equation (1.37) represent a linear system of equations for the unknowns λ^* and μ^*. The result is $\lambda^* = 1$, $\mu^* = 1$. For u^* we find the relation:

$$\begin{aligned} u^* &= u_0 + (u_1 - u_0) + (u_2 - u_0) \Rightarrow \\ u^* &= u_1 + u_2 - u_0 \end{aligned} \tag{39}$$

$$\begin{aligned} \text{substituting} \quad u^* &= u_{i-1/2,j,k} \\ u_1 &= u_{i-1/2,j,k-1} \\ u_2 &= u_{i+1/2,j,k} \\ u_0 &= u_{i+1/2,j,k-1} \qquad \text{yields} \end{aligned} \tag{40}$$

$$u_{i-1/2,j,k} = u_{i-1/2,j,k-1} + u_{i+1/2,j,k} - u_{i+1/2,j,k-1} \tag{41}$$

(1.41) is the answer for the preliminary value $u_{i-1/2,j,k}$ in case that the mountain is on the west side. For the other sides the formula looks very similar.

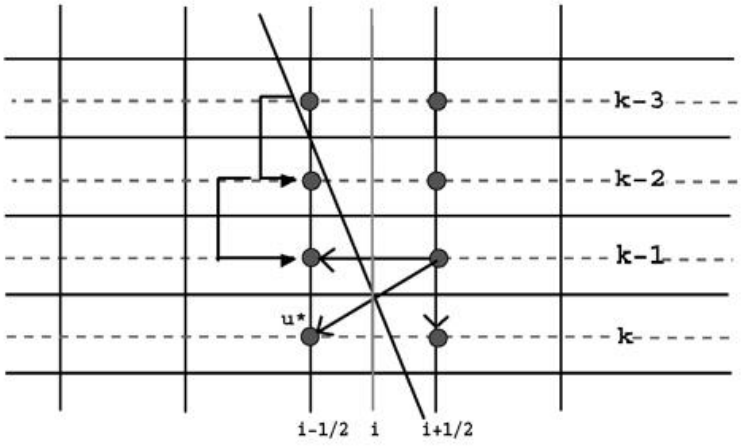

FIGURE 2.9: The interpolation in case of a steep mountain going from top to bottom.

Fig. 1.9 illustrates the situation in case of a steep slope. Applying (1.28) would fail for u^* if the calculation were started from below because $u_{i-1/2,j,k-1}$ is also unknown. Since the calculation procedure starts from upper levels downward, first $u_{i-1/2,j,k-1}$ is calculated because $u_{i-1/2,j,k-2}$ is available and finally u^* at k can be computed. In case of a flat terrain

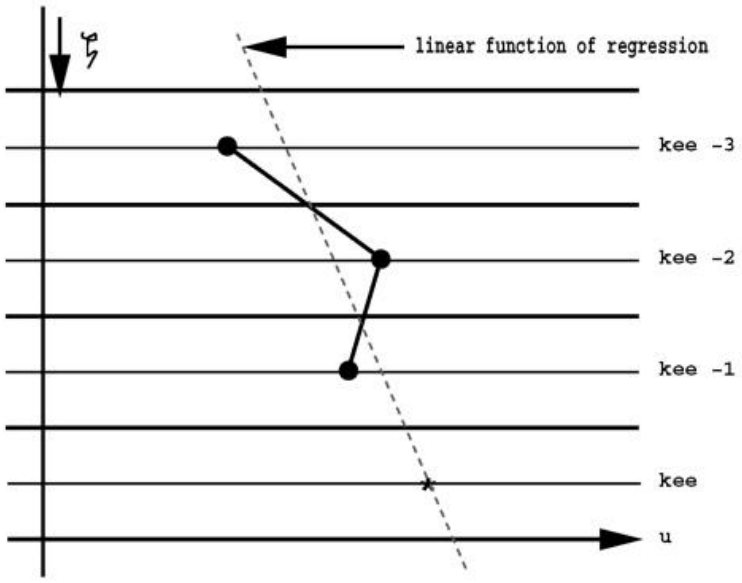

FIGURE 2.10: The linear regression used near the surface.

(Fig. 2.6) instead of the formula of a plane, a one dimensional linear function of regression is applied to compute u^*.

Let's assume that kee in Fig. 2.10 is the first level under the terrain with respect to the ζ-direction. Then $u_{i+1/2,j,kee-1}$, $u_{i+1/2,,j,kee}$ and $u_{i+1/2,j,kee-3}$ are taken to determine the linear function of regression:

$$
\begin{aligned}
u^*_{i+1/2,j,kee} &= um + 2us \qquad (42)\\
&\text{with}\\
um &= \frac{1}{3}\left(u_{i+1/2,j,kee-3} + u_{i+1/2,j,kee-2} + u_{i+1/2,j,kee-1}\right)\\
&\text{and}\\
us &= \frac{u_{i+1/2,j,kee-1} - u_{i+1/2,j,kee-3}}{2\Delta\zeta}\\
\text{because} \quad \Delta\zeta &= 1 \qquad \text{yields:}\\
us &= \frac{1}{2}\left(u_{i+1/2,j,kee-1} - u_{i+1/2,j,kee-3}\right)
\end{aligned}
$$

The preliminary star values of the other parameters are computed in the same way. Finally, all the necessary star values are processed and all the derivatives close to the boundary can be determined. The calculation procedure can be done in a subroutine which is called in the model before the slow tendencies are calculated. The advantage of this program structure is: no if statement is necessary while the slow tendencies are processed. At all the other gridpoints under the surface the field is filled with 0. For the calculation procedure they don't have any importance. In fact they must not have any importance. The program can be tested by writing strange numbers under the surface (except the star values). They should not have any impact on the solution of the flow field. Do loops in i-, j- and k-direction don't need to be interrupted at the boundaries. This is important in order to keep the integration sweeps in x-, y- and z-direction efficient.

2.4 Spatial Discretization

To present the difference form of equations (1.16)-(1.25) the following notations for horizontal and vertical averaging and differencing are defined.

$$\begin{aligned}
\overline{\psi}^{\lambda} &= \frac{1}{2}\left(\psi\left(\lambda+\frac{\Delta\lambda}{2}\right)+\psi\left(\lambda-\frac{\Delta\lambda}{2}\right)\right)\\
\overline{\psi}^{\varphi} &= \frac{1}{2}\left(\psi\left(\varphi+\frac{\Delta\varphi}{2}\right)+\psi\left(\varphi-\frac{\Delta\varphi}{2}\right)\right)\\
\overline{\psi}^{m\zeta} &= \frac{1}{2}\left(\psi_{k+1/2}+\psi_{k-1/2}\right)\\
\overline{\psi}^{h\zeta}_{k-1/2} &= \frac{\Delta\left(p_0\right)_{k-1}\psi_k+\Delta\left(p_0\right)_k\psi_{k-1}}{\Delta\left(p_0\right)_{k-1}+\Delta\left(p_0\right)_k}\\
\delta_{\lambda}\left(\psi\right) &= \psi\left(\lambda+\frac{\Delta\lambda}{2}\right)-\psi\left(\lambda-\frac{\Delta\lambda}{2}\right)\\
\delta_{\varphi}\left(\psi\right) &= \psi\left(\varphi+\frac{\Delta\varphi}{2}\right)-\psi\left(\varphi-\frac{\Delta\varphi}{2}\right)\\
\delta_{\varphi}\left(\psi\right) &= \psi\left(\zeta+\frac{1}{2}\right)-\psi\left(\zeta-\frac{1}{2}\right)
\end{aligned}$$

The vertical advection $-w\frac{\partial\psi}{\partial z}$ is still written with the contravariant vertical velocity $\dot{\zeta}$ (see LM operational version):

$$\begin{aligned}
-w\frac{\partial\psi}{\partial z} &= -\dot{\zeta}\frac{\partial\psi}{\partial\zeta} \qquad ; \qquad \dot{\zeta}_{k-1/2}=\frac{w^*_{k-1/2}}{\Delta\left(p_0\right)_{k-1/2}}=\frac{w_{k-1/2}}{\Delta z_{k-1/2}}\\
w^*_{k-1/2} &= -g\overline{(\rho_0)}^{h\zeta}_{k-1/2}w_{k-1/2} \qquad ; \qquad \Delta\left(p_0\right)_{k-1/2}=\frac{1}{2}\left(\Delta\left(p_0\right)_k+\Delta\left(p_0\right)_{k-1}\right)\\
\Delta z_{k-1/2} &= \frac{1}{2}\left(\Delta z_k+\Delta z_{k-1}\right)
\end{aligned} \tag{43}$$

With these notations the slow tendencies of (1.10) - (1.20) read:

$$\begin{aligned}
f_u &= -\frac{1}{a\overline{\cos\varphi}^{\varphi}\Delta\lambda}\overline{\overline{u}^{\lambda}\delta_{\lambda}\left(u\right)}^{\lambda}-\frac{1}{a\overline{\cos\varphi}^{\varphi}\Delta\varphi}\overline{\overline{v}^{\lambda}\cos\varphi\delta_{\varphi}\left(u\right)}^{\varphi}\\
&\quad \overline{-\dot{\zeta}^{\lambda}\delta_{\lambda}\left(u\right)}^{m\zeta}+\frac{u\overline{v}^{\lambda,\varphi}\overline{tan\varphi}^{\varphi}}{a}+\overline{f}^{\varphi}\overline{v}^{\lambda,\varphi}
\end{aligned} \tag{44}$$

$$\begin{aligned}
f_v &= -\frac{1}{a\cos^{\varphi}\Delta\lambda}\overline{\overline{u}^{\varphi}\delta_{\lambda}\left(v\right)}^{\lambda}-\frac{1}{a\cos\varphi\Delta\varphi}\overline{\overline{v}^{\varphi}\overline{\cos\varphi}^{\varphi}\delta_{\varphi}\left(v\right)}^{\varphi}\\
&\quad \overline{-\dot{\zeta}^{\varphi}\delta_{\zeta}\left(v\right)}^{m\zeta}-\frac{\left(\overline{u}^{\lambda,\varphi}\right)^2}{a}tan\varphi-\overline{f}^{\lambda}\overline{u}^{\lambda,\varphi}
\end{aligned} \tag{45}$$

$$f_w = -\frac{1}{a\overline{\cos^{\varphi}}^{\varphi}\Delta\lambda}\overline{\overline{u}^{h\zeta}\delta_{\lambda}\left(w\right)}^{\lambda}-\frac{1}{a\overline{\cos\varphi}^{\varphi}\Delta\varphi}\overline{\overline{v}^{h\zeta}\cos\varphi\delta_{\varphi}\left(w\right)}^{\varphi}-\overline{\dot{\zeta}^{m\zeta}\delta_{\zeta}\left(w\right)}^{m\zeta} \tag{46}$$

$$f'_p = -\frac{1}{a\overline{\cos^{\varphi}}^{\varphi}\Delta\lambda}\overline{u\delta_{\lambda}\left(p'\right)}^{\lambda}--\frac{1}{a\overline{\cos\varphi}^{\varphi}\Delta\varphi}\overline{v\cos\varphi\delta_{\varphi}\left(p'\right)}^{\varphi}-\overline{\dot{\zeta}\delta_{\zeta}\left(p'\right)}^{m\zeta} \tag{47}$$

$$f_T = -\frac{1}{a\overline{\cos^{\varphi}}^{\varphi}\Delta\lambda}\overline{u\delta_{\lambda}\left(T\right)}^{\lambda}-\frac{1}{a\overline{\cos\varphi}^{\varphi}\Delta\varphi}\overline{v\cos\varphi\delta_{\varphi}\left(T\right)}^{\varphi}-\overline{\dot{\zeta}\delta_{\varphi}\left(T\right)}^{m\zeta} \tag{48}$$

The slow tendencies are finally multiplied by the digital factors 0 or 1 depending on whether the location of the parameter is under the surface or in the free atmosphere respectively:

$$\begin{aligned} f_{u_{i,j,k}} &= f_{u_{i,j,k}} weightu_{i,j,k} \\ f_{v_{i,j,k}} &= f_{v_{i,j,k}} weightv_{i,j,k} \\ f_{w_{i,j,k}} &= f_{w_{i,j,k}} weight_{i,j,k} \\ f_{p'_{i,j,k}} &= f_{p'_{i,j,k}} weight_{i,j,k} \\ f_{T_{i,j,k}} &= f_{T_{i,j,k}} weight_{i,j,k} \end{aligned} \tag{49}$$

The tendencies of all the parameters under the surface are zero. This implies that those parameters keep their initial value and have to be set only once. The digital factors, here denoted with *weightu*, *weightv* and *weight* are processed in a special subroutine (*z_level.f90* of *src_artifdata.f90*) at the beginning of the program run. In the program code some coefficients can be separated from equations (1.44) - (1.48):

1. horizontal advection of u and v:

$$\begin{aligned} zfadsx(j) &= \frac{1/2}{a\cos\varphi_j \Delta\lambda} \\ zfadsy(j) &= \frac{1/2}{a\cos\varphi_j \Delta\varphi} \\ zfadvx(j) &= \frac{1/2}{a\cos\varphi_{j+1/2} \Delta\lambda} \\ zfpvoy(j) &= \frac{1/2}{a\cos\varphi_{j+1/2} \Delta\varphi} \end{aligned}$$

2. vertical advection of u:

$$\begin{aligned} zfkpx_{i+1/2,j,k+1/2} &= \frac{1}{2}\frac{w^*_{i,j,k+1/2} + w^*_{i+1,j,k+1/2}}{\Delta\left(p_0\right)_k + \Delta\left(p_0\right)_{k+1}} \\ zfkmx_{i+1/2,j,k-1/2} &= \frac{1}{2}\frac{w^*_{i,j,k-1/2} + w^*_{i+1,j,k-1/2}}{\Delta\left(p_0\right)_k + \Delta\left(p_0\right)_{k-1}} \end{aligned}$$

3. vertical advection of v:

$$\begin{aligned} zfkpx_{i,j+1/2,k+1/2} &= \frac{1}{2}\frac{w^*_{i,j,k+1/2} + w^*_{i,j+1,k+1/2}}{\Delta\left(p_0\right)_k + \Delta\left(p_0\right)_{k+1}} \\ zfkmx_{i,j+1/2,k-1/2} &= \frac{1}{2}\frac{w^*_{i,j,k-1/2} + w^*_{i,j+1,k-1/2}}{\Delta\left(p_0\right)_k + \Delta\left(p_0\right)_{k-1}} \end{aligned}$$

4. vertical advection of w:

$$\begin{aligned} zgcvx_{i,j,k} &= \frac{1}{4}\frac{w^*_{i,j,k-1/2} + w^*_{i,j,k+1/2}}{\Delta\left(p_0\right)_k} \\ zgavx_{i,j,k-1} &= \frac{1}{4}\frac{w^*_{i,j,k-11/2} + w^*_{i,j,k-1/2}}{\Delta\left(p_0\right)_{k-1}} \end{aligned}$$

In none of the previous equations a flux limiter does occur. The equations are not written in flux form.

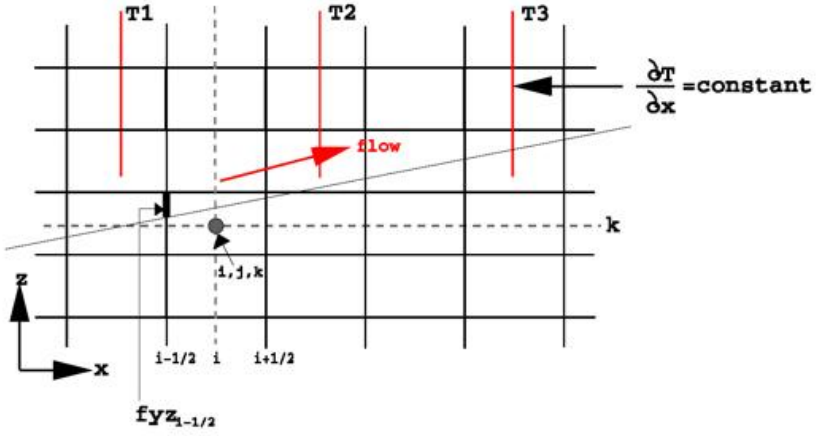

FIGURE 2.11a: Definition of the flux limiter in the grid.

Fig. 2.11a and Fig. 2.11b illustrate why the introduction of flux limiters in the advection terms would be faulty. The flux limiter $fyz_{i-1/2}$ is the fraction of the free interface of the volume $_{i,j,k}$ divided by the total area $\Delta y \Delta z$ of the interface. The so defined flux limiters take values between 0 and 1. If for example the temperature gradient $\frac{\partial T}{\partial x}$ is constant and the flow vector is parallel to the mountain's slope and constant with height, that means, a uniform flow uphill, then the advection $-u\frac{\partial T}{\partial x}$ is constant in the entire domain shown in Fig. 2.11a. Thus the volume element at $_{i,j,k}$ which is cut by mountains slope experiences the same temperature advection as all the other volume elements. For the mentioned volume element:

$$\frac{\partial T}{\partial t} = -\underline{fyz_{i-1/2}} u_{i-1/2} \left.\frac{\partial T}{\partial x}\right|_{i-1/2} \qquad \text{wrong!!} \tag{50}$$

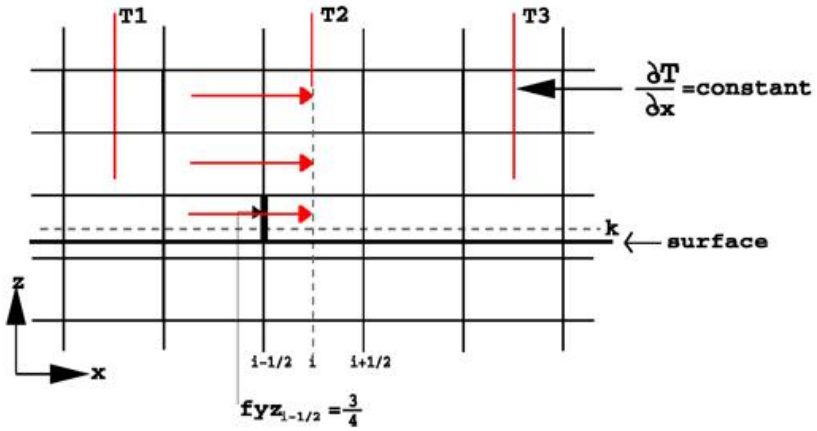

FIGURE 2.11b: Flux limiters for $\frac{\partial T}{\partial x}$ in the case of a horizontal terrain.

Fig. 2.11b illustrates the same situation in a simpler case. The current is uniform in x-direction and $\frac{\partial T}{\partial x} = const.$ The temperature gradient is assumed to be constant $\frac{\partial}{\partial z}\left(\frac{\partial T}{\partial x}\right) = 0$. The temperature tendency due to the advection $\frac{\partial T}{\partial t} = -u\frac{\partial T}{\partial x}$ is constant in the entire domain. If the surface would fill $\frac{1}{4}$ of the volume elements at level k, the free interfaces fyz of all the volume elements at that level would be $\frac{3}{4}$. If the carrier velocity u were premultiplied

by $fyz = \frac{3}{4}$ at level k, this would reduce the temperature tendency due to the advection of 25%, which would be wrong!

The explained treatment of the boundary values has to be done with much carefulness. The calculation of the corrrect derivatives close to the boundary are most important. The respond of the flow field is very sensitive with respect to the calculation of the boundary.

3 Time Integration and Numerical Solution

3.1 Fast Tendencies

According to the mode splitting time integration method proposed by Klemp and Wilhelmson (1978) the time step for stable explicit integration of the slow modes is subdivided into a number of small time steps. The tendencies represented in equations (1.21) - (1.25) are computed only once every big time step.

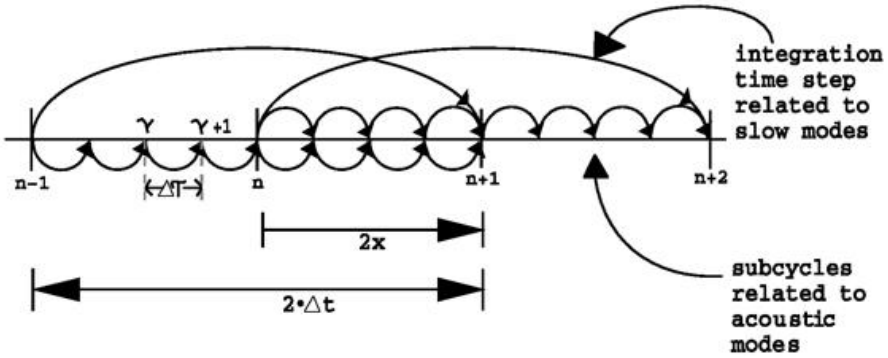

FIGURE 3.1: The Klemp Wilhelmson scheme.

Fig. 3.1 visualizes the mode splitting technique. The sound waves show up in the pressure gradient force, in the horizontal and vertical wind velocity and in the divergence term of the pressure tendency equation. High frequency oscillation is also caused by the buoyancy term. Additionally the vertical gravity wave propagation is also included in the reduced set of equations (1.21) - (1.25). As one can see from Fig. 3.1 the time step from n to $n+1$ is computet two times in the subcycle procedure. This will later be one of the reasons for approaches of a two time level integration scheme. The reduced set of equations which becomes subject to a split time integration using small time steps is revealed by rewriting the model equations (1.10) - (1.14) for the wind components, the pressure perturbation and the temperature in the following form:

$$\frac{\partial u}{\partial t} = \frac{1}{\rho a \cos^{\varphi}} \frac{\partial p'}{\partial \lambda} + f_u \tag{51}$$

$$\frac{\partial v}{\partial t} = \frac{1}{\rho a} \frac{\partial p'}{\partial \varphi} + fv \tag{52}$$

$$\frac{\partial w}{\partial t} = \frac{g}{\Delta p_0} \frac{\rho_0}{\rho} \frac{\partial p'}{\partial \zeta} + g \frac{\rho_0}{\rho} \left[\frac{T - T_0}{T} - \frac{T_0}{T} \frac{p'}{p_0} \right] + f_w \tag{53}$$

$$\frac{\partial p'}{\partial t} = g\rho_0 w - \frac{c_p}{c_v} p \left[D_h - \frac{g\rho_0}{\Delta p_0} \frac{\partial w}{\partial \zeta} \right] + f_{p'} \tag{54}$$

$$\frac{\partial T}{\partial t} = \frac{1}{\rho c_v} p \left[D_h - \frac{g\rho_0}{\Delta p_0} \frac{\partial w}{\partial \zeta} \right] + f_T \tag{55}$$

The threedimensional divergence D_3 in equation (1.7) is separated into a horizontal part D_h

$$D_h = \frac{1}{a\cos\varphi}\left[\frac{\partial u}{\partial\lambda} + \frac{\partial}{\partial\varphi}(v\cos\varphi)\right] \tag{56}$$

and a vertical part D_v

$$D_v = -\frac{g\rho_0}{\Delta p_0}\frac{\partial w}{\partial\zeta} \tag{57}$$

where the transformation (1.26) was applied in order to rewrite $\frac{\partial}{\partial z}$.

The set of equation (2.1) - (2.5) with acoustically active terms the big leapfrog time step $2\Delta t$ (see fig. 2.1) is subdivided into a number of small timesteps $\Delta\tau$. $2\Delta t$ must be an integer number times the small time step $\Delta\tau$. $\Delta\tau$ is determined by the fastest signal velocity, this means the sound speed:

$$\Delta\tau \leq \frac{\Delta s}{\sqrt{2}c_s} \qquad c_s = \text{ velocity of sound} \tag{58}$$

Δs is the horizontal spatial gridsize, $\Delta s = a\Delta\lambda = a\Delta\varphi$ with $\cos\varphi = 1$, supposed $\Delta\lambda = \Delta\varphi$. The vertical gridsize does not matter as long as the integration is carried out implicitely. For test cases the integration is sometimes carried out explicitely, then $\Delta\tau$ is limited by

$$\Delta\tau \leq \frac{\Delta z_{min}}{\sqrt{2}c_s} \tag{59}$$

where Δz_{min} is the minimum vertical grid spacing (usually this is the thickness of the lowest model layer).

Concerning the finite difference algorithms related to fast modes, second-order accurate differencing is used for spatial discretization of the reduced set of equations (2.1) - (2.5). The vertical velocity, the pressure pertubation and in the current model also $T - T_0$ are subject to time averaging with respect to the small time step $\Delta\tau$. Time averaging is realized in the same way as in the program code of the operationel LM

$$\overline{\psi}^{\tau} = \frac{1}{2}(1+\beta_{sw})\,\psi^{\nu+1} + \frac{1}{2}(1-\beta_{sw})\,\psi^{\nu}$$

see LM operational version (Doms and Schaettler, 1999). $\nu+1$ is the future time level related to the small steps $\Delta\tau$. The subcycle procedure is a 2 time level integration scheme. To simplify the notations we write

$$\beta^+ = \frac{1}{2}(1+\beta_{sw}) \qquad \text{and} \qquad \beta^- = \frac{1}{2}(1-\beta_{sw}) = 1-\beta^+$$

the model uses $\beta_{sw} = 0.4$ (i.e. $\beta^+ = 0.7$, $\beta^- = 0.3$). The time averaging is then realized with

$$\overline{\psi}^{\tau} = \beta^+\psi^{\nu+1} + \beta^-\psi^{\nu} \qquad \text{for} \qquad \psi = w, p', (T-T_0) \tag{60}$$

The finite difference equations derived from (2.1) - (2.6) are written in the following form, using definitions from Section 2.4.

$$u^{\nu+1} - u^{\nu} = -\frac{\Delta\tau}{\overline{\rho^n}^{\lambda} a\overline{\cos^{\varphi}}^{\varphi}\Delta\lambda}\delta_{\lambda}p'^{\nu} + f_u^n\Delta\tau \tag{61}$$

$$v^{\nu+1} - v^{\nu} = -\frac{\Delta\tau}{\overline{\rho^n}^{\varphi} a\Delta\varphi}\delta_{\varphi}p'^{\nu} + f_v^n\Delta\tau \tag{62}$$

$$\begin{aligned} w^{\nu+1} - w^{\nu} = {} & g\frac{\Delta\tau}{\Delta p_o}\frac{\overline{\rho_0}^{h\zeta}}{\overline{\rho^n}^{h\zeta}}\left[\beta^+\delta_{\zeta}\left(p'\right)^{\nu+1} + \beta^-\delta_{\zeta}\left(p'\right)^{\nu}\right] \\ & -g\Delta\tau\frac{\overline{\rho_0}^{h\zeta}}{\overline{\rho^n}^{h\zeta}}\left[\beta^+\overline{\frac{T_0}{T^n p_0}p'^{\nu+1}}^{h\zeta} + \beta^-\overline{\frac{T_0}{T^n p_0}p'^{\nu}}^{h\zeta}\right] \\ & -g\Delta\tau\frac{\overline{\rho_0}^{h\zeta}}{\overline{\rho^n}^{h\zeta}}\left[\beta^+\overline{\frac{T^{\nu+1}-T_0}{T^n}}^{h\zeta} + \beta^-\overline{\frac{T^{\nu}-T_0}{T^n}}^{h\zeta}\right] + f_w^n\Delta\tau \end{aligned} \tag{63}$$

$$\begin{aligned} p'^{\nu+1} - p'^{\nu} = {} & g\rho_0\Delta\tau\left[\beta^+\overline{w^{\nu+1}}^{m\zeta} + \beta^-\overline{w^{\nu}}^{m\zeta}\right] \\ & +g\frac{\rho_0\Delta\tau}{\Delta p_0}\frac{p^n c_p}{c_v}\left[\beta^+\delta_{\zeta}\left(fxyw^{\nu+1}\right) + \beta^-\delta_{\zeta}\left(fxyw^{\nu}\right)\right] \\ & -\Delta\tau\frac{p^n c_p}{c_v}D_h^{\nu+1} + f_{p'}^n\Delta\tau \end{aligned} \tag{64}$$

$$\begin{aligned} T^{\nu+1} - T^{\nu} = {} & g\frac{\rho_0\Delta\tau}{\Delta p_0}\frac{p^n}{\rho^n c_v}\left[\beta^+\delta_{\zeta}\left(fxyw^{\nu+1}\right) + \beta^-\delta_{\zeta}\left(fxyw^{\nu}\right)\right] \\ & -\Delta\tau\frac{p^n}{\rho^n c_v}D_h^{\nu+1} + f_T^n\Delta\tau \end{aligned} \tag{65}$$

The horizontal divergence D_h is computed at the centre of a grid box i, j, k even then when the volume contains only a little piece of air. The horizontal divergence reads:

$$D_h^{\nu+1} = \frac{1}{a\overline{\cos\varphi}^{\varphi}\Delta\lambda}\delta_{\lambda}\left(fyzu^{\nu+1}\right) + \frac{1}{a\overline{\cos\varphi}^{\varphi}\Delta\varphi}\delta_{\varphi}\left(\cos\varphi fxzv^{\nu+1}\right) \tag{66}$$

the vertical part D_v of equation (2.7) is:

$$D_v = \beta^+\delta_{\zeta}\left(fxyw^{\nu+1}\right) + \beta^-\delta_{\zeta}\left(fxyw^{\nu}\right) \tag{67}$$

The horizontal divergence D_h is first computed with the new velocities $u^{\nu+1}$ and $v^{\nu+1}$ at the new time level $\nu+1$. The equations (2.11), (2.12) and (2.16) remain in the explicit part of the integration procedure if the calculation is carried out implicitely. Most important now is the occurence of the so called flux limiters fxz, fyz and fxy. The last two letters denote the interfaces of a control volume, see Fig. 2.2. xz for example denotes an interface stretched in the xz-plane. All the flux limiters are non dimensional numbers between 0 and 1.

$fxy = \frac{s_{xy}}{\Delta x\Delta y}$ where s_{xy} is the real free interface expressed in m^2 and $\Delta x\Delta y$ is the total area of the interface. In case of fyz that reads: $fyz = \frac{s_{yz}}{\Delta y\Delta z}$. Only through these factors, in the divergence term the current feel the boundary. If the slope is small, $\frac{\Delta z}{\Delta x} < 1$ the factors are decreasing smoothly to zero as the flow is running in x-direction. Thus the current does not notice a step size topography but a smooth terrain as it should be. This is the most important difference of the shaved element method with respect to the Legoland topography. In equation (2.14) the flux limiters are affecting the pressure and the pressure again affects the vertical velocity. The term $g\rho_0 w$ is not premultiplied by the flux limiters. As we see, the

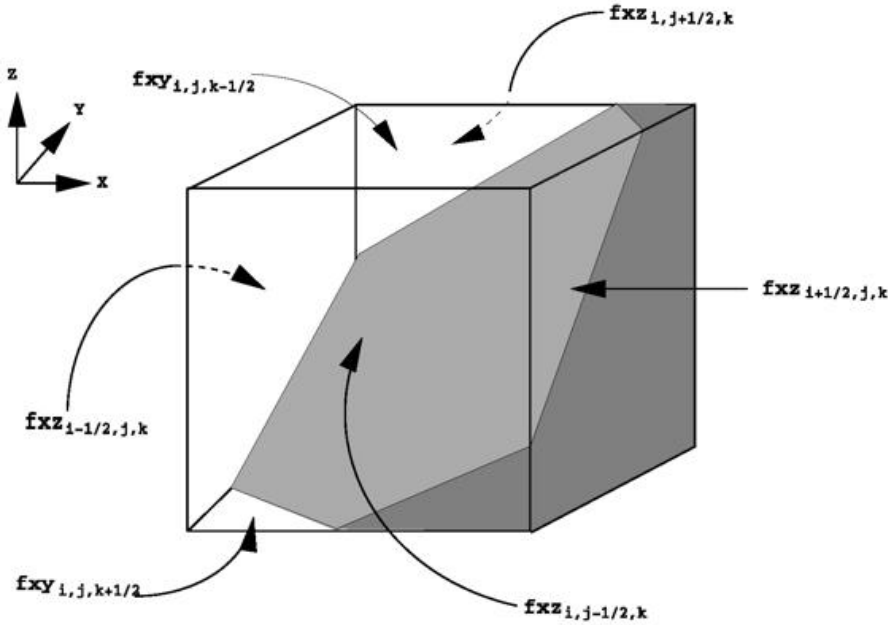

FIGURE 2.2: Flux limiters in three dimensions.

reference atmosphere is hiding here.

$$\begin{aligned} \frac{\partial p_0}{\partial z} &= -g\rho_0 \qquad \text{this implies} \\ g\rho_0 w &= -w\frac{\partial p_0}{\partial z} \end{aligned}$$

but $-w\frac{\partial p_0}{\partial z}$ is an advection term and above it was stated that the advection must be without a flux limiter.

3.2 Method of Solution

A vertically implicit integration scheme is applied for the solution of equation (2.1) - (2.5). Equations (2.3), (2,4) and (2.5) for the vertical velocity, the pressure perturbation and the temperature become coupled due to time averaging. In the current version the temperature deviation term

$$\frac{T^\nu - T_0}{T^n}$$

is drawn into the implicit calculation procedure. The temperature equation (2.15) in differencing form can be written as follows:

$$T_k^{\nu+1} = T_k^\nu + R_k \tag{68}$$

where R_k is the rest of the right hand side of equation. From (2.18) we gain:

$$T_k^{\nu+1} - (T_0)_k = T_k^\nu - (T_0)_k + R_k$$

respectively

$$\frac{T_k^{\nu+1} - (T_0)_k}{T_k^n} = \frac{T_k^\nu - (T_0)_k}{T_k^n} + \frac{R_k}{T_k^n} \tag{69}$$

In (2.19) we call $\frac{T_k^{\nu+1}-(T_0)_k}{T_k^n} = s_k^{\nu+1}$ and

$$\begin{aligned} \frac{T_k^\nu - (T_0)_k}{T^n} &= s_k^\nu \qquad \text{(2.19) then becomes} \\ s_k^{\nu+1} &= s_k^\nu + \frac{R_k}{T_k^n} \end{aligned} \tag{70}$$

with the substitutions (A.1) - (A.7), see appendix, the equation for the vertical velocity (2.13) can be written in the following way:

$$\begin{aligned} w_{k-1/2}^{\nu+1} - w_{k-1/2}^\nu &= g\Delta\tau 2y_{k-1/2}\left[\beta^+\left(p_k^{\nu+1} - p_{k-1}^{\nu+1}\right) + \beta^-\left(p_k^\nu - p_{k-1}^\nu\right)\right] \\ &\quad -g\Delta\tau\beta^+ 2y_{k-1/2}\left[(\Delta p_0)_{k-1}\frac{1}{2}x_k p_k^{\nu+1} + (\Delta p_0)_k\frac{1}{2}x_{k-1}p_{k-1}^{\nu+1}\right] \\ &\quad -g\Delta\tau\beta^- 2y_{k-1/2}\left[(\Delta p_0)_{k-1}\frac{1}{2}x_k p_k^{\nu} + (\Delta p_0)_k\frac{1}{2}x_{k-1}p_{k-1}^{\nu}\right] \\ &\quad +g\Delta\tau\beta^+ 2y_{k-1/2}\left[(\Delta p_0)_{k-1}\frac{1}{2}s_k^{\nu+1} + (\Delta p_0)_k\frac{1}{2}s_{k-1}^{\nu+1}\right] \\ &\quad +g\Delta\tau\beta^- 2y_{k-1/2}\left[(\Delta p_0)_{k-1}\frac{1}{2}s_k^{\nu} + (\Delta p_0)_k\frac{1}{2}s_{k-1}^{\nu}\right] \end{aligned} \tag{71}$$

After reorganizing the terms and applying (A.8) - (a.10), see appendix, the equation for the vertical velocity reads:

$$\begin{aligned} w_{k-1/2}^{\nu+1} &= w_{k-1/2}^\nu + C_{k-1/2}^w + \beta^+ C_{k-1/2}^{w1}\left[\alpha_{k-1/2}^B p_k^{\nu+1} - \alpha_{k-1/2}^T p_{k-1}^{\nu+1}\right. \\ &\quad \left. + \left((\Delta p_0)_{k-1}\frac{1}{2}s_k^{\nu+1} + (\Delta p_0)_k\frac{1}{2}s_{k-1}^{\nu+1}\right)\right] \end{aligned} \tag{72}$$

$$\begin{aligned} C_{k-1/2}^w &= (f_w^n)_{k-1/2}\,\Delta\tau + \beta^- C_{k-1/2}^{w1}\left[\alpha_{k-1/2}^B p_k^{\nu} - \alpha_{k-1/2}^T p_{k-1}^{\nu}\right. \\ &\quad \left. + \left((\Delta p_0)_{k-1}\frac{1}{2}s_k^{\nu} + (\Delta p_0)_k\frac{1}{2}s_{k-1}^{\nu}\right)\right] \end{aligned} \tag{73}$$

consequently the pressure tendency equation from (2.14) reads in differencing form:

$$\begin{aligned} p_k^{\nu+1} - p_k^\nu &= \left(f_p^n\right)_k\Delta\tau - \frac{p_k^n c_p}{c_v}\left(D_h^{\nu+1}\right)_k\Delta\tau + \beta^-\frac{1}{2}g\Delta\tau\,(\rho_0)_k \\ &\quad \left(w_{k+1/2}^\nu + w_{k-1/2}^\nu\right) + \beta^-\frac{g\,(\rho_0)_k}{(\Delta p_0)_k}\frac{p_k^n c_p}{c_v}\Delta\tau \\ &\quad \left(fxy_{k+1/2}w_{k+1/2}^\nu - fxy_{k-1/2}w_{k-1/2}^\nu\right) + \beta^+\frac{1}{2}g\Delta\tau \\ &\quad (\rho_0)_k\left(w_{k+1/2}^{\nu+1} + w_{k-1/2}^{\nu+1}\right) + \beta^+\frac{g\,(\rho_0)_k}{(\Delta p_0)_k}\frac{p_k^n c_p}{c_v}\Delta\tau \\ &\quad \left(fxy_{k+1/2}w_{k+1/2}^{\nu+1} - fxy_{k-1/2}w_{k-1/2}^{\nu+1}\right) \end{aligned} \tag{74}$$

Applying (A.11) and (A.12), (2.24) reads:

$$p_k^{\nu+1} = p_k^{\nu} + C_k^p + \beta^+ C_k^{p2}\left(w_{k+1/2}^{\nu} + w_{k-1/2}^{\nu}\right) + \beta^+ C_k^{p1} \left(fxy_{k+1/2} w_{k+1/2}^{\nu+1} - fxy_{k-1/2} w_{k-1/2}^{\nu+1}\right) \tag{75}$$

$$C_k^p = \left(f_p^n\right)_k \Delta\tau - \frac{p_k^n c_p}{c_v} \Delta\tau \left(D_h^{\nu+1}\right)_k + \beta^- C_k^{p2} \left(w_{k+1/2}^{\nu} + w_{k-1/2}^{\nu}\right) + \beta^- C_k^{p1} \left(fxy_{k+1/2} w_{k+1/2}^{\nu} - fxy_{k-1/2} w_{k-1/2}^{\nu}\right) \tag{76}$$

The temperature equation (2.15) completes the set of differencing equations:

$$T_k^{\nu+1} = T_k^{\nu} + \left(f_T^n\right)_k \Delta\tau - \frac{p_k^n}{\rho_k^n c_v} \Delta\tau \left(D_h^{\nu+1}\right)_k + \frac{g\left(\rho_0\right)_k \Delta\tau}{\left(\Delta\rho_0\right)_k} \frac{p_k^n}{\rho_k^n c_v} \left[\beta^+ \left(fxy_{k+1/2} w_{k+1/2}^{\nu+1} - fxy_{k-1/2} w_{k-1/2}^{\nu+1}\right) + \beta^- \left(fxy_{k+1/2} w_{k+1/2}^{\nu} - fxy_{k-1/2} w_{k-1/2}^{\nu+1}\right)\right] \tag{77}$$

As can be seen, the flux limiters show up in the vertical derivative of w, which is the vertical part of the divergence and they occur also in the horizontal part of the divergence $D_h^{\nu+1}$. For the vertically implicit solution procedure equations (2.22), (2.25) and (2.27) form a coupled system. Eliminating $p_k^{\nu+1}$ and $s_k^{\nu+1}$ at the future time step the w-equation (2.22) leaves $w^{\nu+1}$ as the only unknown. In order to eliminate $p_k^{\nu+1}$ and $p_{k-1}^{\nu+1}$ we use equation (2.25). The derivation of the additional term in (2.22)

$$\left(\left(\Delta p_o\right)_{k-1} \frac{1}{2} s_k^{\nu+1} + \left(\Delta p_0\right)_k \frac{1}{2} s_{k-1}^{\nu+1}\right) \tag{78}$$

which contains the vertical velocities at time step $\nu+1$ too is outlined in the appendix (A.13) - (A.16). Finally (A.15) with (A.16) are used in order to substitute the parenthesis (2.28) in the equation for the vertical velocity (2.22). After rearranging the terms this yields a linear tridiagonal equation system for $w^{\nu+1}$ which is written in the form:

$$a_{k-1/2} w_{k-11/2}^{\nu+1} + b_{k-1/2} w_{k-1/2}^{\nu+1} + c_{k-1/2} w_{k+1/2}^{\nu+1} = d_{k-1/2} \tag{79}$$

The matrix diagonals a, b and c and the inhomogeneous part d read:

$$a_{k-1/2} = -\beta^{+2} C_{k-1/2}^{w1} \left[\alpha_{k-1/2}^T \left(C_{k-1}^{p1} fxy_{k-11/2} - C_{k-1}^{p2}\right) - \left(\Delta p_0\right)_k C_{k-1}^{T1} fxy_{k-11/2}\right] \tag{80}$$

$$b_{k-1/2} = 1 + \beta^{+2} C_{k-1/2}^{w1} \left[\alpha_{k-1/2}^B \left(C_k^{p1} fxy_{k-1/2} - C_k^{p2}\right) + \alpha_{k-1/2}^T \left(C_{k-1}^{p1} fxy_{k-1/2} + C_{k-1}^{p2}\right) + \left(\Delta p_0\right)_{k-1} C_k^{T1} fxy_{k-1/2} - \left(\Delta p_0\right)_k C_{k-1}^{T1} fxy_{k-1/2}\right] \tag{81}$$

$$c_{k-1/2} = -\beta^{+2} C_{k-1/2}^{w1} \left[\alpha_{k-1/2}^B \left(C_k^{p1} fxy_{k+1/2} + C_k^{p2}\right) + \left(\Delta p_0\right)_{k-1} C_k^{T1} fxy_{k+1/2}\right] \tag{82}$$

$$d_{k-1/2} = w_{k-1/2}^{\nu} + C_{k-1/2}^w + \beta^+ C_{k-1/2}^{w1} \left[\alpha_{k-1/2}^B \left(p_k^{\nu} + C_k^p\right) - \alpha_{k-1/2}^T \left(p_{k-1}^{\nu} + C_{k-1}^p\right) + C_{k-1/2}^T\right] \tag{83}$$

The coefficients contain the flux limiters fxy and some additional terms with factors C^{T1} and C^T in the inhomogeneous part d which have their origin in the temperature equation. Actually, according to a suggestion of Janjic (19xx), the vertical advection of pressure pertubation $w\frac{\partial p'}{\partial z}$ should also be put into the implicit scheme - this wopuld further stabilize the integration. The matrix equation (2.29) can be solved for $w^{\nu+1}$ using a standard tridiagonal solver, provided that the vertical velocity at the upper and lower boundary is specified. At the top boundary the vertical velocity is set to zero. At the lower boundary we must allow the flow running parallel to the slope. Thus an appropriate value for w has to be taken at the lower boundary.

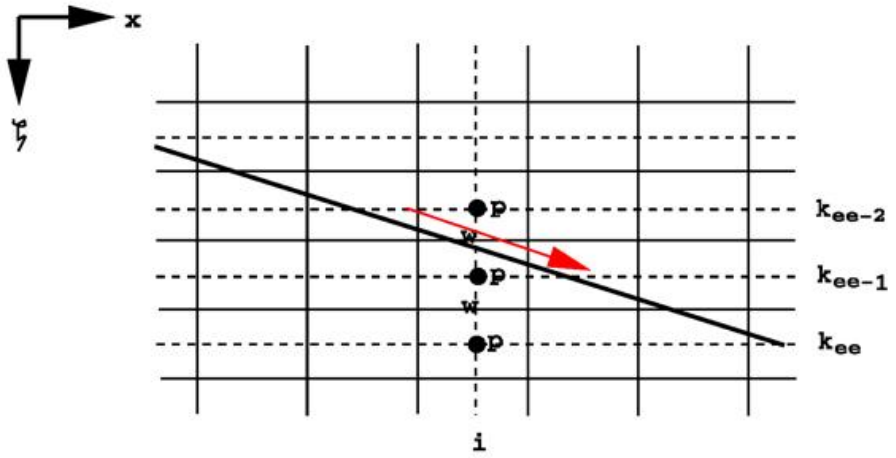

FIGURE 2.3: Boundary values of w under the surface

In Fig. 2.3 the volume element at $_{i,kee}$ lies completely under the surface. The prognostic equation (2.21) for the vertical velocity at $_{i,kee-11/2}$ requires the two pressure values $p_{i,kee-1}$ and $p_{i,kee-2}$ in order to calculate the pressure gradient at $_{i,kee-11/2}$. Since the pressure at $_{i,kee-1}$ is available this is no problem. The pressure at $_{i,kee-1}$ needs the vertical velocity at $_{i,kee-1/2}$. Normally this velocity would be not available but because it is a boundary value which is calculated according to equation (1.39) or (1.42) respectively. In the current model (1.39) or (1.42) is applied every small time step $\Delta\tau$. This is better rather than holding the boundary values constant during the entire subcycle procedure. The best value for the vertical velocity would yield if $w_{i,kee-1/2}$ were calculated dependent on the horizontal velocity with the demand that the total flow vector $\vec{v} = (u, v, w)$ at the surface is exactly tangential to the surface. Such a method is not implemented yet.

3.1 Structure of the Tridiagonal Matrix

In Section 1 the boundary values, necessary for the calculation of the derivatives close to the boundary were explained. The implicit scheme is related to the elimination of $w^{\nu+1}$ in a vertical column. The vertical do loop starts at k+1/2 and would normally end at $_{kee-1/2}$ because $w_{kee-1/2}$ is the lower boundary value. But kee is dependent on the orography, that means, kee is a function of i and j: kee = f(i,j) or in the current model: kee = kfin(i,j). The field kfin(i,j), contains the lowest k values at i,j this is the lowest level for w, the location of the lower boundary value. kfin(i,j) is calculated at the beginning of the program run in subroutine src_artifdata.f90 or z_level.f90 and is available in fast_waves.f90. The end of the do loop in vertical direction would be kee which is a function of i,j. Thus the k-loop had to be disposed to the interior of loop i and j; but this is not suitable. The tridiagonal equation system for $w^{\nu+1}$ runs as follows see Fig. 3.4.

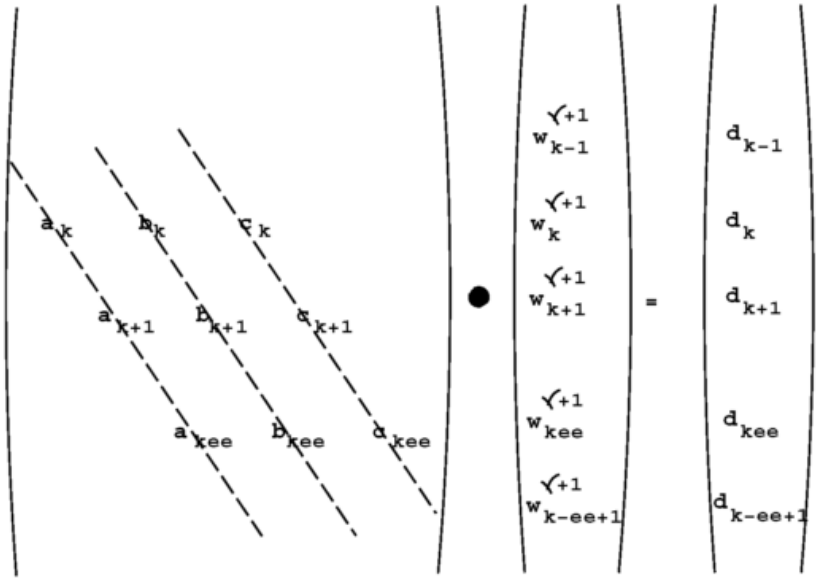

FIGURE 3.4: The matrix of the 1-d implicit scheme.

If we demand from the matrix system that the boundary value w_{kee} should be retrieved, then the coefficients and the inhomogeneous part read:

$$\begin{aligned} a_{kee} &= 0 \\ b_{kee} &= 1 \\ c_{kee} &= 0 \\ d_{kee} &= w^{\nu}_{kee} \end{aligned}$$

With these values w^{ν}_{kee} is reproduced in $w^{\nu+1}_{kee}$

For k > kee we set:

$$\begin{aligned} a_k &= 0 \\ b_k &= 1 \\ c_k &= 0 \\ d_k &= 0 \end{aligned}$$

which generates $w^{\nu+1}_k = 0$ for k > kee.

With this structure of tridiagonal system the do loops within the Gauss solver can be nested in the normal way: k-loop outside, j- and i-loop inside, and again this constellation is supposed to be numerically efficient.

4 Numerical Smoothing

4.1 Horizontal Diffusion

The program needs horizontal and vertical diffusion. At some boundaries some action is necessary in order to process the derivatives close to the boundaries. Here the second order

differencing scheme breaks down to order one. But there is another serious problem. Since the model only uses the complete spatial differences in the derivatives this implies very high errors for small volume elements in the calculation of the divergence term which acts on the pressure tendency equation (see Fig. 4.1). If the volume element is very small it kills the program run immedeately before one big time step is completed.

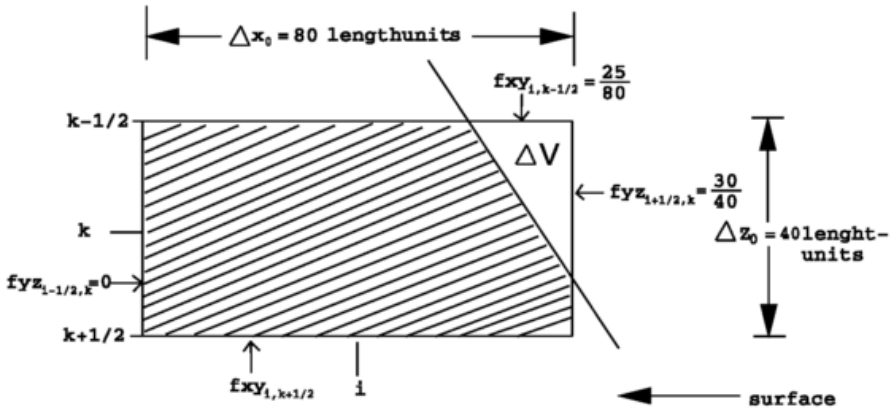

FIGURE 4.1: A small cut cell

Fig. 4.1 illustrates why this error occurs in the divergence term or in the pressure tendency equation which is used to represent the continuity equation. The correct volume Δv can be calculated as:

$$\Delta V = \frac{1}{2} fxy_{i,k-1/2} fxy_{j+1/2,k} \Delta x_0 \Delta z_0 \tag{84}$$

$$\begin{aligned} \frac{\Delta M}{\Delta t} = & -\rho(\Delta v) \left[\left(fyz_{i+1/2,k} u_{i+1/2,k} - fyz_{i-1/2,k} u_{i-1/2,k} \right) \Delta z_0 \right. \\ & \left. + \left(fxy_{i,k-1/2} w_{i,k-1/2} - fxy_{i,k+1/2} w_{i,k+1/2} \right) \Delta x_0 \right] \end{aligned} \tag{85}$$

Equation (3.1) represents the change of mass within the triangle ΔV. The continuity equation is retrieved by dividing (3.1) by ΔV :

$$\begin{aligned} \frac{\frac{\Delta M}{\Delta V}}{\Delta t} = & -\rho(\Delta v) \left[\left(fyz_{i+1/2,k} u_{i+1/2,k} - fyz_{i-1/2,k} u_{i-1/2,k} \right) \right. \\ & \frac{\boldsymbol{\Delta z_0}}{\frac{1}{2} fxy_{i,k-1/2} fyz_{i+1/2,k} \Delta x_0 \boldsymbol{\Delta z_0}} + \left(fxy_{i,k-1/2} w_{i,k-1/2} \right. \\ & \left. \left. - fxy_{i,k+1/2} w_{i,k+1/2} \right) \frac{\boldsymbol{\Delta x_0}}{\frac{1}{2} fxy_{i,k-1/2} fyz_{i+1/2,k} \boldsymbol{\Delta x_0} \Delta z_0} \right] \end{aligned} \tag{86}$$

divided by $\rho(\Delta v)$ yields:

$$\begin{aligned} \frac{1}{\rho} \frac{\Delta \rho}{\Delta t} = & -\left[\frac{1}{\Delta x_0} \left(fyz_{i+1/2,k} u_{i+1/2,k} - fyz_{i-1/2,k} u_{i-1/2,k} \right) \right. \\ & \frac{1}{\frac{1}{2} fxy_{i,k-1/2} fyz_{i+1/2,k}} + \frac{1}{\Delta z_0} \\ & \left(fxy_{i,k-1/2} w_{i,k-1/2} - fxy_{i,k+1/2} w_{i,k+1/2} \right) \\ & \left. \frac{1}{\frac{1}{2} fxy_{i,k-1/2} fyz_{i+1/2,k}} \right] \end{aligned} \tag{87}$$

From equation (3.4) it becomes obvious why the continuity equation or in the current model the pressure tendency equation cannot work for small volume elements. The current model uses the complete differences $\frac{1}{\Delta x_0}$ and $\frac{1}{\Delta z_0}$ but in reality the volume element is much smaller, the space differences Δx_0 and Δz_0 have to be premultiplied by $\left(\frac{1}{2} f x y_{i,k-1/2} f y z_{i+1/2,k}\right)$. This factor is missing in the current model. Unfortunately this factor can be of any smallness and in addition the factor would occure in the horizontal part of the divergence too. This is outside the implicit computation procedure which is directed only in the vertical. Thus the stability criterion would be dependent on the smallest volume element if the factor would be taken into account.

In order to overcome the problem we have to remove the very small volume elements. This is done in subroutine src_artifdata.f90 or in z_level.f90 respectively. Generally volume elements smaller than 1/60 or 1/120 of the total volume of an element are removed. In idealized experiments with a smooth Gaussian mountain the surface will be much rougher. The other volume elements greater than 1/60 or 1/120 are still not calculated correctly because of the mentioned missing factor in the divergence term. The current model is suffering from these deficiencies. The incorrect calculation of the derivatives in the divergence term results into wrong tendencies which appear as an overreaction and creates peaks of the parameters when stepped forward. Of course those peaks show up in the cut volume elements this means direct at the boundary. When we apply a diffusion in order to damp down the overreaction it should mainly act direct at the boundary. The horizontal diffusion is carried out sequentially, first in x- then in y-direction. The fourth order diffusion is drawn to the boundary in the following way:

```
work = 0
!
  do j = jstart-1 , jend+1
  do i = istart-1 , iend+1
    work(i,j) = weight(i+1,j)*(s(i+1,j)-s(i,j)) &
              - weight(i-1,j)*(s(i,j)-s(i-1,j))
  enddo
  enddo
!
  do j = jstart-1 , jend+1
  do i = istart-1 , iend+1
    dcoeff1 = dcoeff
    if((weight(i+1,j) < 0.5).and.(weight(i,j) > 0.5) dcoeff1 = alam
    if((weight(i-1,j) < 0.5).and.(weight(i,j) > 0.5) dcoeff1 = alam
    zsten = -dcoeff1*(weight(i+1,j)-(work(i+1,j)-work(i,j)) &
                     -weight(i-1,j)-(work(i,j)-work(i-1,j)))
!
    sten(i,j) = sten(i,j)+zsten
  enddo
  enddo
endif
```

In case if there is no boundary, the weight-factors are all 1. In this case the diffusion is working like in the operational LM with dcoeff1 = dcoeff which is the diffusion coefficient of the operational version. Now if the boundary is at the east side (see Fig. 4.2) the value at i+1 is beyond the boundary and weight (i+1,j) = 0. The program code above is acting in the following way:

$$\begin{aligned} work\,(i,j) &= -\Delta s_1 & \Delta s_1 &= s\,(i,j) - s\,(i-1,j) \\ work\,(i-1,j) &= \Delta s_1 - \Delta s_2 & \Delta s_2 &= s\,(i-1,j) - s\,(i-2,j) \end{aligned}$$

$$\begin{aligned} zsten &= -alam\,[-\,(work\,(i,j) - work\,(i-1,j))] \\ zsten &= alam\,[work\,(i,j) - work\,(i-1,j)] \\ zsten &= alam\,[\Delta s_2 - 2\Delta s_1] \end{aligned} \tag{88}$$

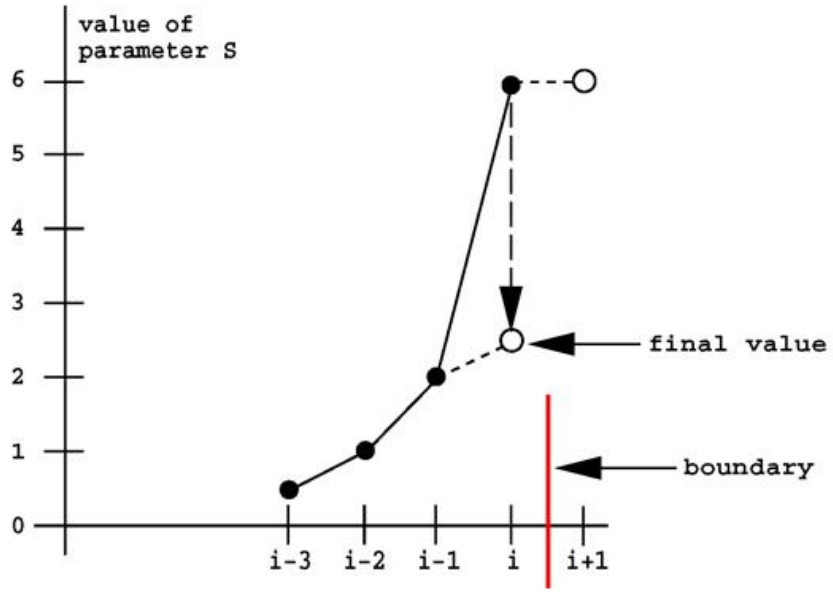

FIGURE 4.2: Action of horizontal diffusion

In the example of Fig. 4.2 $\Delta s_1 = 4$ and $\Delta s_2 = 1$ the tendency according to diffusion yields:

$$zsten = -7alam \tag{89}$$

zsten is negativ which implies, the fluctuating crazy boundary value s(i,j) = 6 is towed to lower values and calmed down. The final value, indicated in Fig. 4.2 with the short dashed line will be 2.5. Then $\Delta s_1 = \frac{1}{2}\Delta s_2$ and according to equation (3.5) zsten = 0. If a boundary is there the diffusion coefficient changes to

$$alam = \frac{1}{12dt2} \tag{90}$$

As illustrated in Fig. 4.2 the final value, caused by the diffusion, fits well into the general spatial distribution of the parameter s. But still the final value cannot represent the exact gradient of s if the gradient is unequal zero. Only if $\frac{\partial s}{\partial x} = 0$ then $\Delta s_2 = 0$ and from $\Delta s_1 = \frac{1}{2}\Delta s_2$ follows $\Delta s_1 = 0$; this implies, the final value s_i would be on the straight line defined by s_{i-2} and s_{i-1}. But it is very important to represent the correct vertical gradients of the velocity components and the temperature. The diffusion must not bend the profile off the gradient which has been established at gridpoints above the obstacle.

4.1 Vertical Diffusion

In order to sustain the established vertical gradient of the velocity and the temperature, the vertical diffusion in the current model effects on the difference function $s1(z) = s(z) - s_{lin}$.

The s(z) is the vertical profile of a parameter, for example u at gridpoint i,j (see Fig. 4.3). s_{lin} is the linear function of regression determined by the six last values above the surface. s_{lin} represents the vertical gradient of s(z) at the boundary properly. This is especially for the temperature gradient very important, otherwise the diffusion would generate artificial buoyancy which finally implies artificial motion at the obstacle.

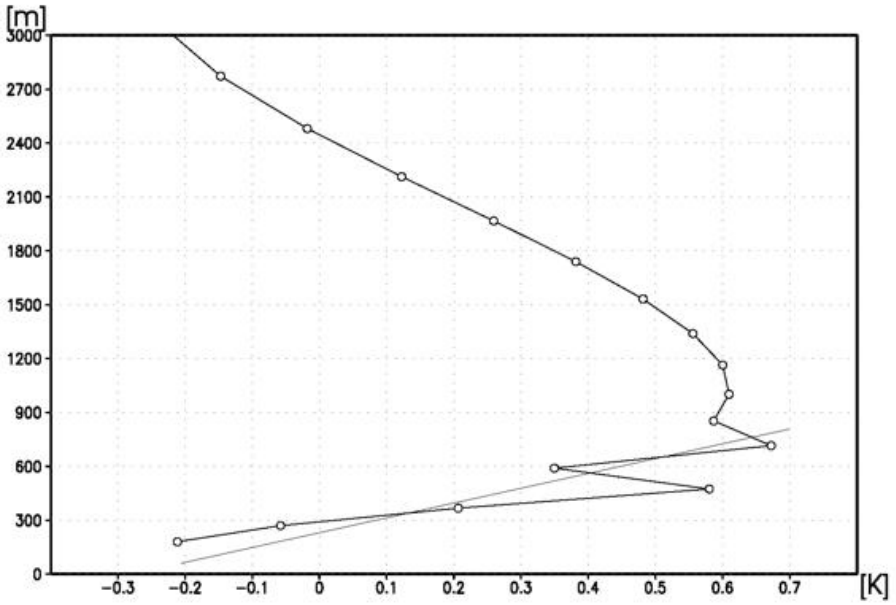

FIGURE 4.3: Vertical profile of the u-velocity with linear regression function.

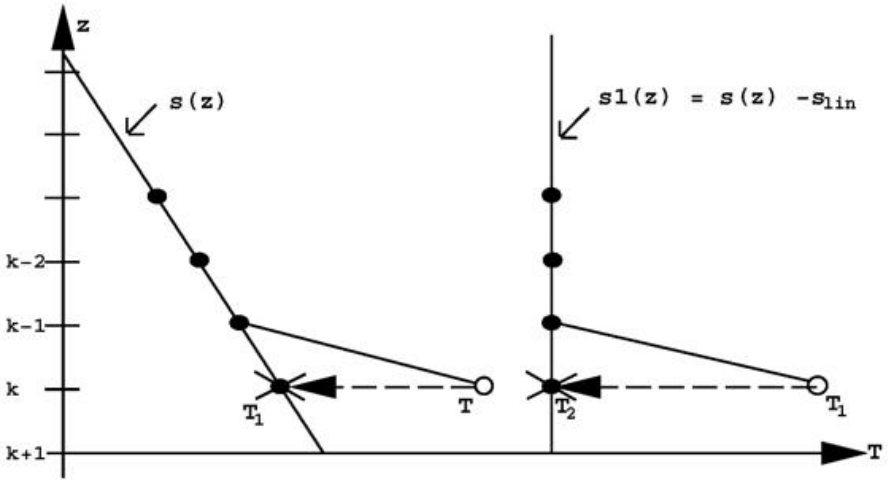

FIGURE 4.5: Action of diffussion for a temperature profile.

Fig. 4.4 shows a linear temperature profile s(z). The corresponding difference function s1(z) = s(z) - s_{lin} is represented on the right side of Fig. 3.4. Applying equation (3.5) for the vertical diffusion an s1(z) yields Δs_2 = s1(k-1) -s1(k-2) = 0 zsten in equation (3.5) is negativ and T_1 in Fig. 3.4 (right side) is nudged towards T_2. Since $\Delta s_2 = 0$ this demands $\Delta s_1 = 0$ if zsten should be 0. Δs_1 = s1(k)-s1(k-1)=0 this imlpies s1(k) = s1(k-1) in the equlibrium state when T_1 equals T_2. With this construction of the vertical diffusion the value T (Fig. 3.4, left side) is nudged towards T_1 which fits well into the vertical temperature distribution and in this way the vertical diffusion does not disturb an established vertical gradient. One particularity of the vertical diffusion has to be mentioned here: The diffusion coefficient is

decaying rapidly with height. Actually we need the diffusion right at the boundary rather than in the free flow domain. The existence of the vertical diffusion is absolutly necessary. One can drop horizontal diffusion rather than vertical diffusion at the boundary.

5 Results for Idealized Test Cases

The ability of the shaved element method can be tested on idealized experiments. The results presented below are carried out with a Gaussian mountain of $h_0 = 400$ m top height. The half width is set to $a = 10$ km. Since $\Delta x = 2$ km there are $5\Delta x$ to cover the half width. Thus the mountain is well resolved by sufficient gridpoints. The formula of the topography reads:

$$h(x,y) = \frac{h_0}{1 + \frac{x^2+y^2}{a^2}} \tag{91}$$

h_0	=	$400m$	top height of mountain
a	=	$10000m$	half width of mountain
u_0	=	10m/s	basic current.

The temperature lapse rate corresponds to an atmospheric stability $N = 0.01\ s^{-1}$. The Scorer number

$$s_c = \frac{N}{u_0} a \tag{92}$$

is in this case equal to 10, which means the horizontal scale of the mountain is much larger than the horizontal wave length of the buoyancy oscillation and the nonhydrostatic effect is small. Thus the results represents the almost hydrostatic case. For small amplitude mountains $\left(\frac{Nh_0}{u_0} << 1\right)$ the steady linear solution is known. The following solutions of the shaved element experiments are verified against the steady solution of the LM-operational version with terrain following coordinates. Of course the results have to be interpolated on the same z-levels which are used for the shaved element experiments, in order to yield a valid comparison. In all the experiments the uniform basic flow is from left to right with 10 m/s. All the experiments show the steady state solution.

Fig. 5.1 shows the u-velocity in a vertiacl cross section (x-z-plane). The plane cuts the mountain through it's centre. The numbers at the contour lines are given in m/s. The flow is decelerated upstream of the mountain and accelerated in the lee, which is realistic. There is no windshadow detectable. No artificial vorticity modification is necessary in order to gain this solution. In Fig. 5.2 the same solution is represented, but here processed with the LM operational version with the terrain following coordinate system. On the first glance glance one cannot detect any difference. If we look in detail we find an additional contour line in Fig. 5.2 at the right side of the plot in lower parts and in upper levels the 10.3 m/s contour line (right half of plot) is a little bit more extended than in the shaved element plot.

Fig. 5.3 and Fig. 5.4 illustrate the vertical velocity w of the shaved element method and the terrain following system respectively. Again the two plots are almost congruent. Small differencies are visible when we look at the - 0.35 m/s contour line in lower levels. The area of the minimum vertical velocity is a little bit larger in the shaved element experiment. One can see the same phnomena in upper levels with the - 0.15 m/s contour line.

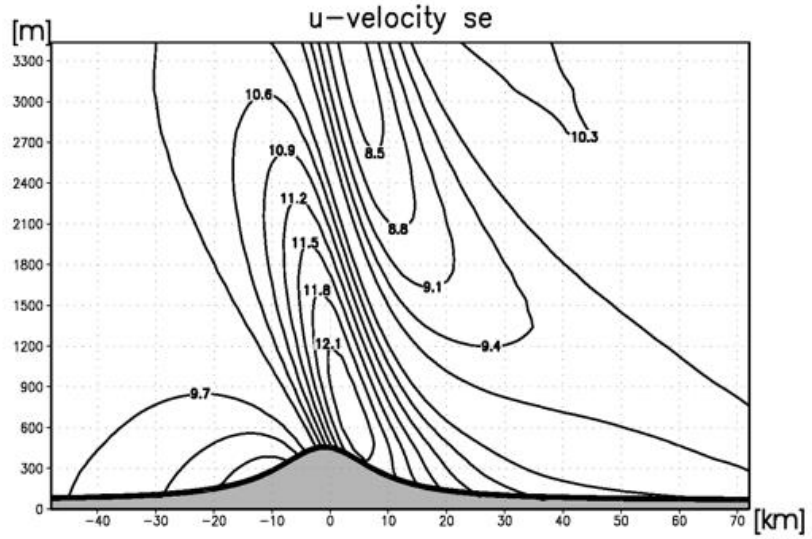

FIGURE 5.1: U-velocity in a vertical cross section computed by shaved elements.

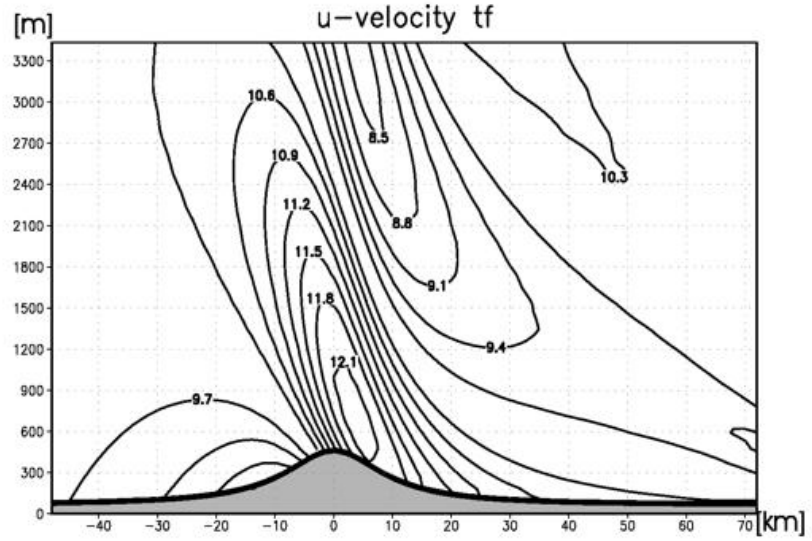

FIGURE 5.2: As in Fig. 5.1, but using the terrain following version of LM.

In Fig. 5.5 and 5.6 the vertical velocity is illustrated in a horizontal cross section at level z = 1164 m for both the shaved element experiments (Fig. 4.5) and the terrain following run (Fig. 5.6). There is no difference detectable.

Fig. 5.7 illustrates a vertical temperature profile which is the temperature deviation of the reference atmosphere (here shaved element experiment). The curvature of the profile in the lowest levels is remarkable. This means, the current model is able to simulate an inversion if the strongly bended profile is resolved with a few gridpoints. If the inversion is the represented just by one gridpoint, the vertical diffusion would act on it. From the mathematical point of view it would not make any sense to demand a resolution just by one gridpoint!

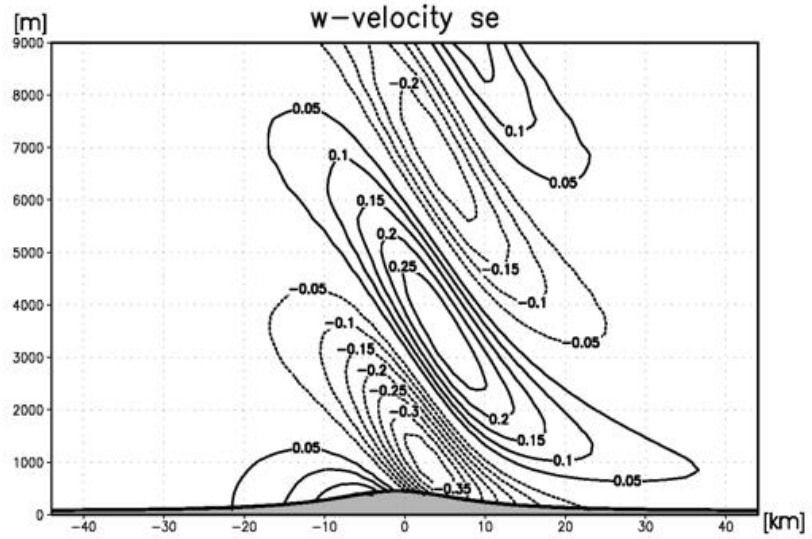

FIGURE 5.3: Vertical velocity in a vertical cross section computed by shaved elements.

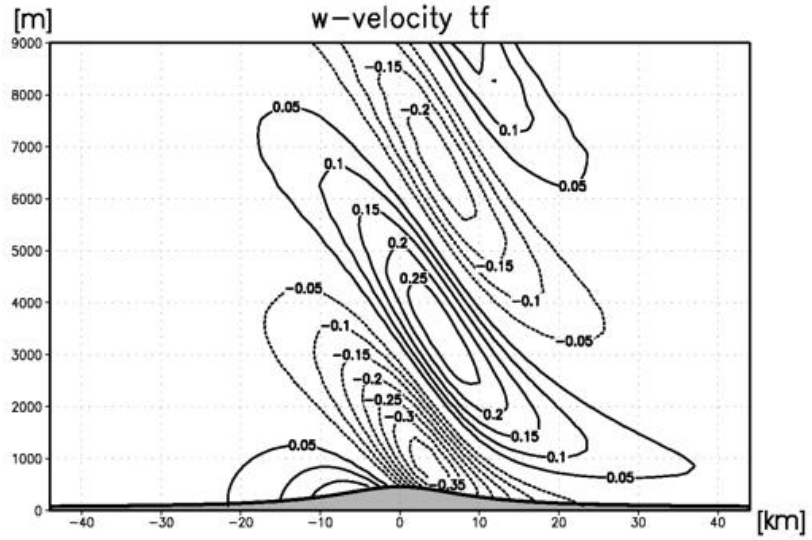

FIGURE 5.4: As in Fig. 5.3 but using the terrain following version of LM.

6 Summary

The new z-coordinate dynamical core of the LM has been described in detail. This version allows for a better orography representation by avoiding the forcing of the atmosphere by numerical errors in the presence of mountains. Problems concerning the prediction of precipitation which have been discussed in the literature in connection with similar approaches are solved by introducing a simplified version of the shaved element finite volume method using the thin wall approximation.

In this approach the mountains are represented by continuous linear splines. A regular grid is cut by this orographic function, which near the surface produces cut cells of different size and shape, which are treated by the finite volume method. For cells not cut by the orographic function the finite volume method produces the finite difference scheme of the operational

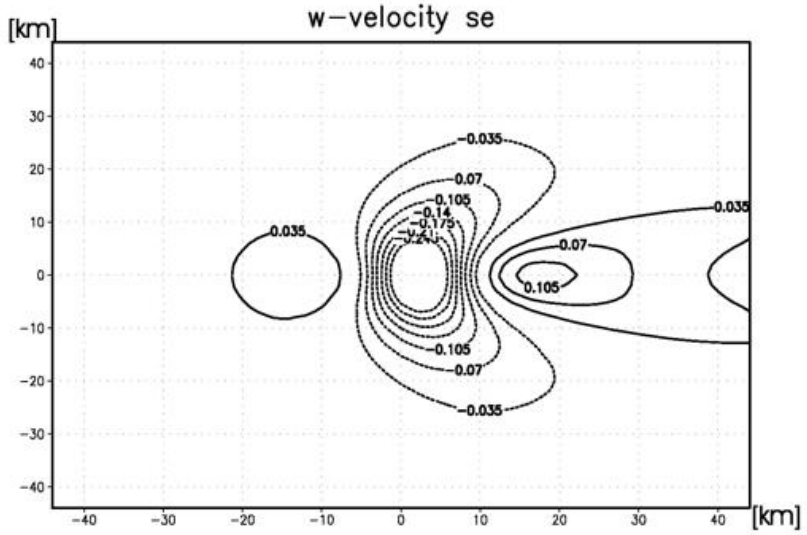

FIGURE 5.5: Vertical velocity in a horizontal cross section computed by shaved elements.

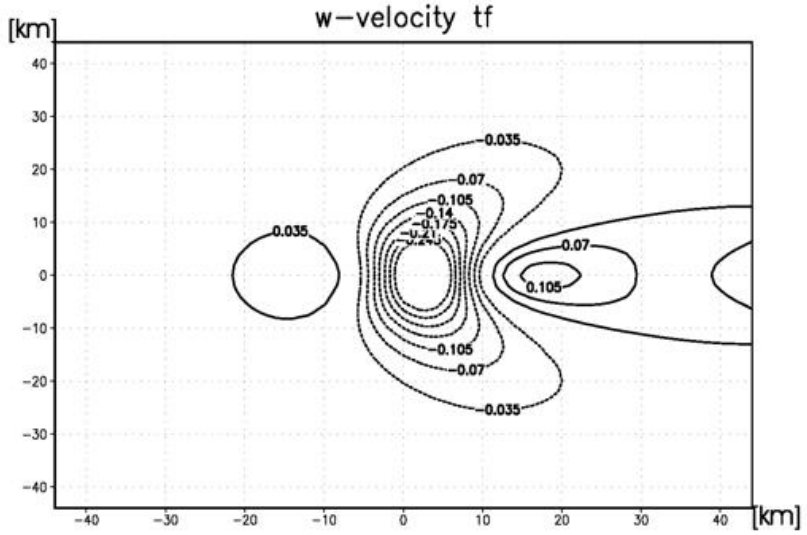

FIGURE 5.6: As in Fig. 5.5, but for the LM with terrain following coordinate.

LM, specialized for the case of flat terrain. The finite difference equations are based on centred difference approximation on the C-grid for those elements which are not cut by the topographic function. For the elements cut by the topographic function the finite difference equations are formulated using flux limiters in the horizontal and vertical directions. A small amount of numerical smoothing is required to stabilize the Leapfrog time-integration scheme.

A number of three-dimensional numerical tests have been performed with the new dynamical core. They showed that the method developed does not suffer from the problems reported in connection with the $\eta-$coordinate (Mesinger, 1988). Especially, the solutions for hydrostatic flow over a bell shaped-smooth mountain are rather similar to those obtained by a terrain following version of the model. Future work will focus on the inclusion of physical paramterizations to allow testing for real cases, aiming at an operational application of the z-coordinate version of the LM.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *Consortium for Small-Scale Modelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (UGM, ARPA-SMR) and Switzerland (MeteoSwiss). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the Lokal-Modell (LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completition of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

EUCOS Impact Study Using the Limited-Area Non-Hydrostatic NWP Model in Operational Use at MeteoSwiss

Abstract

The EUCOS program aims to optimize the ground segment of the European observing system. A drastic reduction of the number of radiosondes has been proposed, compensated by a higher observing frequency of the remaining stations and additional AMDAR platforms. To assess the impact of such a scenario, sensitivity studies have been done with aLMo, the COSMO limited area NWP model in operational use at MeteoSwiss.

This non-hydrostatic model, in operational use at MeteoSwiss, is integrated on a 2700 km × 2300 km mesh covering occidental and central Europe, with a 7 km mesh size. A continuous assimilation cycle based on the nudging technique is used to assimilate all conventional observations. A 27 day test period has been defined (19.10.1999 - 14.11.1999) and daily 24 hour forecasts have been calculated to measure the impact of the proposed radiosonde network modification and to assess the effect of the additional AMDAR platforms on the model analysis and forecast quality.

A significant degradation of the model quality is associated with the reduction of the number of radiosonde stations at analysis time and in the very short range; the increased observation frequency does not compensate for the reduced horizontal resolution of the observing system. On the other side, the additional AMDAR platforms bring a clear local improvement of wind, temperature and humidity; however this improvement does not compensate the quality loss brought by the radiosonde network degradation. An improved horizontal coverage by AMDAR observations and additional information about local structures in the humidity field could be a necessary addition to the EUCOS scenario.

1 Context and Objectives

The main goal of the EUMETNET Composite Observing System program (EUCOS) is to define the optimum ground based observing system for the support of short range numerical weather prediction (NWP) over Europe. The current ground segment of the European observing system is quite dense over the continental area, but sparse over the ocean. A preliminary study [Pailleux et al., 1997] indicated that a significant reduction of the number of radiosondes over the data dense area and the addition of profiles over the Atlantic Ocean and the Mediterranean could optimize the NWP quality for the available financial resources. Based on this study two EUCOS network scenarios have been proposed: a first configuration using half the number of radiosonde stations over continental areas (about 40 remaining stations) but with higher sampling rate at these remaining stations (4 ascents a day) and

additional aircraft observations, and a second configuration which extends the first one by introducing new observations over sensitive areas of the Atlantic Ocean and Mediterranean.

In order to better evaluate the impact of these scenarios on NWP quality, it has been decided to perform observing system experiments (OSE) with both global and limited area NWP models. A special observing campaign took place from 20 September to 14 November 1999. 27 uniformly distributed radiosonde stations have been activated four times a day over the continent and 116 supplementary aircraft platforms providing wind and temperature were added. The set of all available observations collected during this period is the base for conducting EUCOS OSE[1].

A first impact study has been done with the ECMWF global model [Cardinali, 2000]: the observed impact on the short and medium range forecast was very small. It was also shown that during the two months of the EUCOS observing period the most sensitive areas where errors are fast growing were not located over Europe but over the North Pacific. However, this does not preclude an impact at smaller horizontal and shorter time scale (the ECMWF model used a T319 spectral truncation corresponding to a resolution of about 60km over Europe). Two countries committed to do OSE with their high resolution limited area models: the Danish Meteorological Institute with the HIRLAM model and its optimum interpolation analysis and MeteoSwiss with aLMo - its current operational model - and its associated continuous assimilation scheme. The results of the first study have been published [Amstrup, 2000], this report presents the results obtained with aLMo.

2 The NWP Model

In the frame of the Consortium for Small-scale Modelling (COSMO), the National Weather Services of Italy, Greece and Switzerland under the lead of the National Weather Service of Germany have developed a new non-hydrostatic meso-scale model called the Local Model. This model is based on the primitive hydro-thermodynamical equations describing non-hydrostatic flow in a moist atmosphere, without any scale approximations. The model equations are solved numerically using the finite difference method on a Arakawa C-grid with generalized terrain-following vertical coordinates. A thorough description of the Local Model itself can be found on the COSMO web site at www.cosmo-model.org or in the first COSMO newsletter [Doms, 2001].

The version of the Local Model running at MeteoSwiss is named aLMo (for *al*pine *mo*del). Two daily 48 h forecasts are calculated since the first of July 2000, and the model is used operationally since the first of April 2001. It is calculated on a 385 $\times$ mesh, with a 1/16 $^\circ$ mesh size (about 7 km), on a domain covering most of western Europe (see figure 2-1). In the vertical a 45 layers configuration is used; the vertical resolution in the lowest 2 km of the atmosphere is about 100 m (see figure 2-2). A filtered (smoothed) orography has been introduced in order to reduce the unrealistic forcing of 2 Δx waves produced by a mean orography. Lateral boundary conditions are assimilated by a 1-way nesting procedure according to Davies [Davies, 1976]. Rayleigh damping is applied in the 8 upper model layers, starting at 11 km, with a top boundary condition set by the driving model.

The model configuration defined for the OSE performed in this study is based on the operational configuration just described. The only differences are the driving model (the Global

[1]It has to be noted, that this EUCOS campaign coincided with the Special Observing Period of the Mesoscale Alpine Programme [Bougeault et al., 2001], whose data set offers a large potential for additional OSE's.

FIGURE 2-1. Domain and orography of aLMo (min: - 5 m, max: 3109 m).

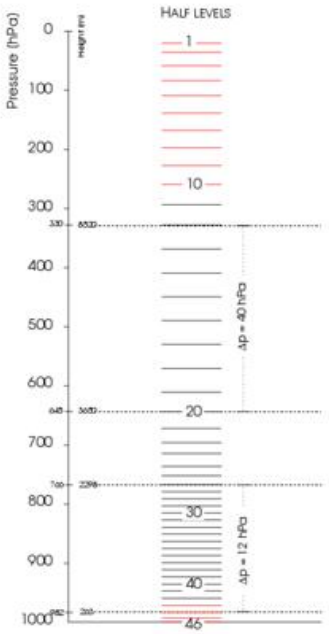

FIGURE 2-2. Vertical distribution of layers in aLMo.

Model of the German Weather Service is used for production, the ECMWF model for the OSE) and the initialization procedure (an interpolation of the driving model analysis is currently used in production, the nudging scheme is used for the OSE).

3 The Assimilation Scheme

Data assimilation with the Local Model is based on the nudging or Newtonian relaxation method. This technique has been implemented using relaxation of model dynamical fields towards direct observations [Schraff, 1997].

The observations being assimilated are horizontal wind, temperature, and relative humidity at all levels, and pressure at the lowest model level. Currently only conventional observing systems are used: surface observations (SYNOP, SHIP, DRIBU), aircraft observations (AIREP, AMDAR) and vertical soundings (TEMP, PILOT). The conditions defining the use of a specific observation are summarized in table 3-1.

TABLE 3-1. Conditions for assimilation of a specific observation.

	Surface Observation (SYNOP, SHIP, DRIBU)	**Vertical profile (TEMP, PILOT)**		**Aircraft (AIREP, AMDAR)**
		Standard level	Significant level	
Surface pressure	Height diff. [a] < 100m > −400m	Yes		No
Horizontal wind	Obs. height < 100m a.s.l.	Yes	Yes if > 100 hPa	Yes
Temperature	No	Yes	Yes if > 100 hPa	Yes
Relative humidity	Abs(height diff) < 160 m	Yes if > 300 hPa		No

[a] Difference between model orography and station height.

During aircraft ascent and descent phases, the aircraft observations are grouped together to form piecewise vertical profiles. All observations from the same aircraft are first collected and a base report is defined by selecting the report with the highest pressure. All observations within 15 minutes and 20 kilometers of the base report are then grouped in a multi-level report. This procedure is then repeated with the remaining reports. Finally each multi-level report is assimilated in a way similar to a TEMP profile (in particular a multi-level report is associated to a single location, neglecting any horizontal drift). As a result of this scheme, most aircraft observations are assimilated as part of multi-level reports below 700 hPa – with a vertical resolution of about 10 to 20 hPa – and as original single-level reports above 400 hPa.

The nudging weight (main coefficient of the nudging term in the model equations) is set to 6×10^{-4} s^{-1} which corresponds to an e-folding time of about half an hour. The temporal influence of a vertical profile extends from 3 h before the observation time to 1 h after, and the influence of surface and upper air single level observations extends from 1.5 h before the observation time to 0.5 h after. The typical half-width of the horizontal influence radius of an observation is between 120 km and 220 km, with smaller values near the ground and larger values aloft.

The conservation of the specific humidity is enforced when assimilating any temperature report. In order to better assimilate surface pressure information, a temperature and a partly geostrophic wind correction is associated with any surface pressure increment; hydrostatic upper-air pressure increments balancing the total analysis increments are also added. Because no soil model analysis is currently available at MeteoSwiss, the fields describing the soil state, including snow related quantities and sea surface temperature, are updated twice a day from the driving model analysis. A simple quality control is regularly performed by comparing the observation increments (difference between an observation and the corresponding model value) with predefined thresholds.

Since the first of March 2001, a continuous data assimilation cycle based on the configuration described above is in pre-operational mode at MeteoSwiss. Systematic subjective and objective verification, covering a 5 months period, has shown a consistent behaviour of this assimilation scheme and a clear positive impact on the forecasts.

The data assimilation scheme defined for the OSE performed in this study is based on the pre-operational scheme just described.

4 The Experimental Set-Up

Due to time constraints it was not possible to calculate EUCOS OSE for the whole EUCOS observing period. I chose the same four weeks as the one defined by the Danish Meteorological Institute, namely from 19 October 1999 00 UTC to 15 November 1999 00 UTC. This period includes 2 of the 3 case studies presented in the ECMWF report [Cardinali, 2000], and seven MAP heavy precipitation events (MAP is the Mesoscale Alpine Program, see the web site at www.map.ethz.ch or [Bougeault et al., 2001]); this last fact is of interest because we can anticipate a larger impact of the proposed EUCOS scenario on "wet" weather regimes due to the reduction of humidity observations.

Three observing systems called S1, S2 and S3 have been considered. S1 is the observing system which uses the same radiosonde and aircraft data as before the EUCOS campaign; S2 has 37 radiosonde stations less, but 13 more stations measuring every 6 hours; S3 has the same radiosonde configuration as S2, but is complemented by 121 more AMDAR plat-

TABLE 4-1. Typical number of observations assimilated by aLMo during a 24 h period (the active stations number differs from the blacklist derived value because only the stations inside aLMo domain are considered).

		TEMP	PILOT	AIRCRAFT	SYNOP	DRIBU

forms. The blacklists used to define the different observing systems are available in the annex (supplementary soundings by stations which changed their operations during EUCOS observation campaign have not been included in S1, contrary to the ECMWF study). The typical number of bulletins assimilated by aLMo during a 24 h period for each of these observing systems is listed in table 4-1, and the typical daily coverage of AMDAR platforms in observing system S3 is displayed in figure 4-1.

A 27 days assimilation has been run with the Local Model for each of S1, S2 and S3. These three assimilation cycles have been started the 19 October 1999 at 00 UTC from the ECMWF operational 4-d variational analysis[2]. This same ECMWF analysis stream has been used to update the lateral boundary conditions every 6 hours, and to update the soil model once a day at 00 UTC (no soil model analysis is available at MeteoSwiss).

Daily 24 hour forecasts starting at 12 UTC have been run with aLMo for each of S1, S2 and S3. Initial conditions for these forecasts were obtained from the corresponding assimilation

[2]the MARS retrieval parameters are: stream *oper*, class *od*, type *4v*, expver *001*.

cycle, described in the previous section. Observations were still assimilated during the first forecast hour, in order to mirror the (pre-) operational configuration used at MeteoSwiss. Lateral boundary conditions were updated every 6 hours from the ECMWF operational deterministic forecast[3].

I would like to stress that all three experiments S1, S2 and S3 have been calculated with the same set of ECMWF lateral boundary conditions. Although EUCOS OSE dataset were available at ECMWF for both assimilation and forecast, it was not possible to use them: the liquid water field – required by aLMo – was missing in the ECMWF archive. However, in view of the weak impact observed in the ECMWF EUCOS OSE, this should not significantly alter the conclusions of this study.

5 Impact on Forecast Quality

The impact of the observing system modifications *on aLMo forecast quality* has been evaluated with two verification packages in operational use at MeteoSwiss: a package for the verification of the vertical structure of the atmosphere over the whole aLMo domain (section 5.1) and a package for the verification of near-surface weather parameters over Switzerland (section 5.2). One of the three cases presented in the ECMWF study [Cardinali, 2000] is also briefly presented (section 5.3).

5.1 Vertical Structure of the Atmosphere

A statistical verification of the vertical structure of the model atmosphere against radiosonde data for a set of 28 stations regularly distributed over the whole aLMo domain has been applied. The reference stations are Hemsby (03496), Crawley (03774), Camborne (03808), Long Kesh$^-$ (03920), Valentia (03953), Payerne$^+$ (06610), Brest$^-$ (07110), Trappes$^-$ (07145), Nancy$^-$ (07180), Lyon$^-$ (07481), Bordeaux$^+$ (07510), Nimes$^+$ (07645), Ajaccio$^-$ (07761), La Coruna (08001), Madrid$^-$ (08221), Mallorca$^+$ (08301), Schleswig (10035), Emden$^-$ (10200), Lindenberg^o (10393), Essen$^-$ (10410), Stuttgart$^-$ (10739), München$^-$ (10868), Wien (11035), Innsbruck^o (11120), Prag (11520), Udine (16044), Milano$^-$ (16080), San Pietro$^-$ (16144), Roma$^-$ (16245) and Cagliari (16560) (a "+" means increased observing frequency in S2, a "-" means not present in S2, a "o" means neither present in S1 nor in S2). A quality assessment in the frame of MAP [Häberli, 1998] has shown good observation scores for these stations. Bias and standard deviation for temperature, relative humidity (over water), wind direction and wind speed are calculated for the whole set of available forecasts and for different forecast times (+00 h, +06 h, +12 h, + 24h).

The main results of this verification can be summarized by the four statements presented below, and are illustrated by the statistical scores displayed in figures 5-1 to 5-5:

- Decreasing the spatial density of radiosondes and increasing the observing frequency of some (from S1 to S2) results in a significant increase of the standard deviation of both dynamical and thermodynamical fields *at analysis time* (+00 h). For instance, in the middle troposphere a 50% increase in variance of relative humidity is observed (fig. 5-2).

  This fact reflects a degradation of the mesoscale structures due to the modification of the observing system. This is consistent with one of the conclusion of an earlier observing system simulation experiment (OSSE), which showed that a high temporal

[3]the MARS retrieval parameters are: stream *oper*, class *od*, type *fc*, expver *001*.

resolution of wind profiler observations does not compensate for a poor horizontal resolution of the observing system [Bettems, 1999].

One can argue that the observed impact is maximized by the applied verification method, the scores being (partly) calculated at the exact locations where the observing network is modified. This is certainly true, but a relevant impact is also observed at locations where no observing system modification is applied, as shown in figures 5-6 and 5-7.

- Increasing the number of aircraft observations does not compensate for the quality loss observed by going from S1 to S2. In fact the global impact of a fourfold increase of AMDAR bulletins is only marginally positive on all verified parameters. This is not surprising for the humidity field - AMDAR do not contain humidity information - but such a weak impact on the wind field was not anticipated.

  However one should note the highly non-uniform distribution of AMDAR observations in the model domain (see figure 4-1) which could partly explain this fact. A look at figures 5-8 and 5-9 shows that AMDAR data have at least locally a remarkable impact, and are even able to improve the humidity field.

- All differences observed at analysis time have vanished *after 6 to 12 hours forecast.* This is again consistent with our experience, that for a limited area model similar to aLMo the impact of the initial conditions does not generally extend more than 12 to 18 hours into the forecast.

- A verification with a higher spatial granularity (Alpine region, the four quadrants west, north, east and south of the Alps) presents the same patterns.

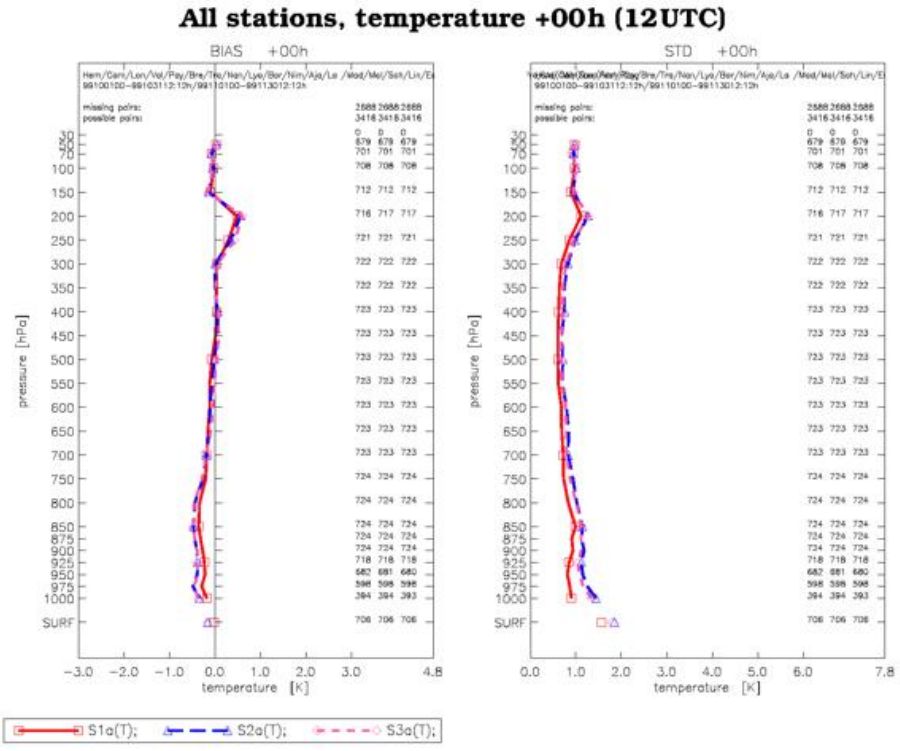

FIGURE 5-1. Bias (left panel) and standard deviation (right panel) of the temperature at initialization time calculated for the 27 forecasts against the 28 stations defined in section 5.1. Red curves are for observing system S1, blue curves for observing system S2 and magenta curves for observing system S3.

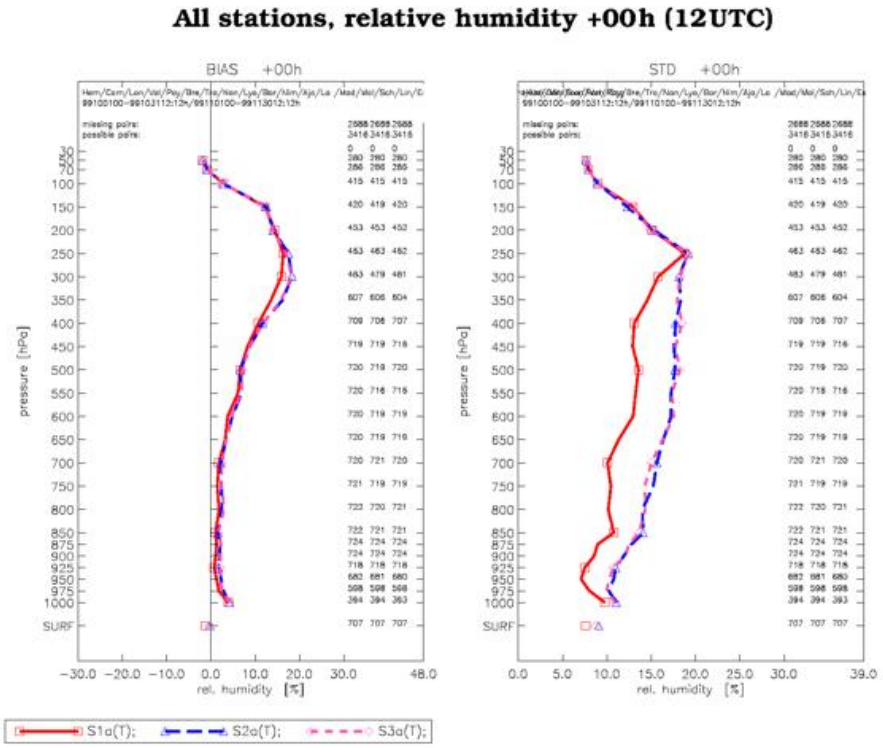

FIGURE 5-2. Bias (left panel) and standard deviation (right panel) of the relative humidity at initialization time calculated for the 27 forecasts against the 28 stations defined in section 5.1. Red curves are for observing system S1, blue curves for observing system S2 and magenta curves for observing system S3.

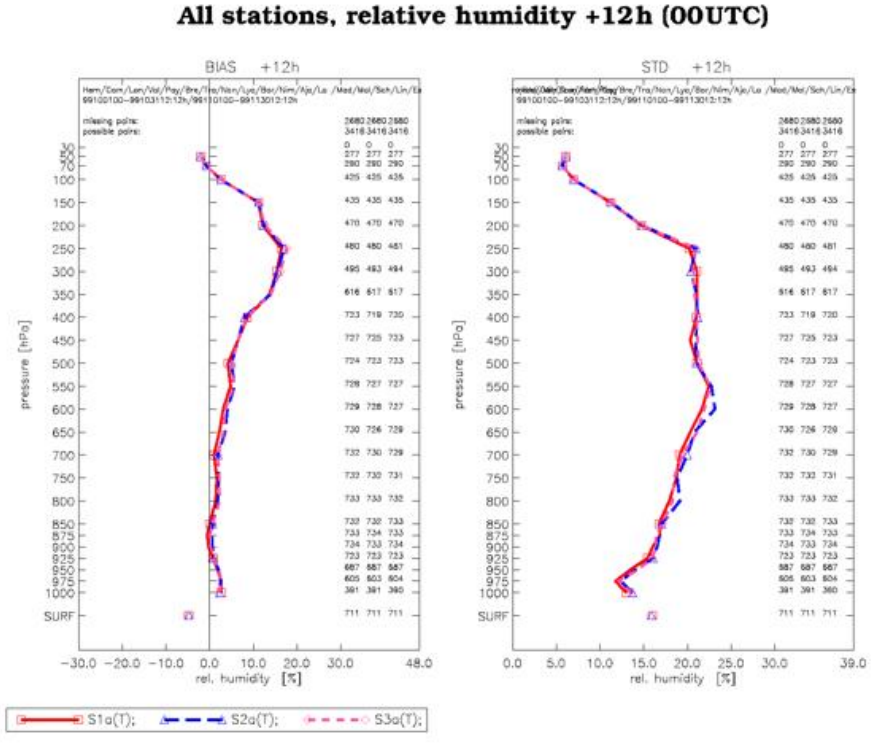

FIGURE 5-3. As in figure 5-2, after 12 hour forecast.

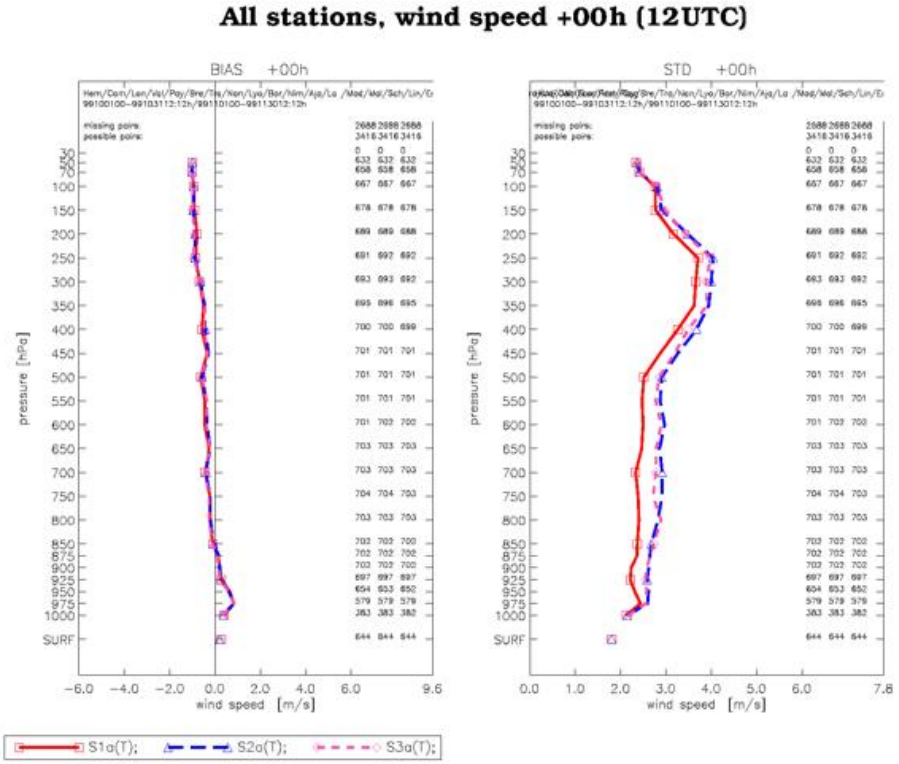

FIGURE 5-4. Bias (left panel) and standard deviation (right panel) of the wind speed at initialization time calculated for the 27 forecasts against the 28 stations defined in section 5.1. Red curves are for observing system S1, blue curves for observing system S2 and magenta curves for observing system S3.

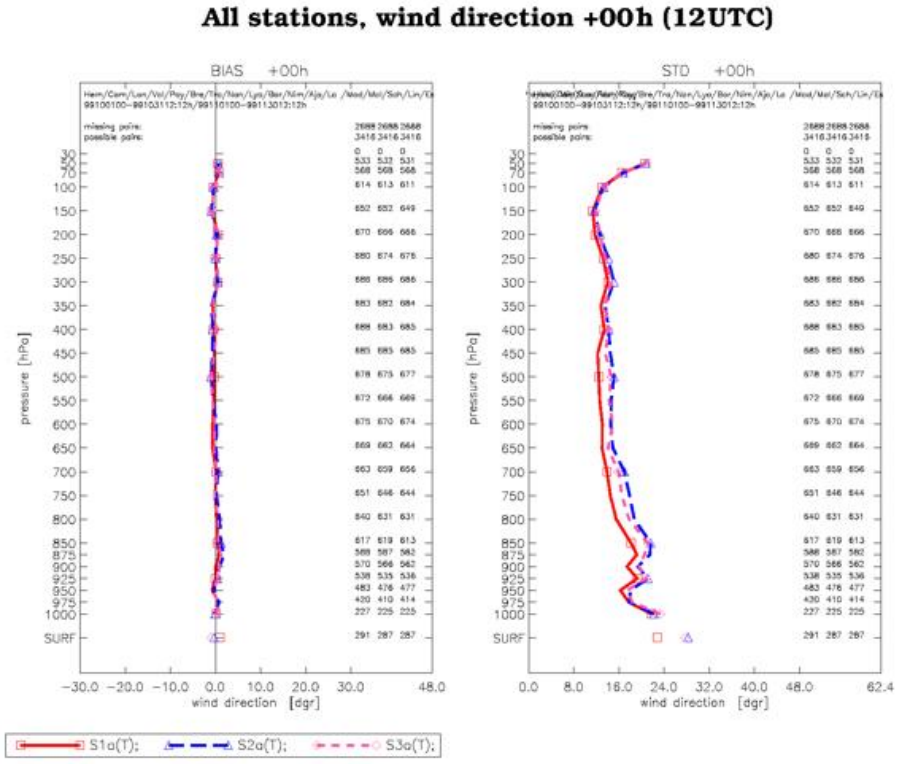

FIGURE 5-5. As in figure 5-4, for the wind direction.

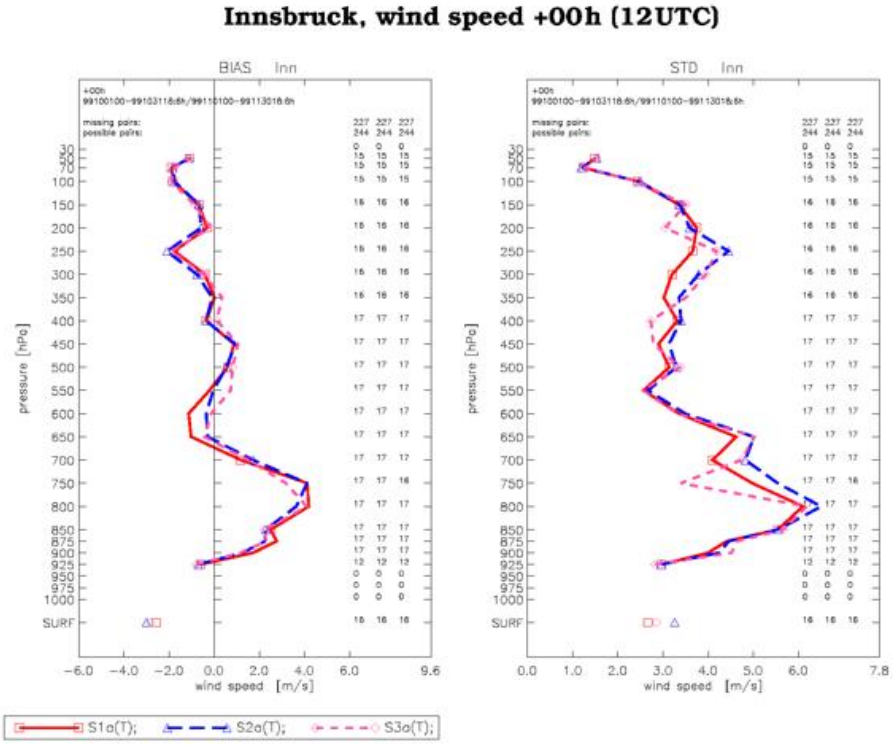

FIGURE 5-6. Bias (left panel) and standard deviation (right panel) of the wind speed at initialization time calculated for the 27 forecasts against the vertical sounding at Innsbruck. Red curves are for observing system S1, blue curves for observing system S2 and magenta curves for observing system S3. Innsbruck is a radiosonde station which is not used in our OSE.

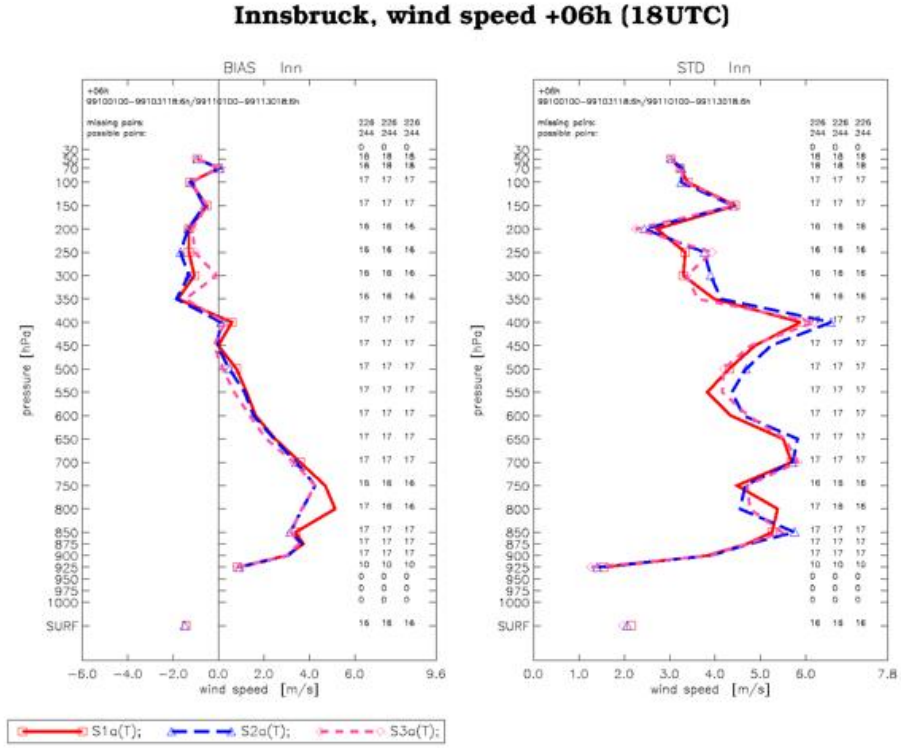

FIGURE 5-7. As in figure 5-6, after 6 hour forecast.

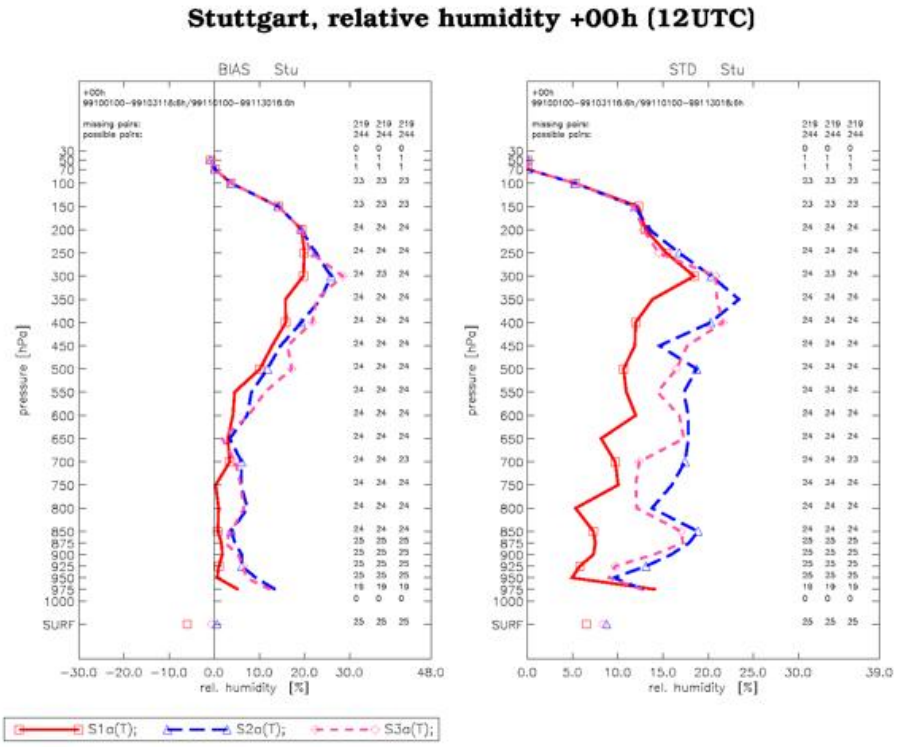

FIGURE 5-8. Bias (left panel) and standard deviation (right panel) of the relative humidity at initialization time calculated for the 27 forecasts against the vertical sounding at Stuttgart. Red curves are for observing system S1, blue curves for observing system S2 and magenta curves for observing system S3. Stuttgart is a radiosonde station which is blacklisted in S2 and S3, and is a location with many AMDARs data.

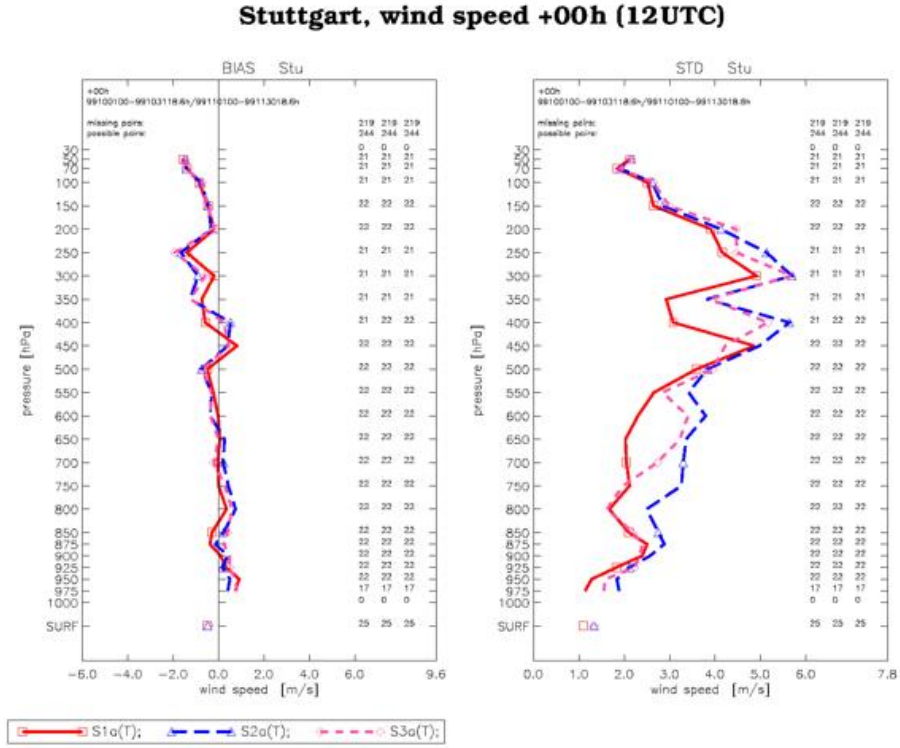

FIGURE 5-9. As in figure 5-8, for wind speed.

Another comment can be made about the figure 5-2: in all three experiments the humidity *bias* in the lower troposphere is about zero, meaning that the global water vapour budget is correct and very similar for all experiments (this is consistent with the fact that fluxes through lateral boundaries and soil model state are identical in S1, S2 and S3). What is clearly degraded by the reduction of the number of radiosonde stations is *the distribution* of humidity in the integration domain, resulting in the observed increase of standard deviation.

5.2 Near-Surface Weather Parameters over Switzerland

A statistical verification of 2-m temperature, 2-m dewpoint depression, 10-m wind, hourly sums of precipitation and cloud cover over *Switzerland* against data from the 72 stations of the Swiss automatic surface stations network (ANETZ) has been applied. Precipitation scores have also been calculated. To interpret these results it is important to realize that the observing system modifications associated with S2 resulted in a local increase of the number of radiosonde observations (Payerne station, on the Swiss Plateau, going from 2 to 4 daily soundings).

The results of this verification can be summarized by the three following statements and are illustrated by the statistical scores of figures 5-10 to 5-13:

- The sensitivity of the near-surface parameters to the modifications of the observing system is weaker than what has been observed in the verification of the vertical structure of the model atmosphere (e.g. compare the sensitivity of the wind speed standard deviation in fig. 5-4 and in fig. 5-10).
- Over Switzerland the modification of the radiosonde network results in a small degradation of the 10-m wind speed and direction (fig. 5-10) but induces a significant reduction in variance of precipitation, which even persists up to the end of the forecast (fig. 5-12.) The cloud cover bias is also slightly improved (fig. 5-11).

  The small degradation of the 10-m wind field associated with the increased sounding frequency probably reflects a weakness of our near-surface wind assimilation algorithm in presence of strong orographic forcing.

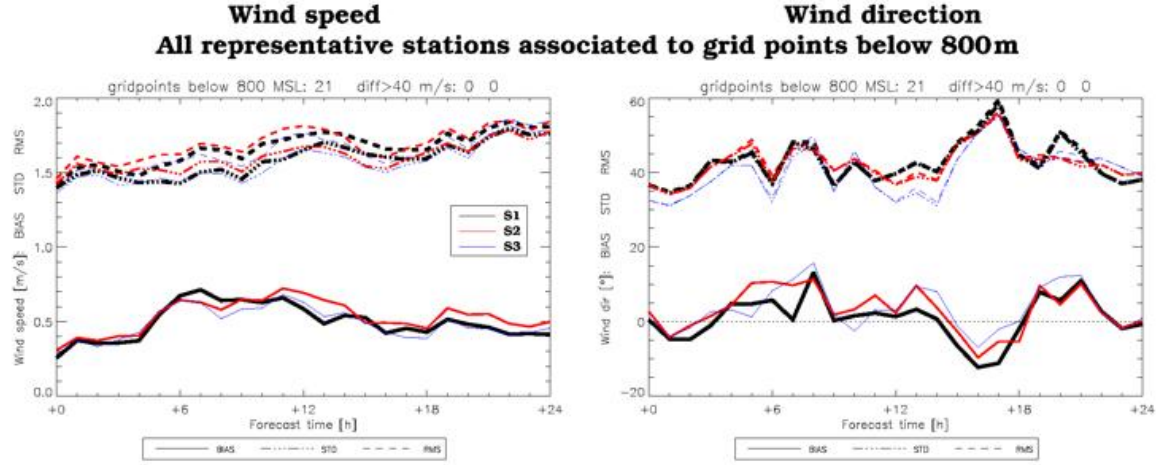

FIGURE 5-10. Hourly variation of some statistical scores for the 10-m wind speed (left panel) and for the 10-m wind direction (right panel), verified against the 21 representative ANETZ stations associated to a model grid point below 800 m. Black curves are for observing system S1, red curves for observing system S2 and blue curves for observing system S3. The plain lines represent the bias, the dotted lines represent the rms and the dash/dotted lines represent the standard deviation.

The observed improvement of cloudiness and precipitation reflects the better three-dimensional fields over Switzerland, due to the increased number of assimilated soundings. In contrast, this confirms the negative impact a reduction of the number of radiosonde observations can locally have on wet weather elements.

- One observes a small but clearly positive impact of AMDAR observations on the temperature standard deviation (compare in fig. 5-13 the impact on the 2-m temperature near an airport, at Kloten, and further away at Bern) and on the wind speed and direction (e.g. look at the wind speed standard deviation in fig. 5-10). This improvement is visible in the analysis *and* in the first 6 to 12 h forecast.

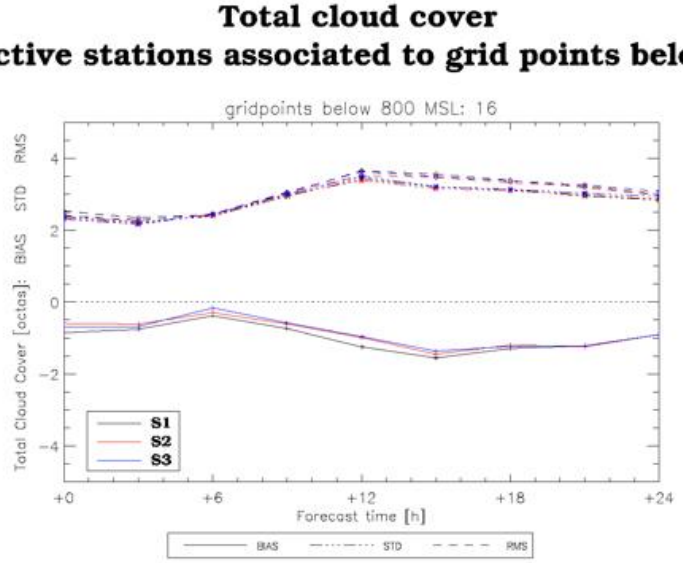

FIGURE 5-11. As figure 5-10, for the total cloud cover verified against the 16 active ANETZ stations associated to a model grid point below 800 m. All grid points within 30 km of an observation location are considered when calculating the scores.

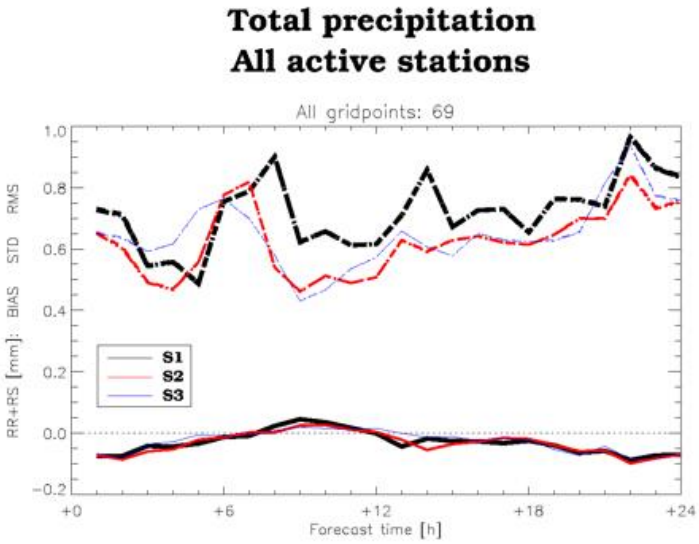

FIGURE 5-12. As figure 5-10, for the hourly total precipitation verified against all 69 active ANETZ stations. The plain lines represent the bias, the dash/dotted lines the standard deviation. A mean of 5 grid points around an observation is done before calculating the scores.

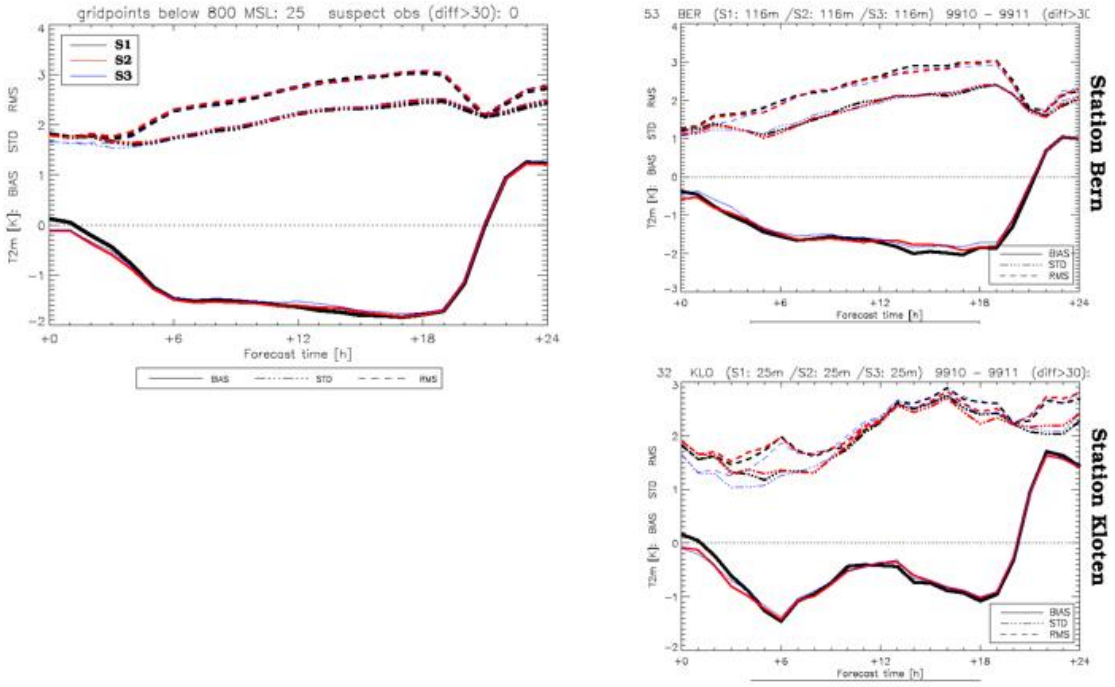

FIGURE 5-13. Upper left panel: hourly variation of bias (solid line) and standard deviation (dashed line) for the 2-m temperature, verified against the 25 active ANETZ stations associated to a model grid point below 800 m. Black curves are for observing system S1, red curves for observing system S2 and blue curves for observing system S3. Right panels: same as upper left panel but for a single ANETZ station. Both Bern and Kloten are on the Swiss Plateau, the latter one is also at an international airport location.

5.3 Case Study

A study of the forecast based on the 6th November 1999 12 UTC analysis has been done. This case is characterized by a blocking situation over the Western edge of the continent with a cut-off low over the South of Europe. Heavy precipitation – partly convective – has been observed in the Southern part of the Alps (Tessin, Lago Maggiore).

This case has been investigated at ECMWF [Cardinali, 2000] and it has been found that the synoptic situation was better described by forecast based on the observing system S1, the information from all the stations over the Atlantic border being very important for this particular meteorological situation.

No such synoptic scale differences are observed by looking at the high resolution short range forecast produced by aLMo; this is consistent with the fact that the synoptic structures are forced by the driving model, which is the same ECMWF operational deterministic forecast in all three experiments. However, smaller scale structures do exhibit significant differences, and a clear improvement of the location and the spread of the heavy precipitation region is brought by the additional AMDAR observations (see figure 5-14). The negative impact due to the suppression of Nancy and Stuttgart radiosondes – north of Switzerland – is also well visible.

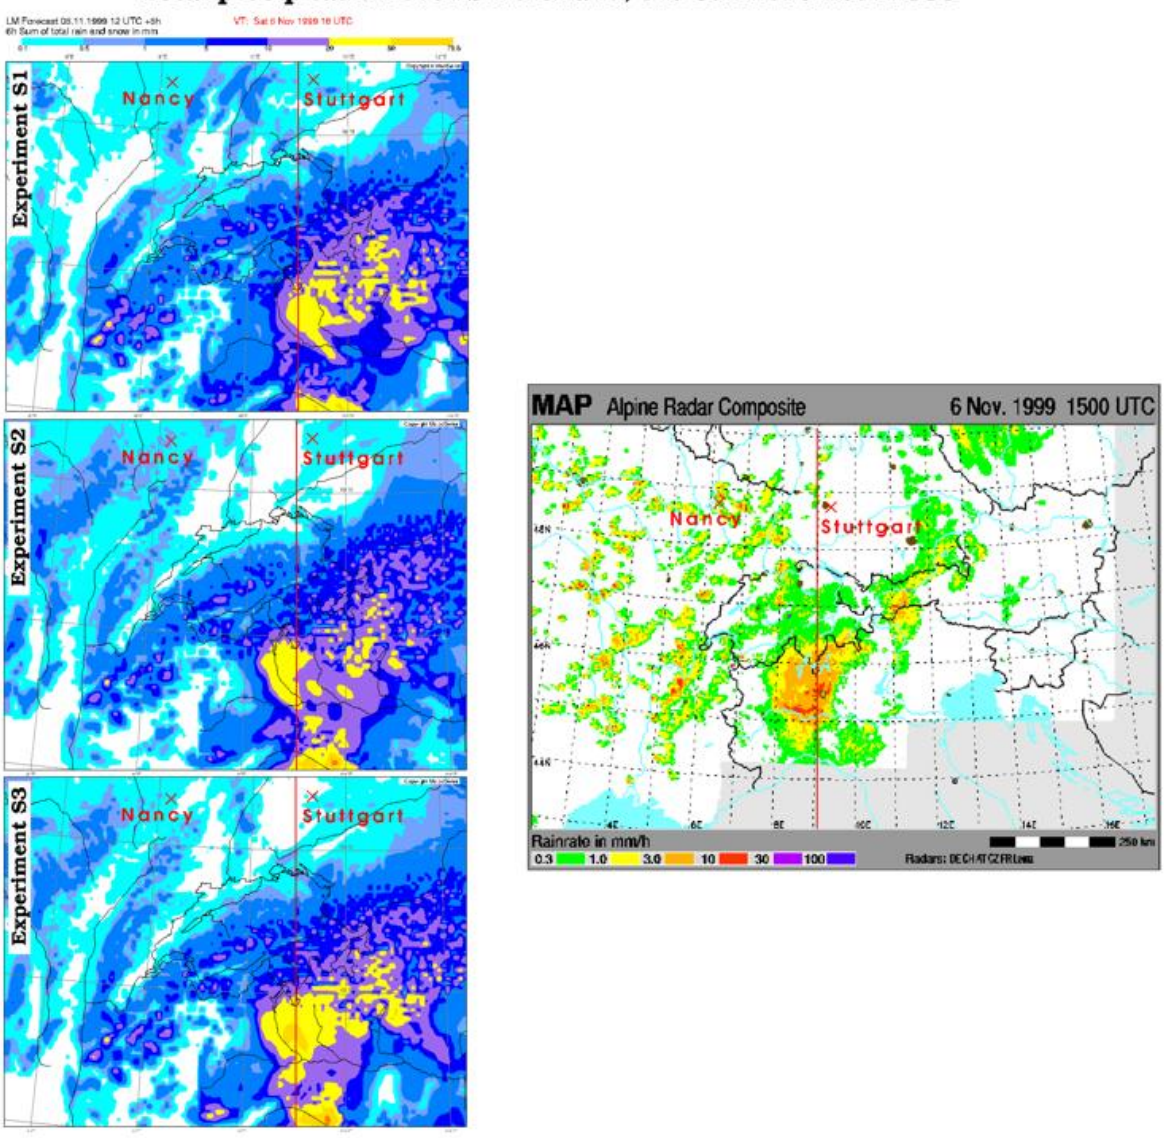

FIGURE 5-13. Sensitivity of a heavy precipitation event over Southern part of the Alps to the observing system. Left panels: 6 hours sum of total precipitation forecast over Switzerland, evaluated on the 6th November 1999 between 12 UTC (analysis time) and 18 UTC. Right panel: Total precipitation rate observed by the MAP Alpine Radar Composite on the 6th November 1999 at 15 UTC (data for the whole MAP period are available on-line at www.map.ethz.ch). Yellow areas in the left panels can be compared with light orange areas in the right panel, and correspond to about 20 to 50 mm precipitation in 6 hours.

6 Conclusion

The motivation of all EUCOS observing system experiments done at ECMWF [Cardinali, 2000], DMI [Amstrup, 2000] and MeteoSwiss was the evaluation of the impact of the proposed EUMETNET observing system modification on the quality of numerical weather forecast. It has been shown that a reduction of the number of active radiosonde stations had a very small but slightly negative impact on both the global ECMWF model and the DMI-HIRLAM-G limited area model, and the additional AMDAR data have been found to slightly degrade the quality of the forecast. The results obtained with aLMo differ substantially. To understand

this fact, one should keep in mind that the two other models have a coarser horizontal resolution (50 to 60 km instead of 7 km), and that the DMI-HIRLAM-G is integrated over a much larger domain than the EUCOS region and uses an intermittent data assimilation scheme. In the present study we have found:

- A *significant* degradation of the model quality at analysis time and in the very short range is associated with the reduction of the number of radiosonde stations. This degradation is mainly visible in the distribution of the 3-dimensional fields inside the model domain (meso-β structures).The quality of precipitation is also degraded.

  The increased observation frequency of the remaining stations does not compensate for the reduced horizontal resolution of the observing system, except in the surrounding of an upgraded station. This is consistent with previous OSSEs [Bettems, 1999].

- Measured over the *whole model domain* the impact of the additional AMDARs is positive but very small. However, a clear improvement of wind, temperature *and humidity* fields is *locally* observed, in regions well covered by AMDAR platforms. This improvement is significant, but does not compensate the quality loss brought by the radiosonde network degradation.

- Even in *regions well covered by radiosonde observations*, the AMDAR data bring a clear improvement of the forecast quality (e.g. see fig. 5-10).

These results suggest a degradation of the (mean) quality of high resolution short range numerical weather forecast associated with the introduction of one of the proposed EUCOS scenario, if no compensatory actions are taken. AMDAR observations have a clear potential, and an improved horizontal coverage (e.g. using regional flights) would certainly mitigate the expected quality loss. However additional information about local structures in the humidity field are needed.

Acknowledgements

This work would not have been possible without the great support of the Swiss Center for Scientific Computing (SCSC) which provided me with the necessary resources on their NEC SX5. I was able to calculate up to 9 days assimilation in 24 h, besides all the operational tasks of MeteoSwiss running on this machine, ... and all the jobs of the other users.

Many thanks also to Claudia Cardinali for providing me with the necessary blacklists for the OSE, and to Carsten Maasz for helping me with the MARS system at ECMWF.

My colleagues Marco Arpagaus and Francis Schubiger processed the OSE results with the verification packages to extract meaningful statistical scores, thanks for your effort!

Annex

This annex gives the blacklists defining the observing systems S1, S2 and S3. These lists have been provided by Mrs. Carla Cardinali from ECMWF and complemented by the information listed in table 1 of the document EUCOS-SPC-003 (radiosonde stations whose operating mode changed during EUCOS observing period).

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *Consortium for Small-Scale Modelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (UGM, ARPA-SMR) and Switzerland (MeteoSwiss). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the Lokal-Modell (LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completition of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

In order to publish a report very soon after the completition of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors. We apologize for typographical and other errors or inconsistencies which may still be present.

The report series is also open for contributions from external users of the LM system at various universities and research institutes.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

Evaluation of Empirical Parameters of the New LM Surface-Layer Parameterization Scheme

Results from Numerical Experiments Including the Soil Moisture Analysis

Dmitrii Mironov and Matthias Raschendorfer

Deutscher Wetterdienst, Abteilung Meteorologische Analyse und Modellierung,

1 Introduction

In this note, we outline some results from numerical experiments aimed at optimizing empirical parameters of the new LM surface-layer parameterization scheme (Raschendorfer 1999). This work is envisaged in frames of the COSMO Work Package 3.1. Both "component testing", where the fidelity of the individual model components are tested independently, and "system testing", where the overall performance of the model is tested (Wyngaard and Moeng 1993), have been performed. First, the new LM surface-layer parameterization scheme has been tested independently, using a single-column atmospheric model developed at DWD and observational data from the Lindenberg Meteorological Observatory (Beyrich 2000, Beyrich et al. 2000a, 2000b). By and large the new surface-layer parameterization scheme showed a rather promising performance. A number of shortcomings have been revealed, and the ways of improving the scheme have been suggested. Results from that study will be described in Mironov et al. (2001) in some detail. We will not further discuss them here.

Although results from component testing are extremely useful in understanding whether a parameterization in question appropriately accounts for the essential physical processes at work, they cannot be conclusive. As far as operational applications are concerned, they can only be suggestive. A parameterization scheme that performs well during independent component tests may not perform equally well in the full three-dimensional model environment due to shortcomings of the other model components which have previously been tuned to compensate each other's errors. Therefore, some tuning is usually required when an improved parameterization is implemented (although it should be avoided whenever possible, see Randall and Wielicki 1997, for discussion).

2 Background

Two types of tuning parameters are distinguished, *model parameters* and *external parameters*. Model parameters are usually independent of space and time but dependent on the model formulation. That is, they are constants in the context of a particular physical parameterization used, but more generally, are functions of other physical variables that are not accounted for. Classical examples of the model parameters are the von Kármán constant and the Charnock constant. External parameters describe the application-specific parts of the

model set-up, such as geometry of the model and characteristics of the model lower boundary. These may vary in space and some also in time. Examples of the external parameters are the aerodynamic roughness of the land surface (space dependent) and the leaf area index (space and time dependent).

The new LM surface-layer parameterization scheme (Raschendorfer 1999) is intimately connected with a new atmospheric turbulence mixing scheme, the latter being a version of the Mellor and Yamada (1974, 1982) level 2.5 closure using the turbulent kinetic energy as a prognostic variable. Both schemes are planned to be used for operational numerical weather prediction at DWD in spring 2001 (a detailed description of the new schemes will be published in a forthcoming issue of the COSMO technical report). The surface-layer scheme is formulated in such a way that dimensionless coefficients in the surface-layer Monin-Obukhov stability functions are expressed through the dimensionless coefficients of the Mellor-Yamada closure. As the Mellor-Yamada closure has been comprehensively tested in numerous applications (see Nurser 1996, for an overview), the estimates of its dimensionless coefficients are fairly reliable. This tends to reduce the number of LM model parameters to be tuned.

However, high complexity of the interaction of the atmosphere with the underlying surface requires the introduction of additional model parameters and external parameters into the LM surface-layer scheme. New model parameters have been introduced which directly affect the resistance of the air layer immediately adjacent to the underlying surface (laminar sub-layer, see Raschendorfer 1999, for details) to the transfer of momentum and of scalar quantities, respectively (in the LM code notation, these are RLAM_MOM and RLAM_HEAT). A new model parameter has been introduced (RAT_CAN in the LM code notation) that controls the "effective" height of the roughness (canopy) elements. It has a pronounced effect on the surface-layer resistance. This parameter would not be required if the above effective height is introduced as a space-dependent external parameter.

New external parameters have also been introduced in the surface-layer scheme to describe various types of the underlying surface in more detail (theses are the surface area indices of bare soil and of non-evaporating surface). Together with the leaf area index that is already present in the operational LM surface-layer scheme, these parameters have a major effect on evapotranspiration. More specifically, they govern the resistance to the transfer of water vapour from/to the upper soil layer and plants to/from the adjacent surface air layer. As these parameters have no influence on the resistance to the heat transfer, they can be used to change the Bowen ratio.

However, the evapotranspiration is also heavily dependent on the soil moisture. Within the LM data assimilation stream (based on the observational nudging analysis technique), the soil moisture field used to be a free-running prognostic model variable that was not corrected using observations. This was the situation until March 2000, when the soil moisture analysis (SMA) scheme was introduced (Hess 2001). With the SMA, the soil moisture can no longer be considered as a purely physical quantity. Rather it is a "fitting" quantity that is determined so that the predicted 2m temperatures at 12 UTC and 15 UTC give the best fit to the observations. The impact of the SMA is a maximum during warm sunny days. In cloud conditions with low radiation impact, the effect of the SMA is much lower. In these conditions, the influence of soil moisture on the 2m temperature is small. In a sense the soil moisture analysis is a "system testing procedure" that adjusts the time and space dependent model parameters, namely the soil moistures in the two soil layers, to improve the model performance for the 2m temperature. Notice that the resulting model soil moisture is not necessarily in agreement with the actual soil moisture. More likely the SMA adjusts the soil moisture so that to compensate for errors in the day-time 2m temperature introduced by

the other LM components. Clearly, an "ideal" model whose forecast is in perfect agreement with observations would not require any SMA-induced changes of the soil moisture. Thanks to the SMA, the abovementioned external parameters of the surface-layer scheme have now a minor effect on the forecast of the 2m temperature and of the 2m dew point. Any changes of the external parameters that affect evaporation would be compensated by changes in the soil moisture induced by the SMA.

The above is not true for the model parameters of the LM surface-layer scheme, first of all, for the parameters that affect the surface-layer resistance to the transfer of scalars (RAT_CAN and RLAM_HEAT). Setting these parameters incorrectly would not result in large errors in the day-time 2m temperature – the SMA would, to a great extent, make up for the deficiencies by appropriately changing the soil moisture. The shortcomings of the surface-layer scheme would, however, manifest themselves in the amplitude of the diurnal cycle of the weather elements, in the minimum temperatures at night and, most notably, in the 2m dew point. This was indeed the case in the previously performed parallel experiments, where the new LM surface-layer scheme was used but the new model parameters were not appropriately tuned (these are experiments No. 102, hereafter "exp_102", and No. 103, "exp_103"). Verification of results from those experiments, although showing a rather satisfactory overall performance of the new scheme, reveal a considerable negative bias of the 2m dew point. It therefore proved to be necessary to tune a number of parameters of the new LM surface-layer scheme with due regard for the SMA.

Although all empirical parameters of the surface-layer scheme are interrelated, as is the case for all turbulence models which are essentially non-linear, we have found that the 2m dew point is most sensitive to the model parameters that directly affect the surface-layer resistance to the transfer of scalar quantities (RAT_CAN and RLAM_HEAT). As explained above, setting these parameters correctly is hardly possible without the use of a full quasi-operational LM including the SMA. The 10m wind is most sensitive to the model parameter that directly affects the surface-layer resistance to the transfer of momentum (RLAM_MOM). As the results from "exp_102" and "exp_103" indicate, the 10m wind with the new surface-layer scheme has a slight positive bias that can be reduced by changing the value of the above parameter. Fortunately, a rough evaluation of this parameter could be made through the LM runs without the use of SMA that are much less expensive computationally.

Finally, a parameter referred to as "pattern length" (PAT_LEN in the LM code notation) helps improve predictions of the weather elements in a stably stratified boundary layer. This parameter controls the degree of enhancement of turbulence due to the sub-grid scale horizontal inhomogeneities of the surface temperature and thus affects turbulence transport. This is a feature of the new LM turbulence scheme which is not present in the operational LM. By tuning the pattern length, predictions of the minimum temperature and the nocturnal wind can be improved. Pattern length should be tuned together with the other model parameter (RLAM_MOM) that directly affects the surface-layer resistance to the transfer of momentum. A rough estimate of the pattern length could be obtained through the LM run without SMA.

Notice that pattern length is actually a location-dependent external parameter. It is related to the length scale of the inhomogeneities of the underlying surface which induce the surface temperature inhomogeneities. As this location dependence of pattern length cannot be rationally determined at present, a constant value is used in LM as if this parameter were a model parameter.

3 Experiments Performed

Since running the full LM suite in a quasi-operational mode over an extended period of time is computationally expensive, evaluating the model parameters by repeatedly performing long parallel experiments deemed unrealistic. Therefore, a series of particularly designed experiments has been performed. A few warm sunny days have been chosen, when the soil moisture changes due to SMA, and, therefore, also changes in evaporation and in the surface-layer specific humidity and dew point, are a maximum. The abovementioned empirical parameters of the surface-layer scheme are optimized by changing their values and repeating 24-hour long runs. The experiments are performed using the DWD Experimental Modelling System (Hanisch 1995).

Notice that the SMA cost function strongly depends on the background soil moisture fields. That is, the scheme accounts for the soil moisture during the past few days and, therefore, does not immediately respond to changes in the external forcing or in model physics. Then, the use of initial fields that are not in accord with the altered model parameters almost inevitably leads to an unsatisfactory prediction of the weather elements in question, first of all, the day-time 2m temperature. This would not have been the case if the SMA had enough time to overcome its "inertia" and set the soil moisture to match the altered model parameters. Therefore, a modified SMA binary (kindly prepared by Reinhold Hess) is used in our 24-hour experiments, where the effect of the background state is practically eliminated. In this way, the SMA is used to determine the initial soil moisture fields that fit the 12 UTC and 15 UTC observations of the 2m temperature. The LM forecast run is then performed for the same day, using these initial soil moisture fields. This is different from the operational SMA implementation, where the 12 UTC and 15 UTC observations of the 2m temperature from the last day are used to correct the soil moisture fields, and the twenty-four hour tendencies from the last-day routine forecast are then added to the above fields to get the initial fields for the next-day forecast run (see Hess 2001, for details).

A large number of 24-hour runs are performed over 2 April 2000, 20 June 2000 and 23 September 2000, to evaluate the abovementioned parameters of the surface-layer scheme. Other experiments have also been performed, but their results are of intermediate character and are not mentioned. Using the estimates of empirical parameters evaluated through the above experiments, further LM test runs are performed for several dates in January 2001. The first month of the new millennium is chosen for a rather cold weather kept over a considerable part of the LM domain for much of the month. As the effect of the soil moisture changes during cold winter periods are typically small, the SMA is not used. The initial fields are taken from the operational LM. The key experiments are listed in Table 1. The SMA Mode "NBSE" (no background state effect) indicates that a modified SMA binary is used, where the effect of the background state is practically eliminated. The SMA Mode "LM" indicates that the SMA is used in the same way as in operational LM.

In order to further test the performance of the surface-layer parameterization scheme in a quasi-operational mode, a parallel experiment, exp_3306, has been set up, where the SMA is used in the same way as in operational LM. This experiment is performed for the period from 24 September to 7 October 2000. This period partially covers the time span of the exp_102 parallel experiment that was performed with the new LM surface-layer scheme but the model parameters used in exp_102 were not tuned. In order to avoid a long spin-up period due to possible inconsistency of the background soil moisture fields and a modified LM physics, the initial fields for exp_3306 are taken from exp_3321, where the soil moisture is determined to match the modified model physics. A comprehensive verification of the exp_3306 results against observational data is carried out.

Table 1: Key experiments.

Experiment Number	Time Period	SMA Use	SMA Mode
exp_3268	2 Apr 2000	Yes	NBSE
exp_3329	20 Jun 2000	Yes	NBSE
exp_3321	23 Sep 2000	Yes	NBSE
exp_3306	24 Sep – 7 Oct 2000	Yes	LM
exp_23sep2000	23 Sep 2000	No	—
exp_14jan2001	14 Jan 2001	No	—
exp_16jan2001	16 Jan 2001	No	—

4 Results

A net result from the runs performed with the use of SMA in frames of the experiments exp_3268, exp_3229 and exp_3321 is that the values of the new LM parameters, namely (in LM code notation), of RAT_CAN=1.0, RLAM_HEAT=1.0, RLAM_MOM=0.1 and PAT_LEN=500 m, are plausible and are recommended for the operational use.

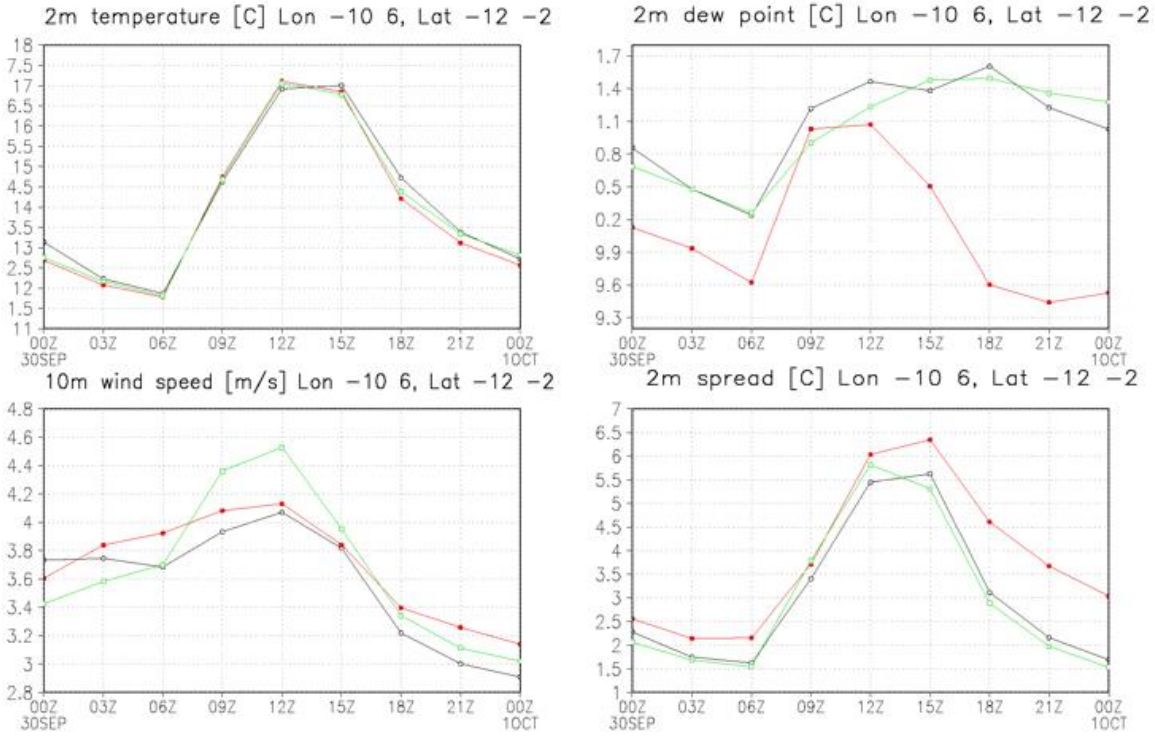

Figure 1: *The 2m temperature, 2m dew point, 10m wind speed and 2m spread from the LM analysis, black curves, from the LM operational forecast, red curves, and from a parallel experiment exp_3306, green curves. The time, UTC, and the date, 30 September 2000, are indicated at the x-axes.*

Figures 1 and 2 illustrate the performance of LM with the new physical package and the above estimates of empirical parameters versus the performance of the operational LM. The results are from a parallel experiment exp_3306. The 2m temperature, the 2m dew point,

the 10m wind speed and the 2m spread (2m temperature minus 2m dew point), predicted by the operational LM, out_LM, and by the new version of LM, exp_3306, are compared with the LM analysis, ana_LM. The curves show values of the weather elements averaged over a portion of the LM domain that is most densely covered with observations. Notice that the 2m temperature and the 2m dew point in the LM analysis come from the synoptic measurements. This is not the case for 10m wind that is a purely diagnostic quantity dependent on the interpolation procedure used in the surface-layer scheme. Therefore, the plots of 10m wind only indicate the difference between the various parameterizations.

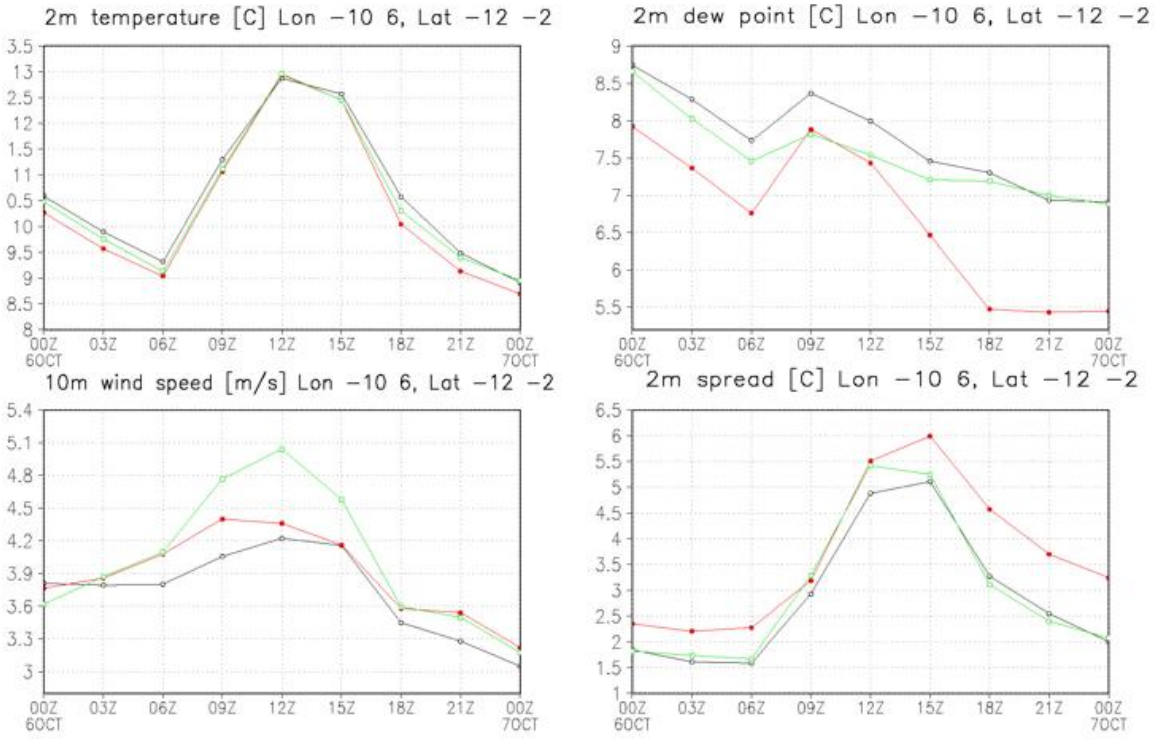

Figure 2: *The same as in Figure 1 for 6 October 2000.*

As seen from the figures, the new version of LM shows a better overall agreement with observations. A marked difference in the diurnal variation of the 2m dew point between the two versions of LM should be emphasised. In the operational LM, the diurnal course of the 2m dew point is a slightly modified re-scaled replica of the diurnal course of the 2m temperature. This is related to the diagnosis of the 2m dew point through the assumption of height-constant relative humidity in the surface layer. It leads to a strong underestimation of the dew point past 15h forecast time and, consequently, to an overestimation of the 2m spread. The latter quantity is of importance for the forecast of fogs. This overestimation is no longer the case with the new version of LM, where the diurnal course of the 2m dew point seems to be more physically realistic and compares better with observations.

Figure 3 compares the 2m temperature forecasts for 18 UTC on 16 January 2001. A test run is performed using the above values of the model parameters. The run is started at 00 UTC on 16 January 2001 with the initial fields from the operational LM. The SMA is not used. As seen from the figure, the 2m temperature is strongly underestimated by the operational LM over a considerable part of Central Europe and United Kingdom. A too rapid decrease of the temperature in the surface layer in the late afternoon hours is a long-standing problem of the LM. The deficiency is partially remedied in the new LM version. This counts in favour

of the new physical package.

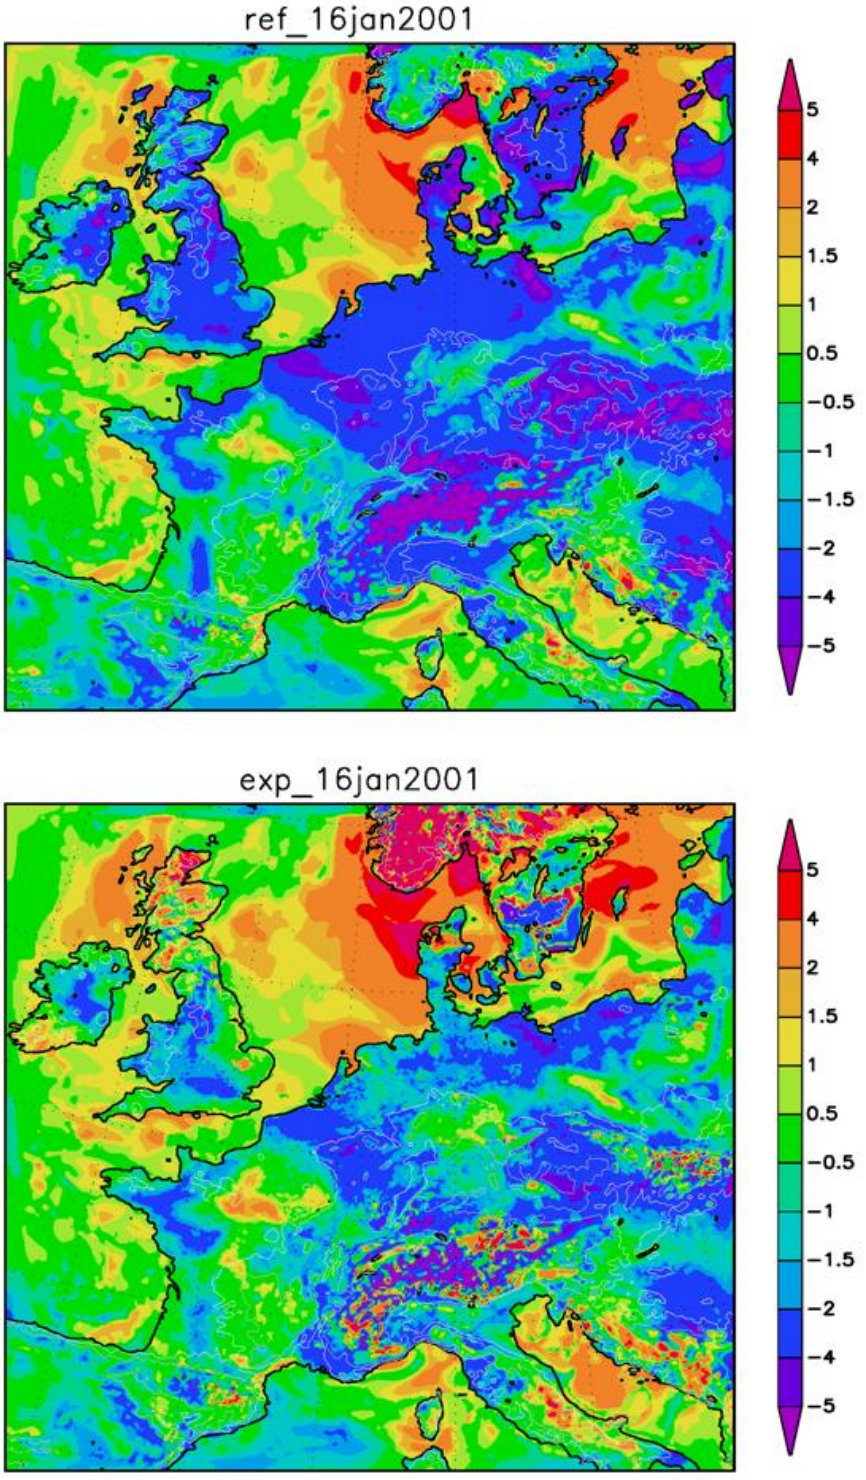

Figure 3: *Forecast error of the 2m temperature (° C), 18 UTC, 16 January 2001; the contour lines indicate the topographical heights of 200m (white) and 500m (grey); reference is the LM analysis. Upper panel: operational LM. Lower panel: test forecast with the tuned values of the model parameters as given in section 4.*

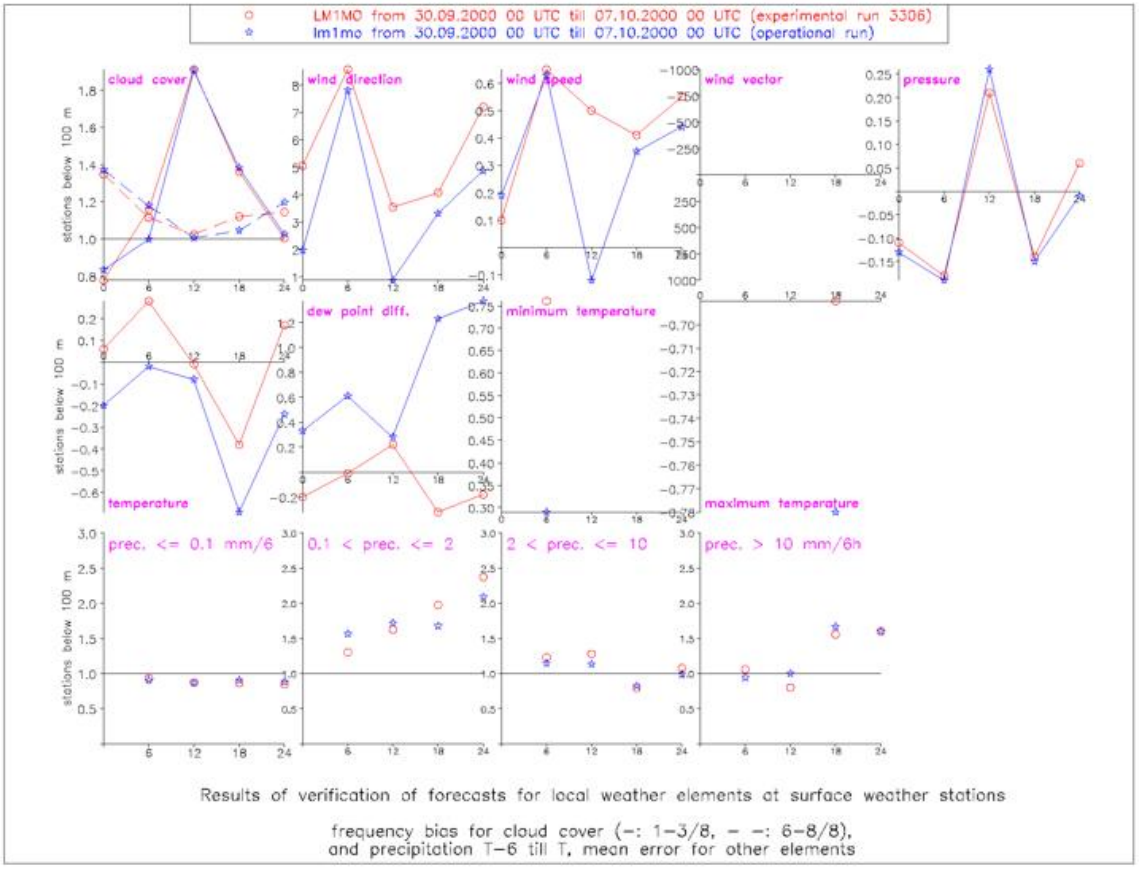

Figure 4: *Mean verification scores of all Synop Stations below 100 m for the period 30 September to 7 October 2000 (00 UTC) as a function of forecast time (00, 06, 12, 18 and 24 h). Red – experimental run exp_3306, blue – operational run.*
Mean error for all elements except for cloud cover and precipitation (frequency bias); numbers are mean values over all forecast times. Top (from left to right): cloud cover, wind direction, wind speed, wind vector and surface pressure. Middle (from left to right): temperature, dew point difference, minimum and maximum temperature. Bottom: frequency bias of 6 h precipitation amounts (prec) for the four indicated threshold intervals.

Figures 4 – 6 show results of verification of exp_3306 performed with the standard verification package of the DWD Department of Research and Development. For the weather stations whose height above the sea level does not exceed 100 m, the new version of LM reveals considerable lower mean error (Figure 4) of the 2m dew point and of the 2m temperature.

For these stations, the root-mean square error (Figure 5) is practically the same for the 2m temperature but is marginally smaller for the 2m dew point. The mean error is slightly higher for the 10m wind speed, however. The new LM version also shows a slight improvement in predicting the cloud cover, as seen in the upper left panel in Figure 5.

For all stations analysed (Figure 6) the major advantage of the new LM version is manifested in the mean error of the 2m dew point, particularly past 12h forecast time, and of the 2m temperature, particularly during the night time.

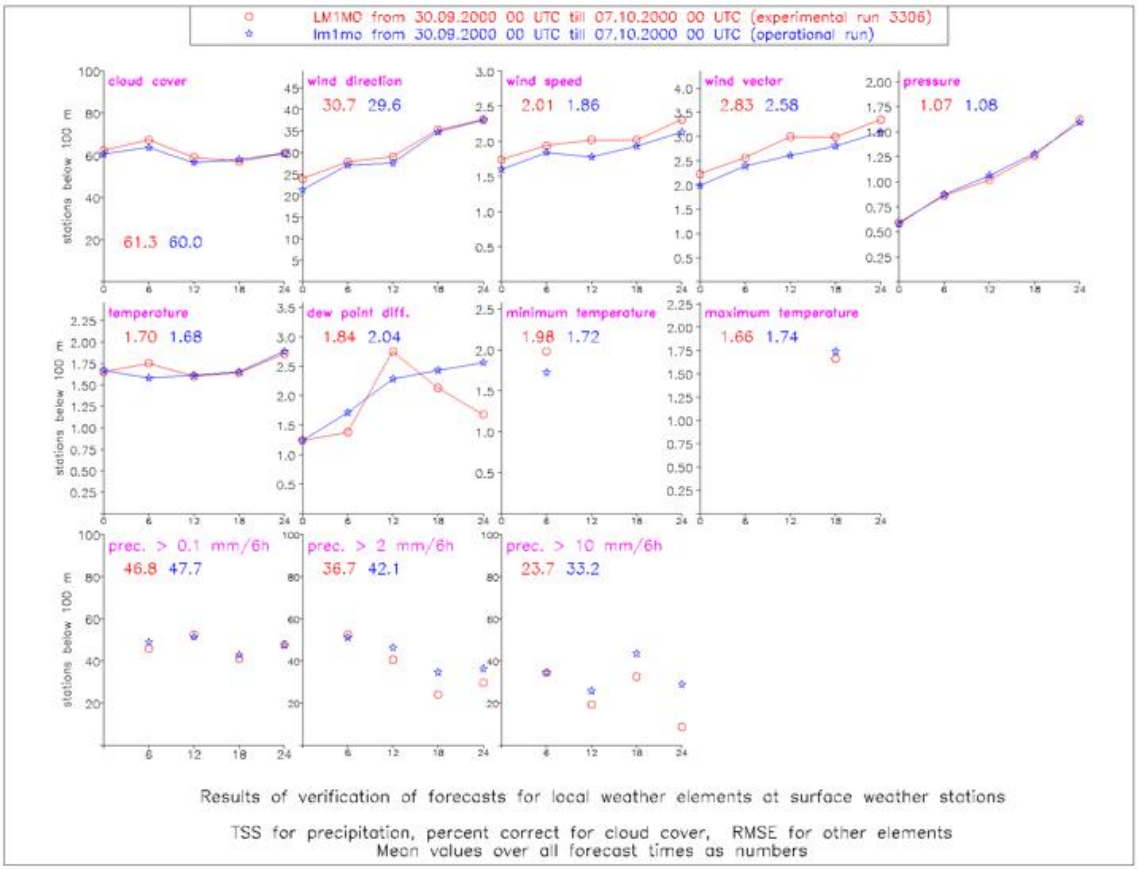

Figure 5: *As in Figure 4, but root-mean-square error for all elements exept for cloud cover (percent correct, upper panel left) and precipipitation (TSS, lower panel).*

5 Conclusions

A preliminary verification of results from the experiments described above lends considerable support to our estimates of parameters of the new LM surface-layer scheme. A negative bias of the 2m dew point is now largely reduced. The 10m wind is now reduced by about 0.4 $\mathrm{m \cdot s^{-1}}$ during the day and by about 0.1 $\mathrm{m \cdot s^{-1}}$ during the night as compared with exp_102. This reduction was suggested by verification (performed by Ulrich Damrath) of results from exp_102 against observations. As compared to the operational LM, the new parameterization scheme yields a number of improvements. Among them are a more realistic diurnal course of the 2m dew point as compared to the operational LM, and higher 2m temperatures during the evening and the night hours which are known to be underpredicted by the LM.

As a word of caution we note that in the experiments described above more emphasis has been placed on the performance of the surface-layer scheme over the land surface. The situation over the water surface motivates further investigation which may entail further modification of the surface-layer scheme.

Finally, the pattern length that is now kept constant independent of location should eventually be turned into a location-dependent two-dimensional field somewhat similar to what is now the aerodynamic roughness length of the land surface.

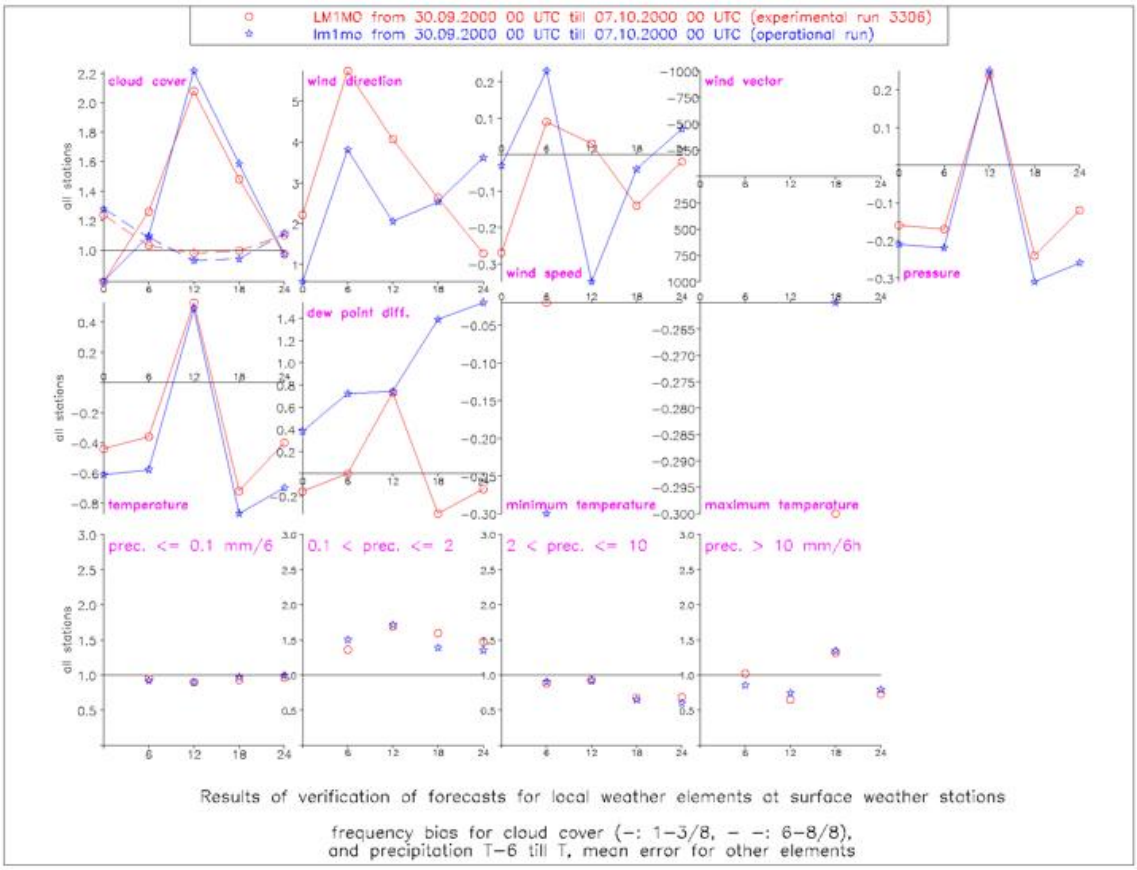

Figure 6: *As in Figure 4, but for all stations in the integration domain.*

Acknowledgements

We thank Erdmann Heise, Reinhold Hess, Günther Doms, Ulrich Damrath, Michael Buchhold and other colleagues at DWD for discussions and helpful suggestions. We are particularly grateful to Thomas Hanisch for innumerable suggestions concerning the use of the DWD Experimental Modelling System. Without his suggestions this work would have hardly ever been completed.

1 Introduction

The "experimental–operational" limited–area ensemble prediction system COSMO–LEPS has been running daily since November 2002 at the ECMWF computer system under the auspices of COSMO (Montani et al., 2003b). COSMO–LEPS aims at the development and pre–operational test of a "short to medium–range" (48–120 hours) probabilistic forecasting system using a LAM over a domain covering all countries involved in COSMO (Fig. 1).

A subjective evaluation of its performance is being carried out by the forecasters of the Meteorological Centres involved in the COSMO Consortium. Furthermore, the system is being objectively evaluated by ARPA–SIM using a set of probabilistic quality indices (Marsigli et al., 2005). In this report, a summary of the performance of COSMO–LEPS is presented, collecting also contributions coming from different COSMO partners.

In the first part, results obtained through an objective verification by ARPA–SIM are presented. In Section 2, an analysis of the methodology on which the system is based is shown, focusing on the results that led to a major modification of the system in June 2004. In Section 3, the quality of the system is assessed in an objective manner, making use of probabilistic indices. In Section 4, the operational suite has been compared with a parallel suite where a different scheme for the parameterization of the deep convection was used.

For a complete description of scores used in this report, the reader is referred to Wilks (1995), Stanski et al. (1989) and Talagrand et al. (1999) for the Brier Skill Score, Mason and Graham (1999) for the ROC Curves and the ROC area, to Richardson (2000) for the Cost-loss Analysis and to Buizza (1997) for the Percentage of Outliers.

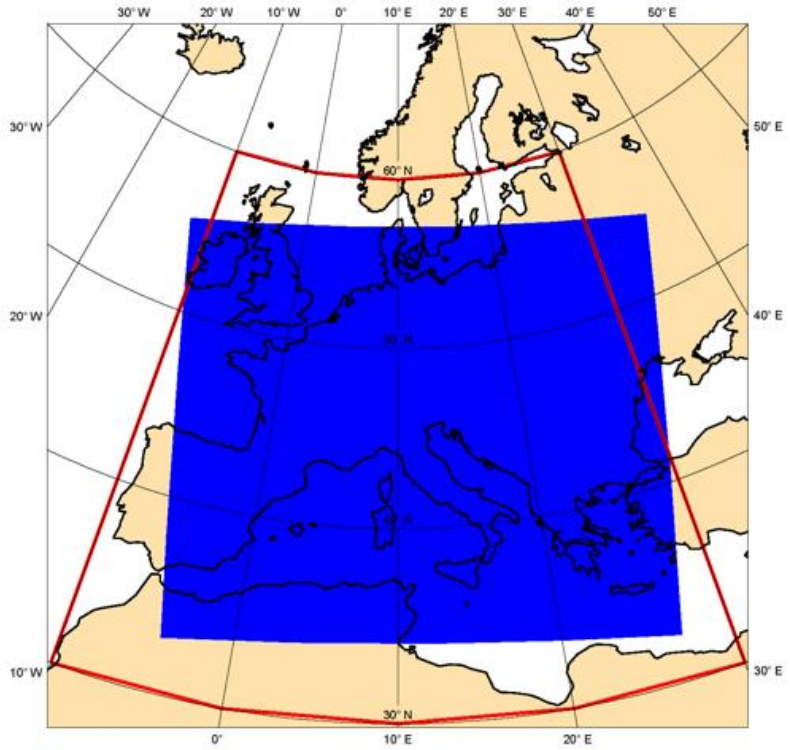

Figure 1: COSMO–LEPS operational domain (blue area) and clustering area (red frame).

In the second part, subjective evaluations of the system made by other COSMO partners are shown. In Section 5, the results from the subjective verification performed by the Regional

Agency for Prevention and Environment of the Liguria Region (ARPAL) are presented. In Section 6, the use of COSMO–LEPS by MeteoSwiss and the impressions got by the forecasters are described. In Section 7, the contribution by the forecasters of DWD is reported.

Finally, in Section 8 some conclusions are drawn.

2 Statistical analysis of the methodology

An analysis of the methodology on which COSMO–LEPS is based is presented in this section.

The idea of joining three consecutive EPS to form a super–ensemble is based on the need of enlarging the size of the ensemble on which the RM selection algorithm is applied. This permits to increase the ensemble spread and to have a wider part of the phase space spanned by the global ensemble members. Nevertheless, this is obtained by paying a price in terms of skill: the older is the EPS, the less skillful are their members. In order to quantify the relative effects of the increased spread and of the decreased skill, the Representative Members chosen with the current methodology are compared to those chosen using only one or two EPS. The three ensembles compared, are:

- the ensemble made up by the 5 RMs selected applying the Cluster Analysis and Representative Member Selection Algorithm on the three most recent EPS (referred to "3–EPS"), which is the original operational configuration
- the ensemble made up by the 5 RMs selected applying the Cluster Analysis and Representative Member Selection Algorithm on the two most recent EPS (referred to "2–EPS")
- the ensemble made up by the 5 RMs selected applying the Cluster Analysis and Representative Member Selection Algorithm on the most recent EPS (referred to "1–EPS")

This analysis is performed in terms of 24–hour precipitation. The forecast values at each grid point are compared with a proxy for the true precipitation occurred chosen as the +24 hours forecast by the ECMWF deterministic model. The extent to which this proxy is a good approximation for the truth is not important, because this is a comparison among different configurations of the same model. The period chosen for this test is September–November 2003 and the area is the clustering area (rectangle in Fig. 1).

Results show that the Brier Skill Score (the higher the better, see Wilks, 1995) is higher when the clustering is based on the most recent EPS only (Fig. 2, black line), while it is lower for the 3–EPS super–ensemble (blue line). The difference between the two is not so remarkable, but it remains at every forecast range. The 2–EPS super–ensemble (red line) has an intermediate skill, equal to the one of the 1–EPS ensemble at the first and last forecast ranges, its general performance being nearest to the one of the 1–EPS ensemble.

The percentage of outliers of the systems is also shown. This is the percentage of times the "truth" falls out of the range of the forecast values. The percentage of outliers (Fig. 3) of the 1–EPS ensemble (black line) is rather higher than the other two, for every forecast range, while there is almost no difference in terms of outliers between the 2–EPS (red line) and the 3–EPS (blue line) ensembles. These results seem to indicate that the use of just two EPS

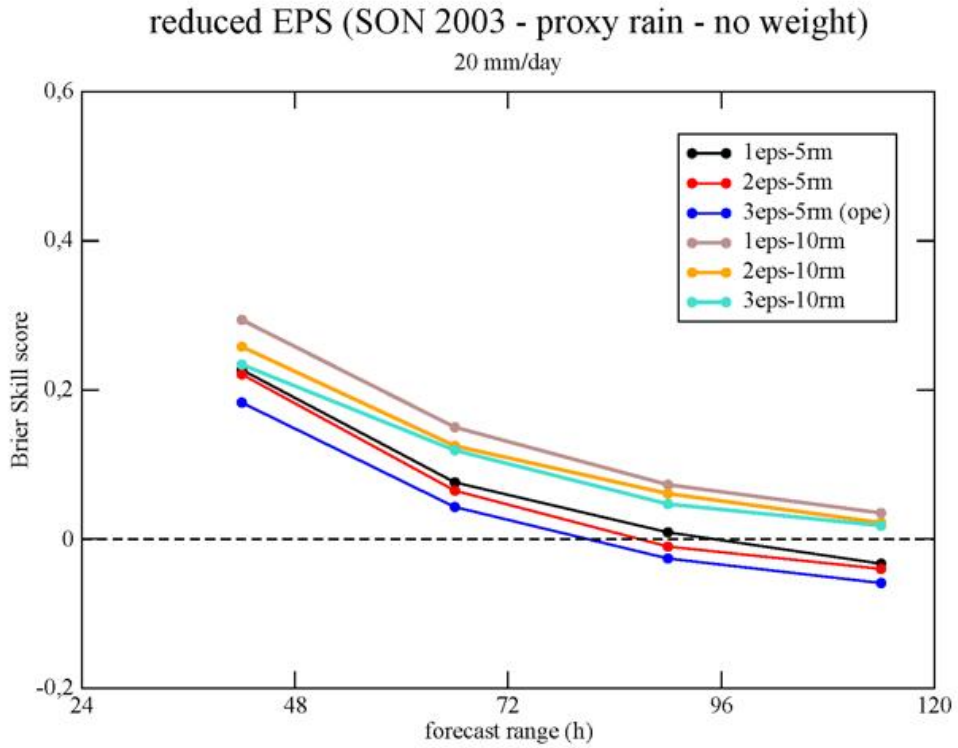

Figure 2: Brier Skill Score as a function of the forecast range for the event precipitation exceeding 20mm/24h relative to the RM EPS. The different configurations are: 5 clusters algorithm based on 1 EPS (black line), on 2 EPS (red line) and on 3 EPS (operational configuration, blue line); 10 clusters algorithm based on 1 EPS (gray line), on 2 EPS (orange line) and on 3 EPS (cyan line).

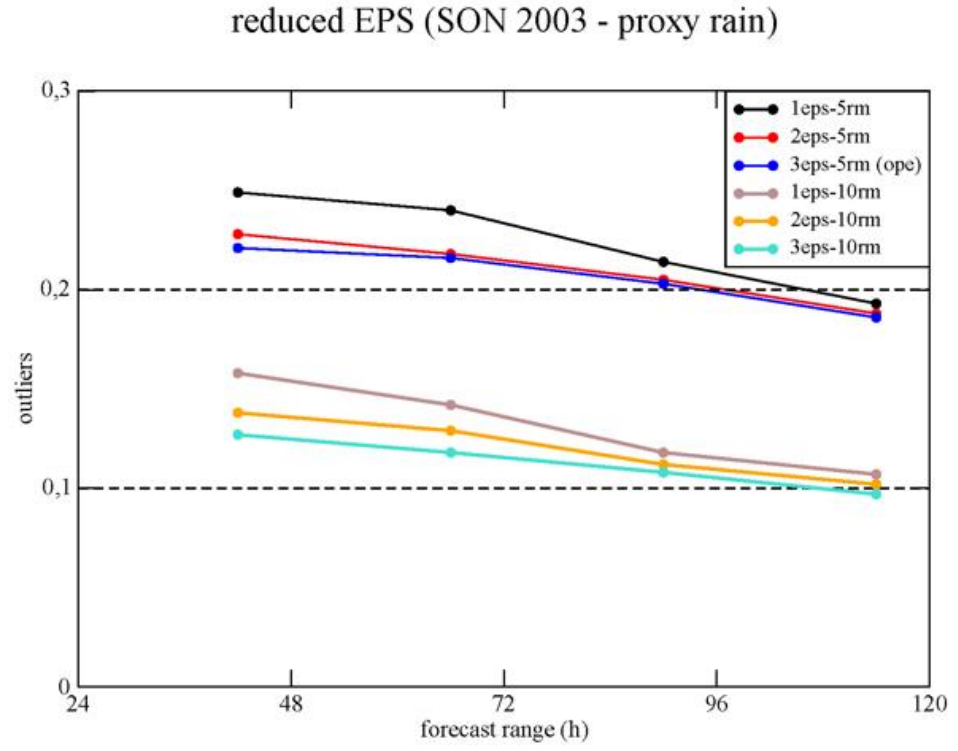

Figure 3: Percentage of outliers for the RM EPS, colours as in the previous figure.

in the super–ensemble can be a good compromise, permitting to decrease the percentage of outliers significantly but leading only to a small worsening of the skill.

In order to quantify the impact of the ensemble size on the performance of the system, the cluster analysis has been repeated by fixing the number of clusters to 10 and by selecting, then, 10 Representative Members. This has been done for each of the three ensemble configurations already considered, leading to the three configurations: 3–EPS–10RMs, 2–EPS–10RMs and 1–EPS–10RMs. The impact of the ensemble size proves to be quite remarkable, the difference between each 5–member ensemble and the correspondent 10–member ensemble being about 0.1 in terms of Brier Skill Score, for every configuration. This is shown in Fig. 2, where the blue line (3–EPS–5RMs) has to be compared with the cyan line (3–EPS–10RMs), the red line (2–EPS–5RMs) with the orange line (2–EPS–10RMs) and the black line (1–EPS–5RMs) with the brown line (1–EPS–10RMs). The impact of doubling the ensemble size is almost the same for every configuration and is predominant with respect to the impact of changing the number of EPS on which the Cluster Analysis is performed.

These results lead to two major modifications of the COSMO–LEPS methodology at the beginning of June 2004: the super–ensemble has been built by using only the 2 most recent EPS and the number of clusters has been fixed to 10, nesting Lokal Modell on each of the 10 RMs selected.

3 Objective verification

In order to quantify the added value brought about by the mesoscale probabilistic system, COSMO–LEPS is compared with the EPS. The comparison is made difficult by two main factors: the difference in the number of ensemble members (5 for COSMO–LEPS and 51 for the EPS) and the difference in terms of resolution (10 km for COSMO–LEPS and 80 km for the EPS). As the population of the ensembles is concerned, COSMO–LEPS is compared also with the small EPS ensemble made up by the 5 Representative Members. This permits to quantify the impact of the increased resolution alone. The problem of the very different resolutions of the two systems is tackled by upscaling both systems to a lower resolution: the grid point forecasts of both model are averaged over boxes of 1.5×1.5 degrees. The comparison is made in terms of 24–hour precipitation, against observed data from a very dense network of raingauges. Precipitation is cumulated from 06 to 06 UTC. In order to properly compare forecast values on grid points and observed values on station points, the observations within a box are averaged and the obtained value can be compared directly with the averaged forecast value. The comparison is carried out over a big area included in the COSMO–LEPS domain, covering Germany, Switzerland and Northern Italy. The very dense network of stations recording daily precipitation is shown in Fig. 4.

In order to avoid problems in the boxes at the boundaries of the domain covered by observations, an "observational mask" is used. This mask was built by assigning a value of 1 to a grid point only if its distance to at least one observation is less than 0.15 degrees; otherwise, it is assigned the value of 0. The mask relative to COSMO–LEPS and to the data–set used in this work is shown in Fig. 5. To compute the average or the maximum forecast value over a box, only grid points that are labelled 1 have been considered.

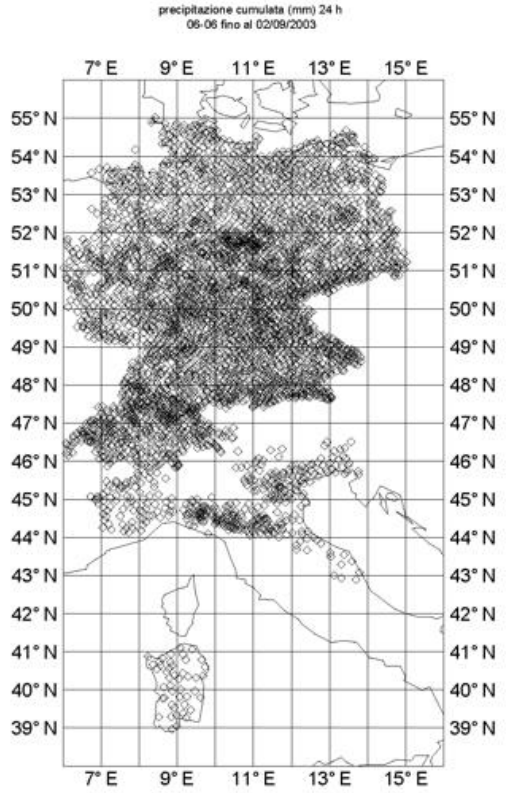

Figure 4: Network of station providing 24–hour precipitation (06 UTC to 06 UTC) for the COSMO verification.

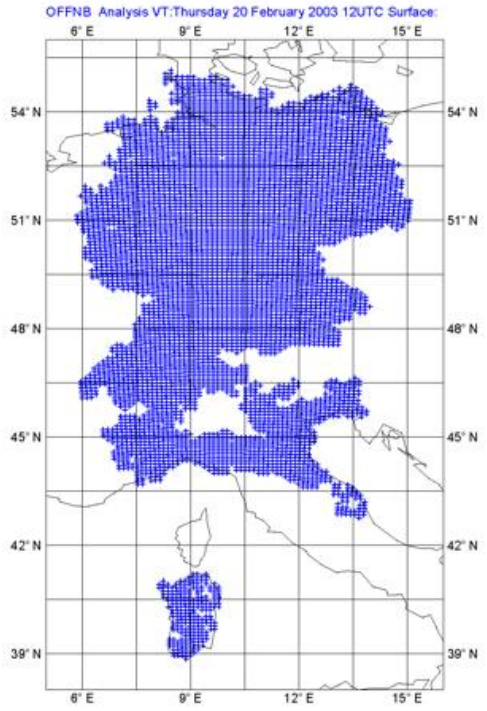

Figure 5: The "observational mask" used for COSMO–LEPS. Only grid points which are not too far from the area covered by the observations are considered.

The 3 ensemble systems compared are:

- the COSMO–LEPS system, made up of 5 members, 10 km of horizontal resolution, referred to as "cleps";
- the EPS mini–ensemble made up by the 5 Representative Members chosen from the super–ensemble, 80 km of horizontal resolution, referred to as "epsrm";
- the operational 51–member ECMWF EPS starting at the same initial time as COSMO–LEPS (the "youngest" EPS constituting the super–ensemble), 80 km of horizontal resolution, referred to as "eps51";

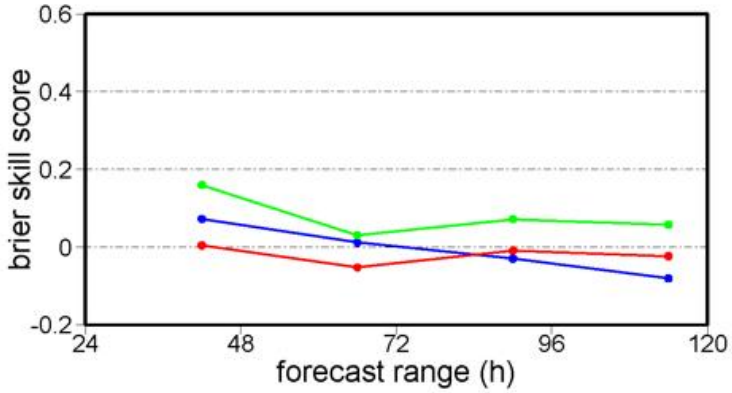

Figure 6: Brier Skill Score values for the precipitation threshold 20mm/24h. The blue line is relative to cleps, the red line is relative to epsrm, the green line is for eps51. Average observed and forecast values are compared.

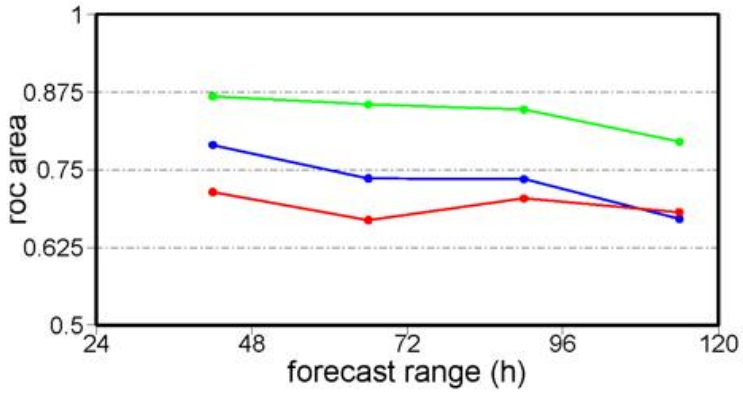

Figure 7: ROC area for the precipitation threshold 20mm/24h. The blue line is relative to cleps, the red line is relative to epsrm, the green line is for eps51. Average observed and forecast values are compared.

In Fig. 6 and Fig. 7 the Brier Skill Score and the ROC area are shown for the three systems (for both index, the higher the better). The average observed value of each box, obtained by computing the mean of all the observations falling in a box, is compared with the average forecast value relative to the same box, for each of the three forecasting systems. The event considered here is precipitation exceeding 20 mm / 24 h over 1.5 x 1.5 degree boxes. Since the observed and forecast values are averaged over an area of 1.5 x 1.5 degrees, this threshold is individuating an intense precipitation.

In terms of Brier Skill Score (Fig. 6) the three lines are rather close together. The BSS values of the full–size 51–member EPS (eps51, green line) are slightly higher than those of the other two systems, that is, its performance is slightly better. The difference between cleps and epsrm is slightly in favour of cleps for the first forecast ranges, while the reverse it is true at the +114 forecast range.

The differences in the performances of the three system are enlighted by the ROC area values (Fig. 7). The full–size 51–member EPS (eps51, green line) has the best scores at this threshold for every time range. The COSMO–LEPS system (cleps, blue line) has lower scores, but higher than those of the 5–RM EPS (epsrm, red line).

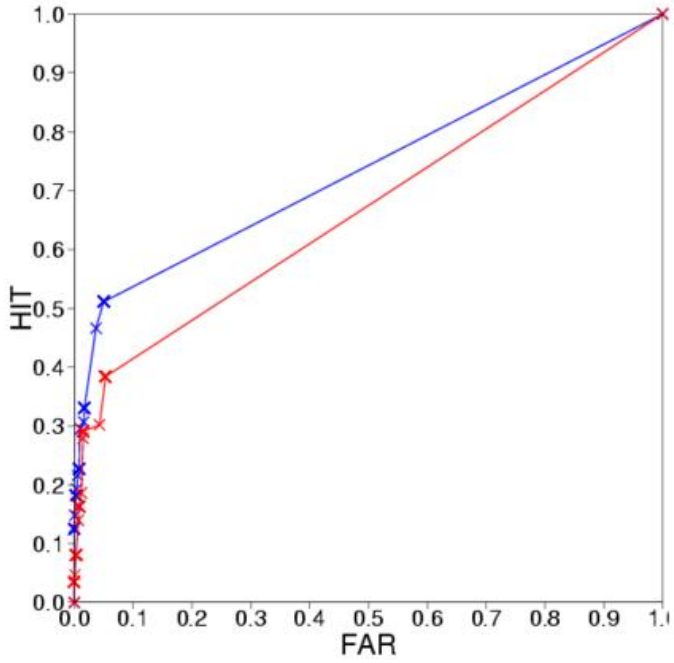

Figure 8: Average values: ROC Curves for the precipitation threshold 20mm/24h and for the +66h forecast range. The blue line is relative to cleps while the red line is relative to the epsrm.

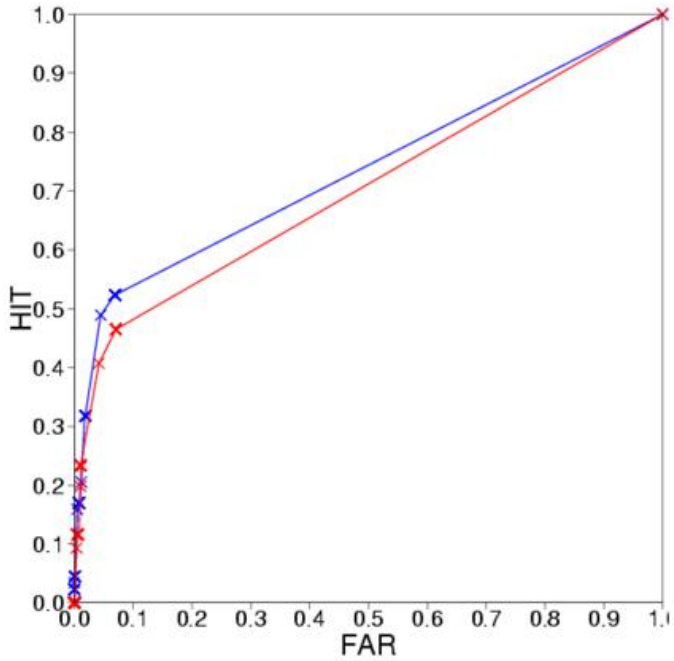

Figure 9: Average values: ROC Curves for the precipitation threshold 20mm/24h and for the +90h forecast range. The blue line is relative to cleps while the red line is relative to epsrm.

The ensemble size often plays a major role in the computation of the probabilistic indices, making a proper comparison between cleps and eps51 difficult. When the two systems with the same size are compared, "cleps" shows an improvement with respect to the "epsrm", especially in terms of ROC area. In order to better understand this result, the ROC Curves for these two systems are also reported.

The ROC Curves relative to COSMO–LEPS and to the 5–RM EPS are shown for the event "precipitation exceeding 20mm/24h", for the forecast ranges +66 hours (Fig. 8) and +90 hours (Fig. 9). The "cleps" curves (blue curves) are higher than the "epsrm" ones (red curves) for both forecast ranges. Considering the first cross from the top right in the diagram, it is evident that the two systems have comparable False Alarm Rates, but COSMO–LEPS obtains higher Hit Rate values. This cross is correspondent to the probabilistic issue "at least one ensemble member is forecasting the event", whose practical meaning can be understood referring to an alert situation. If a user has a damage from the considered event, he can avoid the related loss by taking a preventive action. In order to decide if the action has to be taken, he uses the probabilistic system, but he has to decide on which probability threshold to rely. The first cross of the diagram corresponds to the hit rate and false alarm rate a user can have, if he decides to take a protective action when at least one ensemble member forecasts the event, so he relies on a very low probability threshold. This situation is usually linked with cases in which the possible loss is very high (human lives) with respect to the cost of the preventive action.

Averaging the precipitation over boxes of this size permits to understand if the total amount of precipitation over a vast region is correctly forecast, without giving information on precipitation peaks, which are very important for hydro–geological purposes. A high–resolution system could play a major role in forecasting precipitation peaks, introducing information not available with a lower resolution model. For this reason, a comparison in terms of precipitation maxima has been performed: the maximum forecast value falling in a box is compared with the maximum observed value in the same box. The boxes are of the same size, 1.5×1.5 degrees. In this analysis, higher precipitation thresholds have been considered, due to the fact that the average precipitation over a large area and the maximum precipitation over the same area are two different quantities and can be considered to different "events" to be verified.

The BSS values relative to cleps for the 20 and 30 mm/24 thresholds (top and medium panels of Fig. 10, blue line) are well higher than both the epsrm and eps51 ones, indicating that COSMO–LEPS is more able to correctly forecast high precipitation values over a rather big area. Both eps51 and epsrm have almost no skill and no difference between the two is evident. At the highest threshold, all the three systems show almost no skill in terms of Brier Skill Score and it is not possible to find a difference between their performances.

In terms of ROC area (Fig. 11), cleps has the highest values for all the considered thresholds, exhibiting some skill even for the 50mm/24h thresholds. Then, the COSMO–LEPS system exhibits some skill in forecasting high precipitation peaks not reproduced by the lower resolution ensemble. According to this score measure, eps51 is more skillful than epsrm, showing the positive impact of the ensemble population on this index.

The difference of the behaviour of the scores in the evaluation of the three ensemble systems is due to the characteristics of these scores. In particular, the Brier Skill Score is more sensitive to the probability with which a forecast is issued: an event correctly forecast with low probability has a positive impact on the ROC area and a negative one on the Brier Skill Score. For this reason, it is better to look at a number of indices when evaluating the performances of a forecasting system.

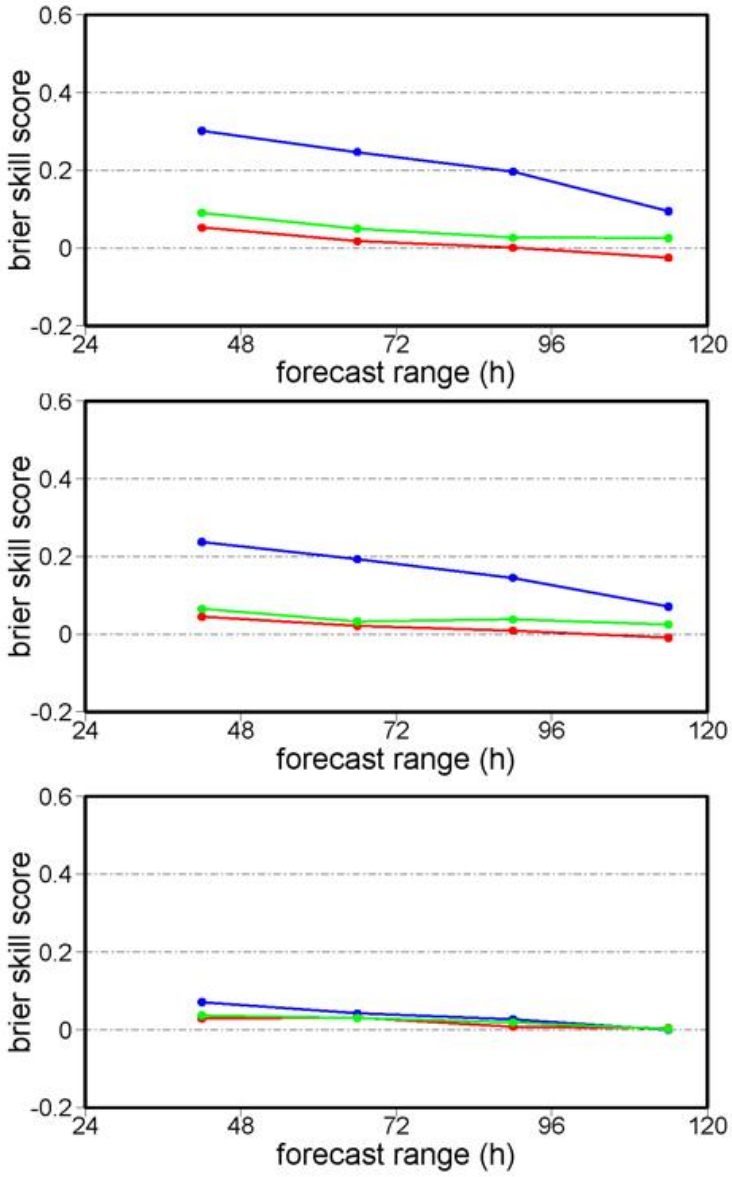

Figure 10: Brier Skill Score values for the precipitation threshold 20mm/24h (top panel), 30mm/24h (medium panel) and 50mm/24h (bottom panel). The blue line is relative to cleps, the red line is relative to epsrm, the green line is for eps51. Maximum observed and forecast values are compared.

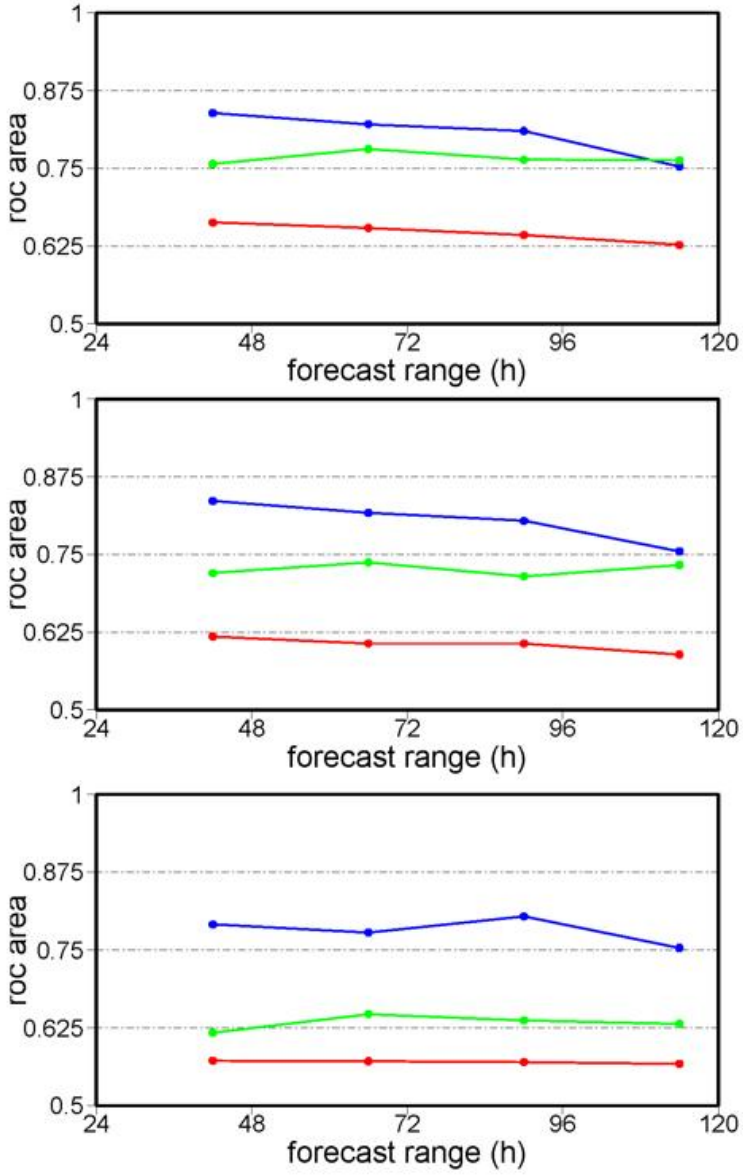

Figure 11: ROC area for the precipitation threshold 20mm/24h (top panel), 30mm/24h (medium panel) and 50mm/24h (bottom panel). The blue line is relative to cleps, the red line is relative to epsrm, the green line is relative to eps51. Maximum observed and forecast values are compared.

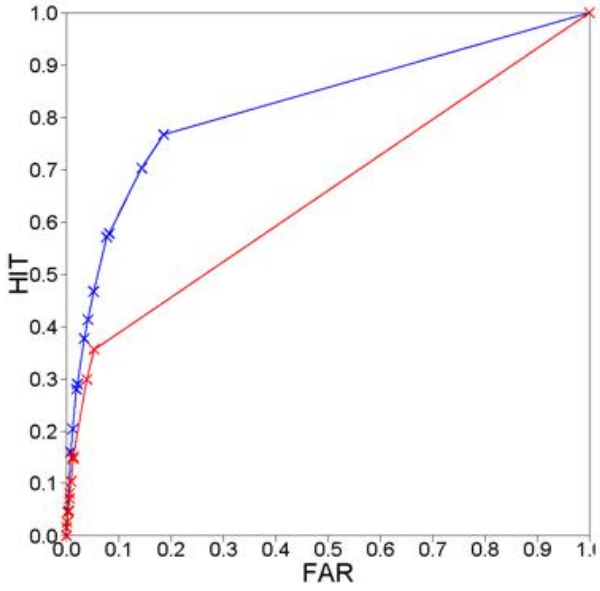

Figure 12: Maximum values: ROC Curves for the precipitation threshold 20mm/24h and for the +66h forecast range. The blue line is relative to cleps while the red line is relative to the epsrm.

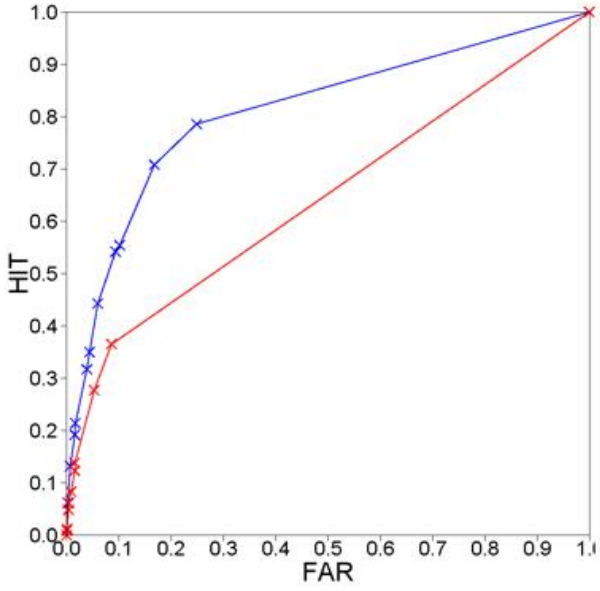

Figure 13: Maximum values: ROC Curves for the precipitation threshold 20mm/24h and for the +90h forecast range. The blue line is relative to cleps while the red line is relative to epsrm.

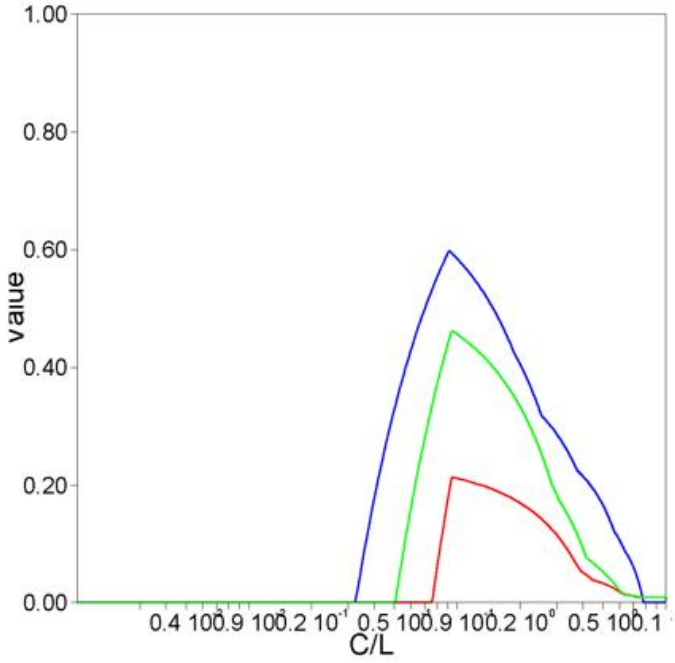

Figure 14: Envelope of the cost-loss curves for the precipitation threshold 30mm/24h (maximum values) for the +66h forecast range. The blue line is relative to cleps, the green line is relative to eps51 and the red line is relative to epsrm.

A general decrease of the cleps scores with increasing forecast range is evident for both BSS and ROC area, the score of cleps reaching that of eps51 at the +114 h forecast range for almost all the thresholds.

The ROC Curves relative to COSMO–LEPS and to the 5–RM EPS are shown for the event "maximum precipitation exceeding 20mm/24h", for the forecast ranges +66 hours (Fig. 12) and +90 hours (Fig. 13). The "cleps" curves (blue curves) are well above the "epsrm" ones (red curves) for both forecast ranges. Considering the first cross from the top right in the diagrams (correspondent to the probabilistic issue "at least one ensemble member is forecasting the event"), the relationship between Hit Rate and False Alarm Rate of the two systems can be easily understood. At the +66 h (+90 h) forecast range, COSMO–LEPS produces more false alarms, FAR being around 0.2 (0.25) for cleps and 0.05 (0.1) for epsrm, but it has a more than double Hit Rate, HIT being around 0.75 (0.8) for cleps and 0.35 (0.35) for epsrm.

Finally, the cost-loss curves relative to the event "maximum precipitation over the box exceeding 30 and 50 mm/24h" are shown for the +66 hour forecast range (figures 14 and 15, respectively. This curves quantify the "value" of the forecast systems (expressed as a percentage, 100% is the value of a perfect forecast system) as a function of the ratio between cost (C) and loss (L). This ratio depends on the user, who incur a loss (L) if a dangerous meteorological event occurs and who can prevent this event by taking an action which cost is C. Each user has to find the position corresponding to his/her own "C/L" on the x–axis of this graph, then he/she can find the value he/she could obtain by using the forecasting system in order to decide when to take a preventive action.

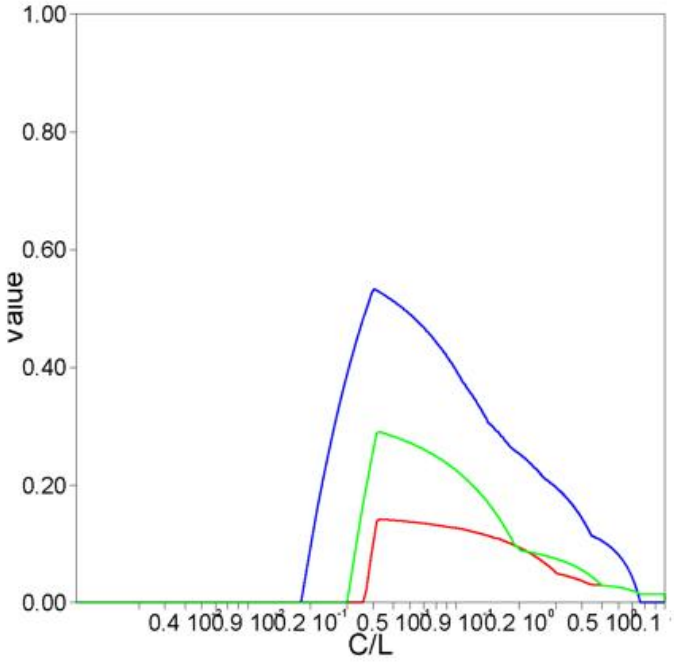

Figure 15: Envelope of the cost-loss curves for the precipitation threshold 50mm/24h (maximum values) for the +66h forecast range. The blue line is relative to cleps, the green line is relative to eps51 and the red line is relative to epsrm.

4 Parallel suite with model perturbations

The COSMO–LEPS members are differentiated only by their initial and boundary conditions, which come from different members of the ECWMF EPS. More spread can be easily added to the mesoscale ensemble by nesting in each of the selected EPS Representative Member more than one limited–area model or, more simply, the same model in different configurations. This is a simple way of adding model perturbations in the ensemble formulation. This was attempted for the COSMO–LEPS system by integrating a pair of LM runs for each set of initial and boundary conditions, the twin runs being different only in the scheme used for the parameterization of the convection. This lead to a 10 member limited–area ensemble. At the same time, two 5–member suite have become available, differentiated only by the configuration of the limited–area model. Then, starting from September 2003 to May 2004, a second suite, parallel to the standard one was running. In the standard suite the Tiedtke scheme was used for the parameterization of the convection, while in the parallel suite the Kain–Fritsch scheme was used. The two systems are referred to as "Tiedtke suite" and"Kain–Fritsch suite".

The 10–member COSMO–LEPS, obtained by simply joining the two suites, is then a system in which perturbations in the model are added to the usual perturbations in the initial and boundary conditions. This system is referred to as "combined suite".

A comparison of the three suites is made in terms of 24–hour precipitation using observed data from a network of raingauges covering Northern Italy (about 600 stations). The comparison is made over boxes of 0.5×0.5 degrees that covers this area. The average (maximum) of the forecast values falling in each box are compared with the average (maximum) of the observed values falling in the same box. The values are computed by considering, for each

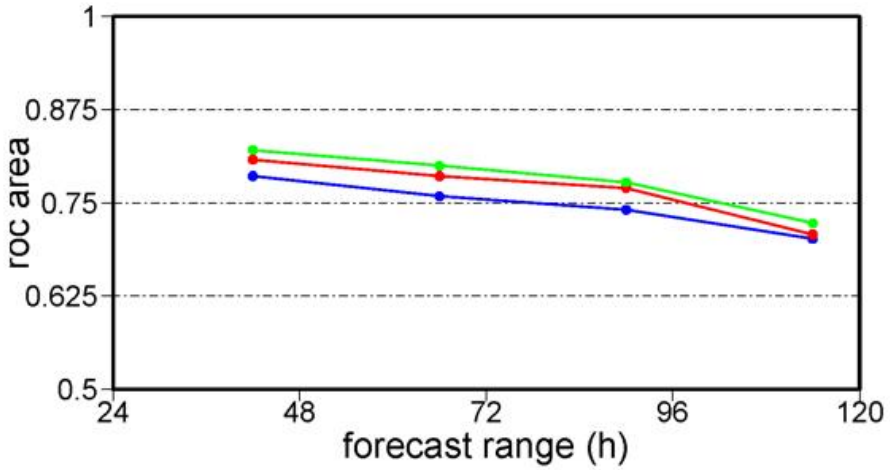

Figure 16: ROC area values as a function of the forecast range for averaged precipitation over 0.5×0.5 degrees boxes exceeding 20mm/24h. The blue line is relative to the Tiedtke suite (operational), the red line is relative to the Kain–Fritsch suite and the green line is for the 10–member combined suite.

box, only the model grid points that lies within a small distance from at least one observation point, following the "observational mask" technique described in the previous section.

In Fig. 16 the ROC area values computed in terms of average values over 0.5×0.5 degrees boxes are shown. The precipitation threshold is 20mm/24h. In terms of ROC area, the Kain–Fritsch suite (red line) improves with respect to the Tiedtke suite (blue line). The score of the combined suite (green line) is a little higher than both 5–member suites, but it is very similar to the one of the Kain–Fritsch suite. This seems to suggest that adding this kind of model perturbations without changing also initial and boundary conditions is not very useful, the spread added by using two different convection scheme being much lower than the other. In order to better understand the difference between the two schemes on the skill in forecasting precipitation, the ROC diagram at the +90h forecast range is reported in Fig. 17.

Looking at the first crosses from the top right corner (low probability classes), the Hit Rate of the Kain–Fritsch suite is rather higher than that of the Tiedtke suite, while only a small increase in terms of False Alarm Rate is shown.

When verification is repeated in terms of maximum values over the same boxes, different results are obtained. Considering maximum values over boxes, a higher precipitation threshold (50mm/24h) is chosen for this analysis. As shown in Fig. 18, higher ROC area values are relative to the Tiedtke suite (blue line), but the difference between the two is narrowing for increasing forecast range. The combined suite line (green) is still the highest, but only by a very little amount.

Considering the ROC Curves at the +90h forecast range (Fig. 19), it appears that the small difference between the two suites is due to a little increase in terms of Hit Rate for the Tiedtke suite, while the False Alarm Rate are almost identical.

Actually, it does not seem possible to establish from these results which convection scheme lead to the best performance of the mesoscale ensemble. Furthermore, it is evident that using this kind of model perturbation in order to increase the ensemble spread does not lead to the expected results, the performance of the 10–member ensemble being almost identical

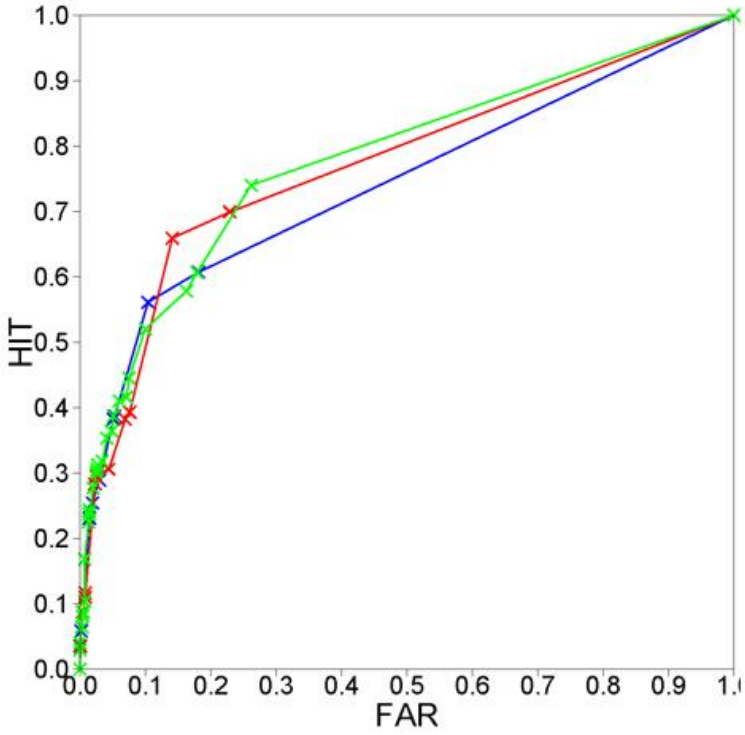

Figure 17: ROC Curves for the precipitation threshold 20mm/24h (average values) and for the +90h forecast range. The blue line is relative to the Tiedtke suite (operational), the red line is relative to the Kain–Fritsch suite and the green line is for the 10–member combined suite.

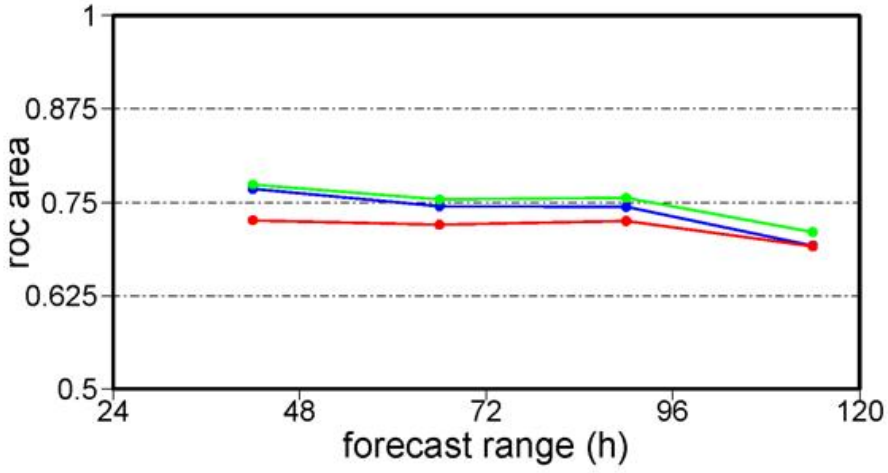

Figure 18: ROC area values as a function of the forecast range for maximum precipitation over 0.5 x 0.5 degrees boxes exceeding 50mm/24h. The blue line is relative to the Tiedtke suite (operational), the red line is relative to the Kain–Fritsch suite and the green line is for the 10–member combined suite.

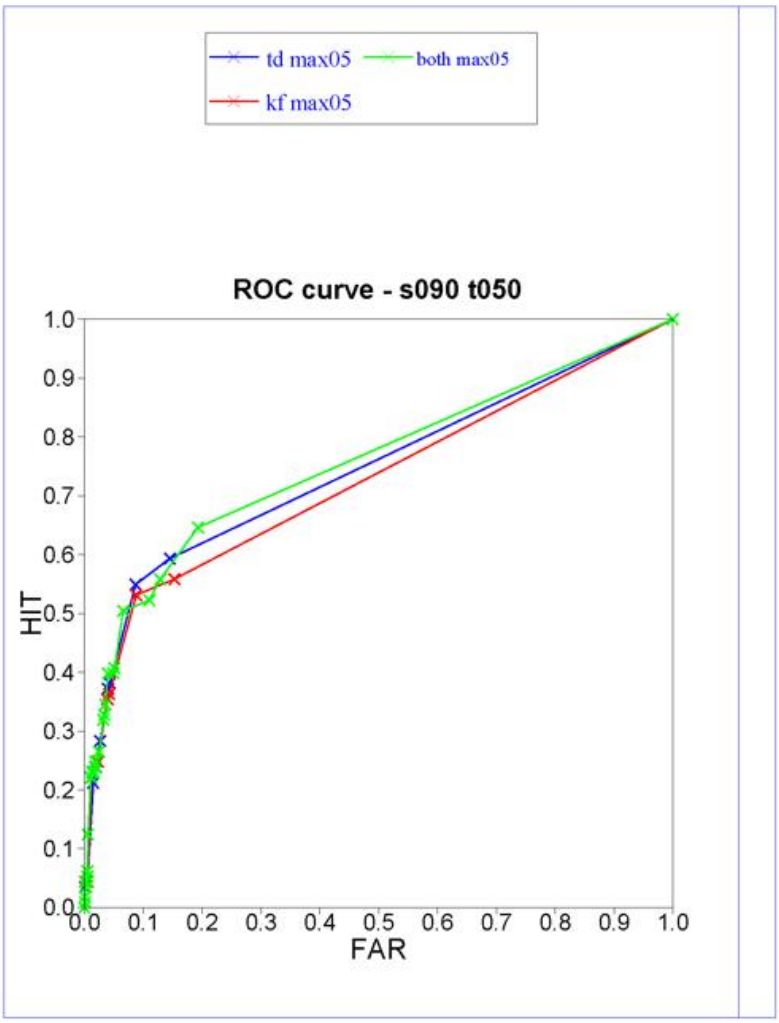

Figure 19: ROC Curves for the precipitation threshold 50mm/24h and for the +90h forecast range. The blue line is relative to the Tiedtke suite (operational), the red line is relative to the Kain–Fritsch suite and the green line is for the combined suite.

to those of both 5–member ensembles. Due to this result, we decided to move to a 10–member COSMO–LEPS by selecting 10 Representative Members out of the EPS, to benefit from the spread introduced by the different initial and boundary conditions. Nevertheless, trying to benefit also from the little spread added by this kind of model perturbations, we decided to perform the 10 LM runs by using both the Tiedtke and Kain–Fritsch schemes for the parameterization of the convection. Then, from June 2004, also this modification was introduced in the COSMO–LEPS suite and the convection parameterization scheme used by each single run is selected randomly.

5 COSMO-LEPS Subjective verification – Contribution by ARPAL, Genova, Italy (Davide Sacchetti)

This analysis aims at evaluating from a quantitative point of view the subjective judgements by the forecasters on the usefulness of COSMO–LEPS as a tool for operational weather forecast. The followed methodology is described in section 5.1 while the results are presented in section 5.2.

5.1 Description of the methodology

The questions we have tried to answer are:

- do the members provide weather scenarios actually different from the forecaster's point of view?
- do the members provide useful informations on both the amount and the localization of the precipitation?
- is the most weighted member the more skillful?
- what kind of information can be obtained by the forecasters from the probability maps for the exceeding of a threshold?
- does the system performance depend on the synoptic situation?

In order to answer these questions, the forecasters have been asked to judge the COSMO–LEPS products following a scheme developed for this purpose.

5.1.1 Subjective evaluation of the precipitation field forecast by the 5 members

A qualitative analysis of the skill of the forecast provided by the 5 COSMO–LEPS members is performed through three steps:

- identification of the member(s) which better forecasts the localization of the precipitation maxima over the considered area
- identification of the member(s) which better forecasts the amount of maxima of precipitation over the considered area
- How many members are significantly different?

In Fig. 20 the mask used by the forecaster for the evaluation of the 5 different scenarios provided by COSMO-LEPS is shown.

It is also possible to signal that no one of the members is representative of the observed scenario.

At this stage the forecaster does not know the weights which are assigned to each member; the comparison between his/her choice and the "a priori" probabilities are carried out afterwards.

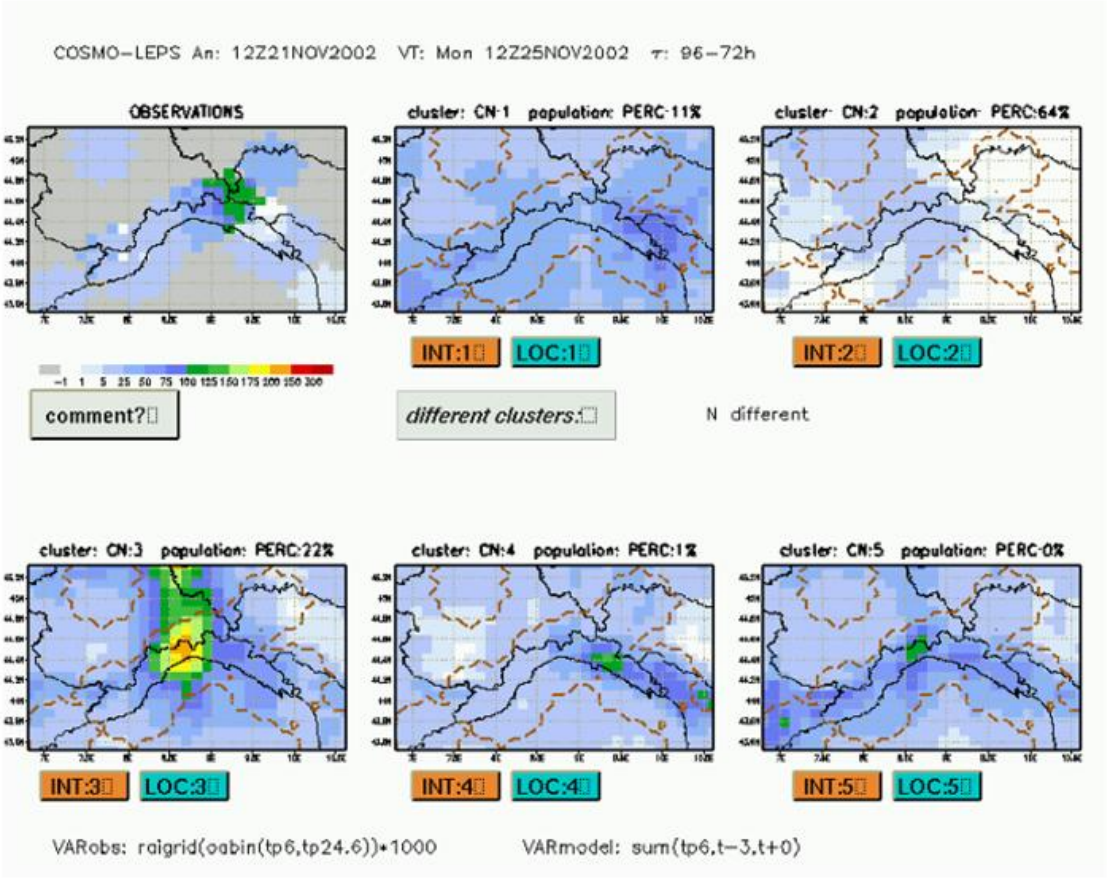

Figure 20: Mask used by the forecasters of the ARPAL Hydro–meteorological Service for the subjective evaluation of the forecast provided by the 5 COSMO–LEPS members.

5.1.2 Subjective evaluation of the COSMO–LEPS probability maps

A qualitative analysis of the skill of the forecast provided by the COSMO–LEPS probability forecast is performed. For each precipitation threshold (20, 50, 100 mm/24h), the probability map is compared with a map of observed precipitation cut at the corresponding threshold (only values exceeding the threshold). The forecaster assigns a score (agreement: poor, reasonable, good) to the probability fields on the basis of their usefulness. This is evaluated only in terms of the "alarm level" suggested by the probability maps, that is on the forecast precipitation amount, giving only small importance to the correct localization of the phenomena. In this phase what is more important is the capability of providing a signal of an intense event.

In Fig. 21 the mask used by the forecaster for the evaluation of the COSMO–LEPS probability maps is shown.

5.1.3 Individuation of the synoptic pattern

Finally, the performance of COSMO–LEPS is related to the synoptic situation associated with the considered event. The forecasters have to answer to the following question: to which synoptic pattern is it possible to associate the considered event? They can choose between four possibilities, which are listed in Table 5.1.3.

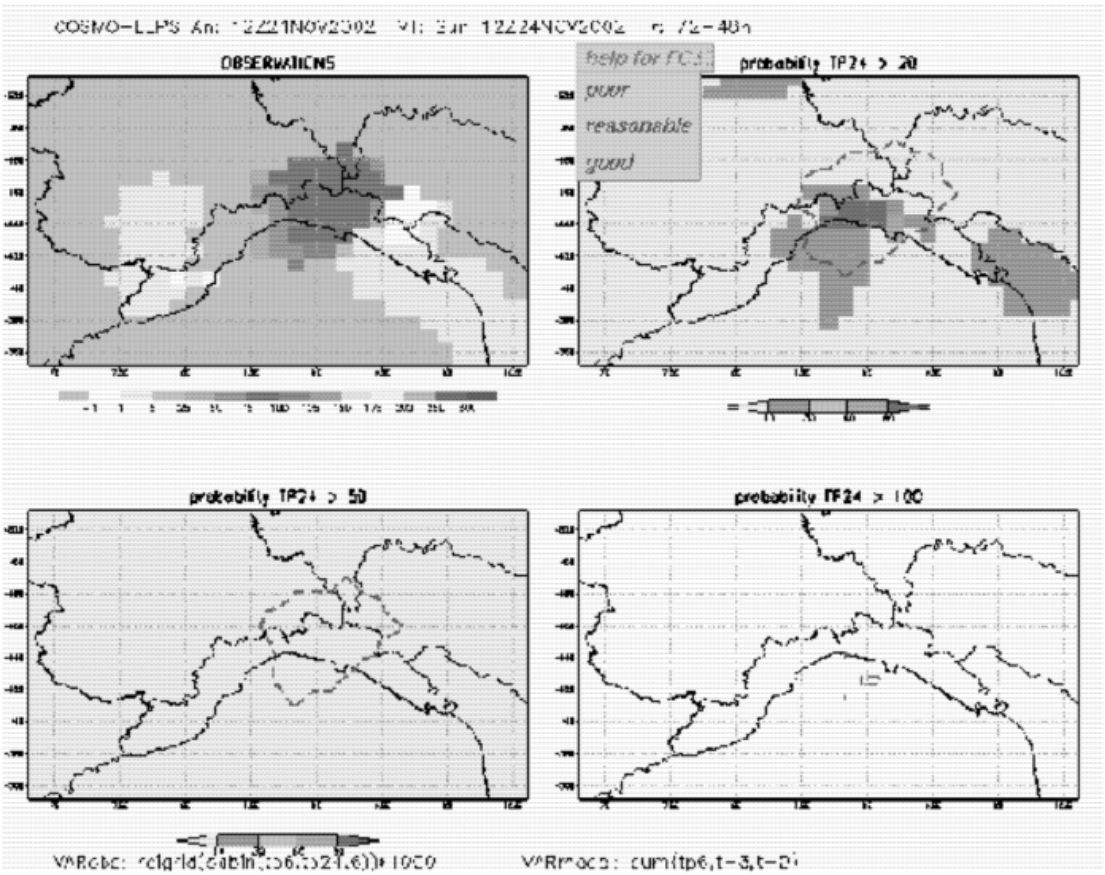

Figure 21: Mask used by the forecasters of the ARPAL Hydro–meteorological Service for the subjective evaluation of the forecast provided by the COSMO–LEPS probability maps.

Table 1: Medium range weather types

Name	Description	Main characteristics of the weather
straight flow	rapid, straight, perturbed	rainy, often windy
undulating flow	alternating ridge and trough, unsettled weather	a rainy period is followed by a sunny one; there is at least one rainy period
warm blocked	anticyclonic conditions	dry weather, sunny in summer, sometimes foggy or dull weather in winter
cold blocked	low-pressure conditions	cool or cold weather, often rainy

5.2 Results

In Fig. 22 the usefulness for the forecasters of the COSMO–LEPS scenarios in terms of precipitation intensity is assessed for different forecast ranges. In the left panel the analysis is relative to the evaluation directly made by the forecasters, ignoring the weight given to each member according to the cluster population, while in the right panel weights have been associated to the COSMO–LEPS members.

A positive impact of the weighting procedure is evident, for all the precipitation intensities and for all the forecast ranges.

The same analysis has been repeated in terms of localization of the precipitation (Fig. 23).

The positive impact of the weighting procedure on the localization is well evident, especially for moderate and intense precipitation.

How the usefulness of the forecasts differentiate with the synoptic situation is shown in Fig. 24.

The "warm blocked" situation seems to be the more predictable, while the "straight" flow is the less predictable. The performances both in terms of intensity and localization improve when the ensemble members are weighted according to the cluster population.

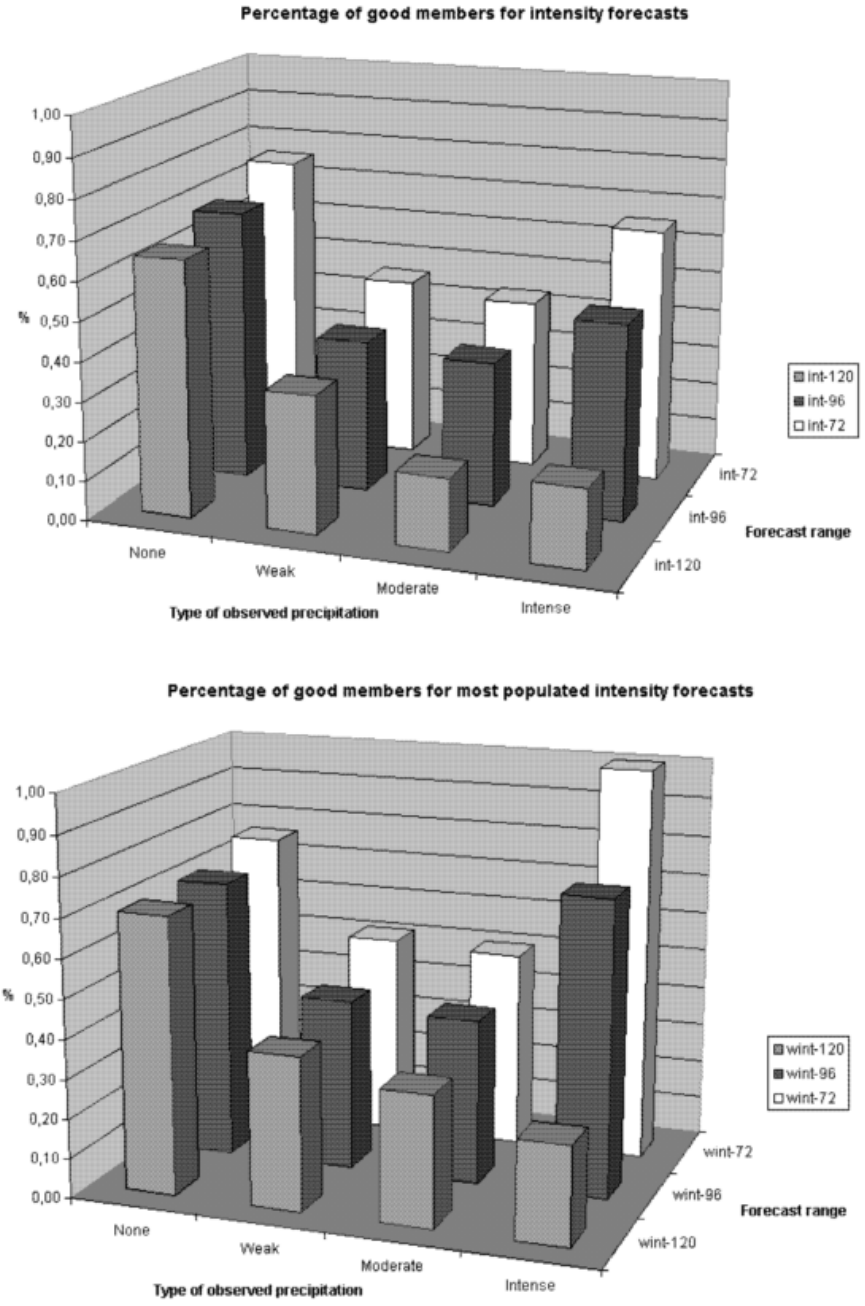

Figure 22: Percentage of "good" members in terms of intensity for four classes of intensity and for the different forecast ranges (+72h, +96h, +120h). The percentage is computed by not weighting (top panel) and by weighting (bottom panel) the ensemble members.

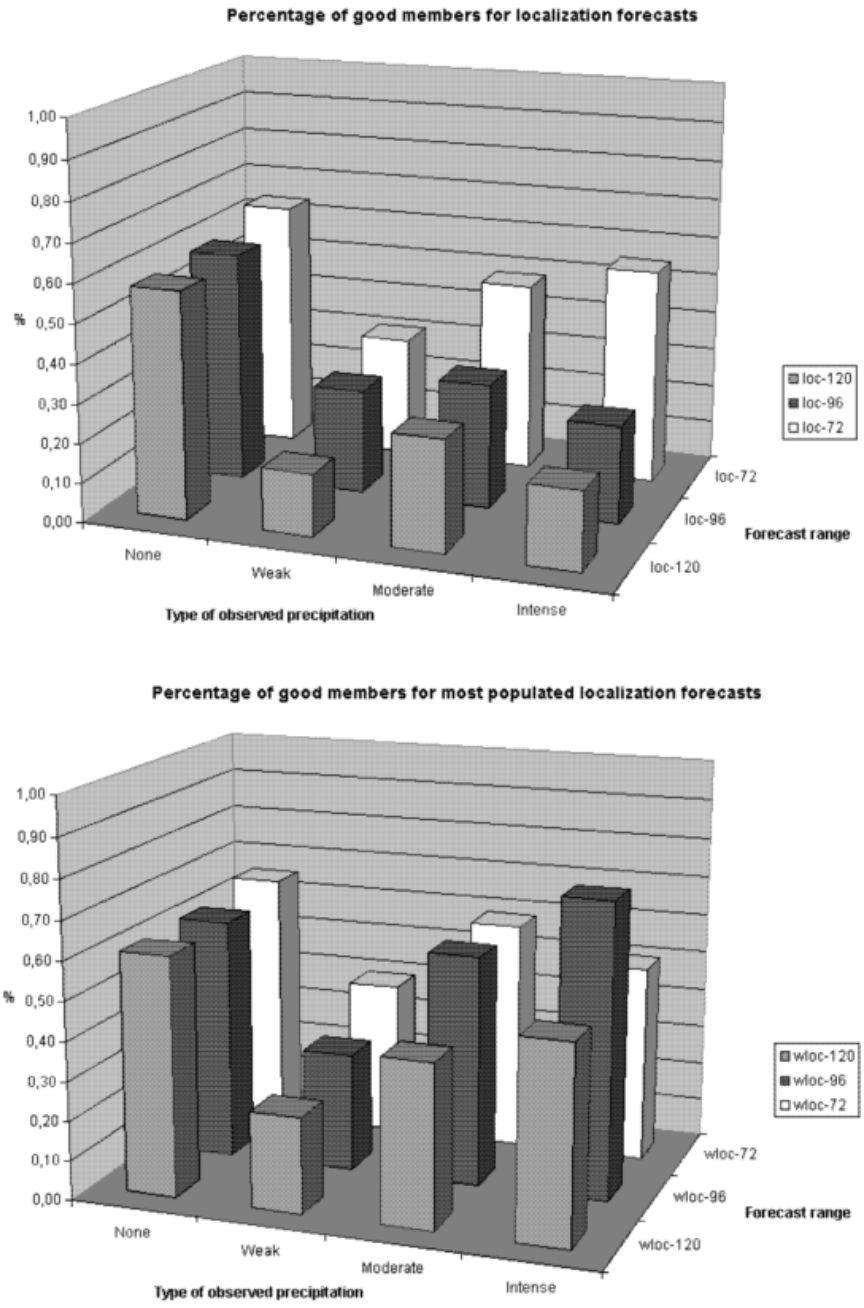

Figure 23: Percentage of "good" members in terms of localization for four classes of intensity for the different forecast ranges (+72h, +96h, +120h). The percentage is computed by not weighting (top panel) and by weighting (bottom panel) the ensemble members.

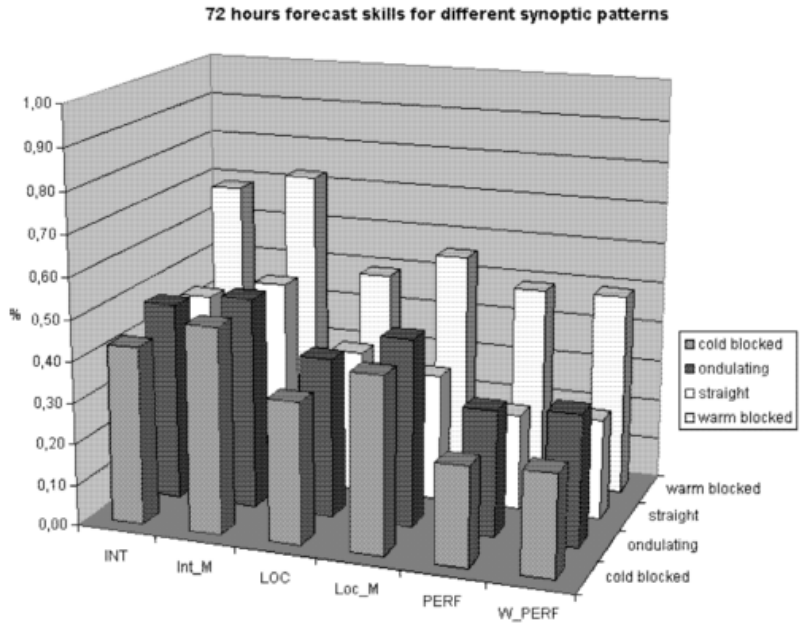

Figure 24: Percentage of "good" members in terms of intensity (int) and localization (loc) for the four types of synoptic situation for the +72h forecast range. A label M is added to int and loc if the percentage is computed by weighting the ensemble members.

6 Use of COSMO-LEPS at MeteoSwiss - Contribution by MeteoSwiss, Zürich, Switzerland (Andre' Walser and Marco Arpagaus)

The quasi-operational COSMO-LEPS has made probabilistic short to early-medium range forecasts available at MeteoSwiss. It motivated scientists and forecasters from the weather department to look closer into the topic of probabilistic weather forecasting and provides an excellent basis for research in this field. Since the optimal use of probabilistic forecasts needs a knowledge transfer from scientists to forecasters, the introduction of COSMO-LEPS had both technical and educational aspects.

This chapter is structured as follows: The MeteoSwiss post-processing of COSMO-LEPS is described in section 6.1. Section 6.2 discusses the experience with COSMO-LEPS from the perspective of the forecasters, while section 6.3 presents the use of COSMO-LEPS forecasts exemplified for a storm event. Finally, conclusions and an outlook are provided in section 6.4.

6.1 MeteoSwiss post-processing

The setup of the MeteoSwiss post-processing of COSMO-LEPS output has been strongly supported by our colleagues of ARPA-SIM and is summarised in Fig. 6.1. This post-processing starts as soon as the COSMO-LEPS forecasts are available at ECMWF and consists of

(i) a transfer of COSMO-LEPS probabilistic model output (PMO) and direct model output (DMO) of all ensemble members to the MeteoSwiss post-processing server at the CSCS[1],

(ii) using the DMO to calculate customer-specific PMO, and

(iii) a visualisation of the PMO in the form of probability maps and meteograms, the latter of which is described in the following paragraph.

These COSMO-LEPS products are presented on the intranet of MeteoSwiss and some selected products are printed out automatically and pinned to the weather board in the meteorological operations room.

A very popular output of the post-processing is the mentioned meteogram. It is currently produced for about 30 grid points within the model domain and summarises the 5-day COSMO-LEPS forecast in terms of cloud cover, precipitation, wind gusts and temperature. Figure 6.1 shows the meteogram for the grid point closest to Zürich from the forecast started on 25 August 2004 1200 UTC. For each variable the median of the 10 COSMO-LEPS members is displayed as red line. The middle two quartiles (25% to 75% probability of occurrence) are indicated by the grey shaded area, and the minimum and maximum values, respectively, by the dashed lines. Median and quartiles are calculated by weighting the members according to the cluster population and with a linear interpolation between the discrete cumulative probabilities for every three hours (corresponding to the current output frequency of the COSMO-LEPS members). Additionally, the meteogram shows the deterministic forecast

[1]Swiss National Supercomputing Centre, Manno.

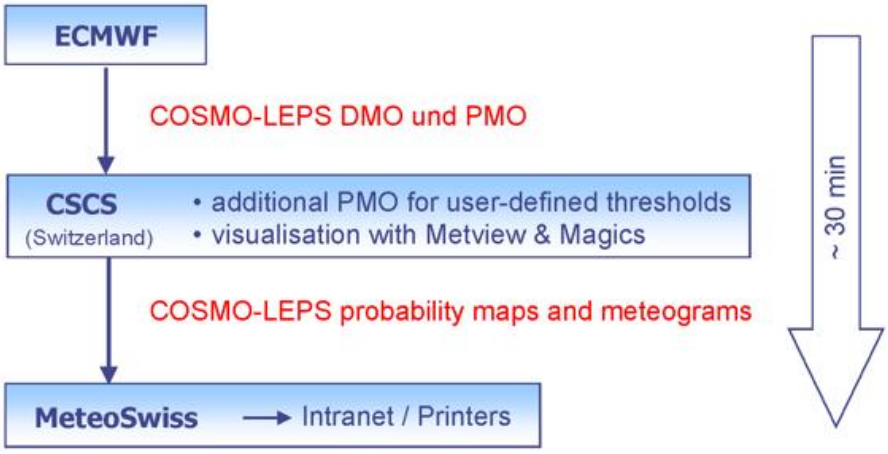

Figure 25: Flow chart of the MeteoSwiss post-processing of COSMO-LEPS output.

of the operational high-resolution model at MeteoSwiss (aLMo) as blue lines. Since the aLMo forecast initialized 12 hours later than COSMO-LEPS is available shortly after the COSMO-LEPS forecast, this newer 72-h forecast is displayed in the meteogram.

The width of the grey shaded area together with the spread between the minimum and maximum values give a measure of the uncertainty of the most likely scenarios given by the aLMo and the COSMO-LEPS median. It is expected that aLMo is the better estimate than the median for short lead-times, however, without yet knowing how long "short" in this context is. Temperature and wind gust forecast show the typical case with increasing spread with increasing forecast time. Clearly, the prediction of cloud cover is associated with the highest uncertainty, this being often associated with a similar uncertainty in the forecast for precipitation.

6.2 Experience with COSMO-LEPS

The change from predicting precipitation amounts to predicting probabilities of occurrence for a certain threshold is a radical paradigm shift which clearly demands some training for forecasters not familiar with probabilistic forecasts. This was essential for the introduction of COSMO-LEPS forecasts at MeteoSwiss. Meanwhile, about half of the forecasters already use COSMO-LEPS together with other products to prepare their weather bulletins for the next few days.

The overall feedback on COSMO-LEPS from the forecasters is clearly positive. They mainly use probability maps of 24-h accumulated precipitation and maximal daily wind gusts for forecast days 2 to 4 (for an example of a probability map, cf. Fig. 28). COSMO-LEPS products for other variables are not yet considered frequently. In addition, some forecasters also look at a small set of meteograms. Forecasters describe the use of COSMO-LEPS for the current bulletin as "considering an additional opinion besides the other models", which are mainly aLMo and deterministic ECMWF. E.g., for forecasting precipitation amounts, a high probability for a threshold below the predicted value and a low probability above would be considered a confirmation of the predicted deterministic estimates.

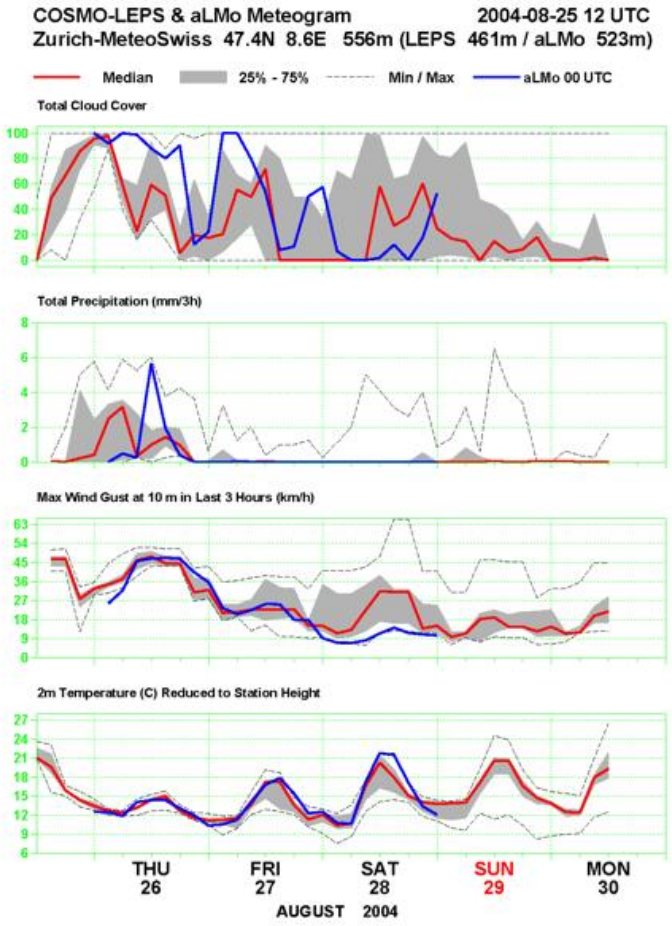

Figure 26: Meteogram as derived from the COSMO-LEPS and aLMo output in terms of cloud cover, precipitation, max. wind gusts, and temperature (see text). Example for Zürich from the forecast starting on 25 August 2004 1200 UTC.

COSMO-LEPS forecasts are studied more thoroughly when they show considerable probabilities for a threshold which represents a warning level or if forecasters have other indications for an extreme precipitation or storm event. Since such extreme events often have low predictability even in the short-range, COSMO-LEPS PMO is also considered for this forecast-range (for which COSMO-LEPS is not designed) due to the lack of an alternative. There is no verification done yet concerning the performance of warnings from forecasters compared to COSMO-LEPS itself in terms of hit rate and false alarm rate. Such a verification for Switzerland would be of strongest interest for the forecasters and would possibly help to extend the use of COSMO-LEPS (personal communication from a forecaster). In discussions with forecasters the following concerns about COSMO-LEPS turn up frequently:

- There is little confidence that COSMO-LEPS is able to predict reliably the probability for convective precipitation events in summer.
- Due to the rather coarse horizontal resolution, it is not expected that COSMO-LEPS is able to give warnings for extreme events related to small-scale orography such as Föhn.
- For short lead-times, the use of the super-ensemble could smooth the predicted probability distribution, reducing the probability for an extreme event and hence the hit rate.

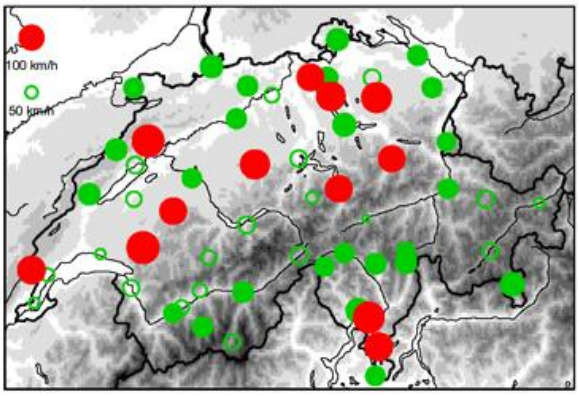

Figure 27: Observed maximal wind gusts on 19 November 2004 as size of centered circles (scale is indicated in the panel) for 59 stations below 2000 m a.s.l. of the Swiss automatic observation network. Green and red filled circles indicate wind gusts above 70 km/h and 100 km/h, respectively. The grey shaded background represents the topography.

Overall, the use of PMO has clearly increased due to the availability of COSMO-LEPS products which are acknowledged by the forecasters. However, the entire potential of COSMO-LEPS is not yet exploited since forecasters are not instructed to complement the weather bulletins with a level of confidence, e.g. with a probability of occurrence for the predicted event. This would mean an even more profound paradigm shift, which clearly needs more confidence in the ability of COSMO-LEPS (or other high-resolution probabilistic weather forecasting system) to predict the probability distributions reliabe for the most important parameters such as temperature, horizontal wind, precipitation, and cloud cover.

6.3 Case study: Storm on 19 November 2004

In this section, the COSMO-LEPS forecasts and their use are discussed on the basis of a case study. In the early morning of 19 November 2004 a cold front crossed Switzerland in a strong westerly flow producing maximal wind gusts of 60-90 km/h on the Swiss Plateau and slightly above 100 km/h in somewhat elevated places, in Alpine valleys, and in the Lago Maggiore Area to the south of the Alps. Figure 6.3 shows the observed maximal wind gusts for 59 stations located below 2000 m a.s.l. of the Swiss automatic network with green and red filled circles indicating maximal gusts above 70 km/h and 100 km/h, respectively, where the latter value corresponds to the warning threshold for the regional authorities.

On 17 November the forecasters on duty decided to issue a pre-warning for wind gusts between 80-100 km/h on the Swiss Plateau during the night from 18 November to 19 November. They based the warning on (i) the mean 850 hPa flow of the deterministic ECMWF forecast, (ii) the predicted aLMo wind gusts, and (iii) the COSMO-LEPS probability maps for maximal 10 m wind gusts. On the following day, this warning was confirmed and a new warning for the Ticino was issued for wind gusts of 75-100 km/h embedded in a strong north Föhn.

While ECMWF and aLMo suggested wind gusts somewhat above and slightly below 100 km/h, respectively, COSMO-LEPS indicated in the four consecutive forecasts started on 15, 16, 17, and 18 November 1200 UTC high probabilities for wind gusts below 100 km/h, but negligible probabilities for wind gusts above this value, shown in Fig. 28. Only the forecast started on 18 November (Fig. 28d) predicted considerable probabilities for maximal wind gusts above 100 km/h for the eastern part of the Swiss Plateau.

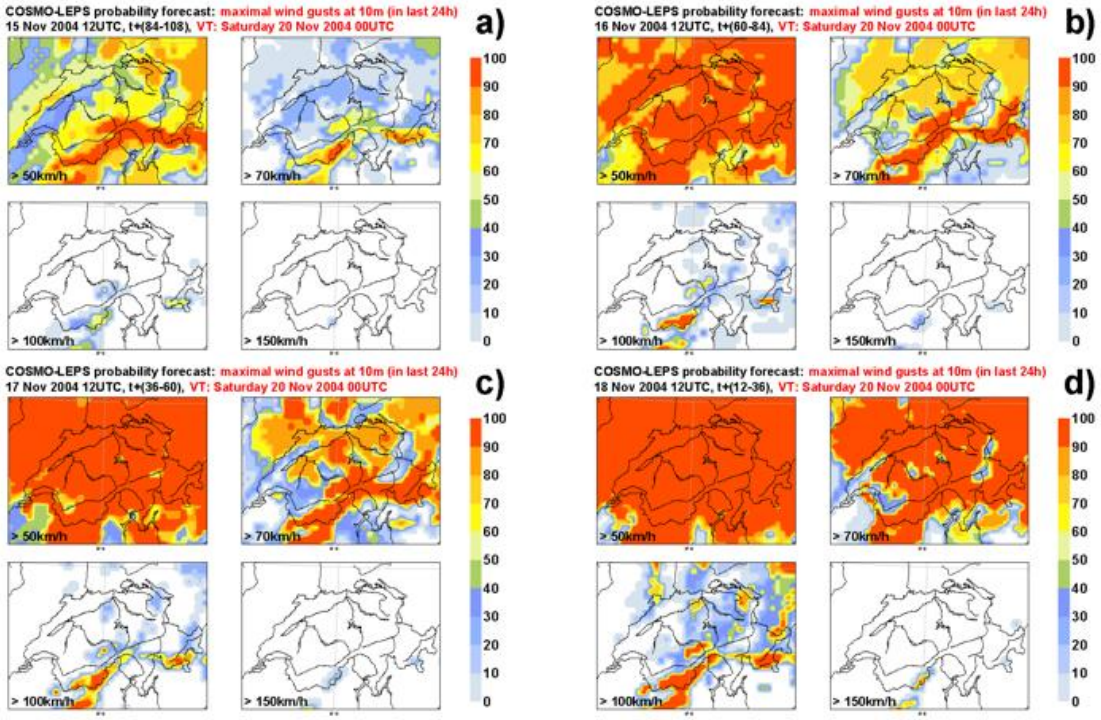

Figure 28: Probability forecast for maximal wind gusts above 50, 70, 100, and 150 km/h, respectively, from four consecutive COSMO-LEPS forecasts for 19 Nov 2004 initialised at (a) 15 Nov, (b) 16 Nov, (c) 17 Nov, and (d) 18 Nov 1200 UTC.

Overall, COSMO-LEPS supported the forecasters well in this case by suggesting a high probability for maximal wind gusts at the observed level on the Swiss Plateau without suggesting a more extreme event. However, COSMO-LEPS missed the wind gusts above 100 km/h at the elevated places in western Switzerland and - as expected - in the Alpine valleys including the strong north Föhn in the Ticino. Considering the four consecutive forecasts, the steady increase in the probabilities for maximal wind gusts below the observations with decreasing lead-time is remarkable, whereas a corresponding decrease of probabilities for maximal wind gusts above the observations cannot be seen. A sharpening of the predicted probability density function with decreasing lead-time as can be partly observed for this case is a key characteristic of a well-designed EPS.

6.4 Conclusions and outlook

The developed probabilistic COSMO-LEPS products try to visualize the complex information of COSMO-LEPS forecast in a concise way. They complement the deterministic forecast products of aLMo and are appreciated both from forecasters and scientists as subjectively skillful information.

We are convinced that high-resolution EPSs such as COSMO-LEPS have a great potential for further improvements in terms of forecast skill. It is planned to continue our research activities in this field in close collaboration with the ARPA-SIM focusing on potential high-impact weather. A key goal is the comparison to different available and newly developed forecasting approaches such as ECMWF extreme forecasts index and neural networks. In addition, a model-based climatology will be assembled to assess the return periods of high-impact weather events as a function of forecast lead-time and compared to observations.

Moreover, this model climatology will allow to identify model biases related to intrinsic model deficiencies.

The interest in high-resolution EPSs will undoubtfully further increase and it is worth to mention here, that the executive board of MeteoSwiss recently declared probabilistic forecasting as a strategic goal.

7 Could the COSMO–LEPS system add value to operational forecasts of the DWD in the case of severe weather? - Contribution by the Central Forecast unit of the DWD in 2004 (Thomas Schumann)

Since 31 January 2003 products of the COSMO–LEPS system are available in the DWD intranet for use in operational forecasts. COSMO–LEPS as a limited area ensemble prediction system is running once a day, driven (since 01 June, 2004) from 10 selected EPS members of 2 consecutive (12-hr lagged) runs of the ECMWF global model. The forecast range is beginning at H+48 in the short range and ending at H+120 in the early medium range from the last of the both ECMWF runs. The main objective of the COSMO–LEPS system is to identify severe weather patterns within a certain time range over a limited area by using probabilistic methods. To reach this, LM-based probabilistic products will be calculated, disseminated and presented to the forecaster in a user-friendly design by using the DWDs intranet or the meteorological application system via workstations. Beginning in March 2003 the COSMO–LEPS system at the DWD will be used pre-operational as well during the medium range as for short range forecasts. COSMO–LEPS is an additional source of information, forecast plots will be checked whether possible severe events could be identified by relevant signals in the probability maps or not. This is dependent of course from the synoptic situation. Products such as a direct model output from COSMO–LEPS were not generated. In the Central Forecast unit a subjective, very comprehensive verification of the COSMO–LEPS probabilistic forecasts has been carried out. The verification has been done by comparing observations against the forecasts verifying at the time of the observation by continuous tables for each weather parameter including a short description of the event. This task is still a part of the operational medium range forecast shift carried out by the duty forecaster of this shift and will be continued. Another verification method used in the Central Forecast Unit is the preparation of case studies. If a severe event occurred the observed values of a certain weather parameter will be compared with the probability forecasts of COSMO–LEPS at certain thresholds verifying at the time of the occurrence of severe weather. Forecasts of other models or centers will be included. The objective of the verification of the COSMO–LEPS system is:

- Is COSMO–LEPS able to add value to the prediction of severe weather events?
- Could COSMO–LEPS outperform other models?
- What are typical weak points and what are the strength of COSMO–LEPS?
- Are there any changes in the COSMO–LEPS system required (design, thresholds, weather parameters, forecast range)?

To answer these questions we have to go more into detail how COSMO–LEPS performs related to weather parameters provided from the system. An overview has been prepared as a result of the continuous verification, forecasters experience and several case studies. This is provided by Table 2.

Parameter	General remarks Predictability by COSMO–LEPS	Further comments / recommendations
Temperature Minimum of the day	Very poor, mostly no signals	Useful in a few cases only without near surface inversion. Outperformed by the KALMAN / MOS output from LM or ECMWF deterministic model.
Temperature Maximum of the day	Sometimes useful	Realistic regional assignment, even heat islands (large cities) visible. Poor results in the case of extreme heat waves (underestimation of temperature maximum). Outperformed by the KALMAN / MOS output from LM or ECMWF deterministic model.
Maximum wind gusts of the day	Major synoptic scale storms: Good forecasts. Convective gusts: No correct signals	Realistic regional assignment, orographic effects well represented. COSMO–LEPS adds value to forecasts. Prediction of gusts caused by convection events not possible. If signals presented they are wrong located, orographic effects overestimated. Thresholds should be changed, levels 30 and 35 m/s more important for severe weather prediction than 10 and 15 m/s
Snow fresh fallen during the last day	Sometimes useful	Synoptic-scale events: Realistic regional assignment, orographic effects well represented. COSMO–LEPS adds value to forecasts. Poor results in the case of minor severe / small scale events
Total precipitation accumulated over 24 hours	Often useful	large-scale events: Realistic regional assignment, orographic effects well represented. COSMO–LEPS could add value to forecasts. Poor results in the case of minor severe / small scale, convective or convective-mixed events
Convective precipitation Thunderstorm (CAPE)	Very poor, mostly no signals. CAPE: more cases needed	Prediction of heavy precipitations caused by convective or convective-mixed events not possible. If signals presented they are wrong located, orographic effects overestimated

Table 2: Overview on Forecasters experience

To summarize this and to answer the questions above, it has to be concluded that COSMO–LEPS did not always met the forecasters requirements and expectations. Valuable predictions of severe events provided only if the event is non-convective and at least a synoptic-scale one. In this situations COSMO–LEPS will be able to add value to the prediction of severe events by providing probabilities exceeding certain thresholds. Then other models mostly are performing very well, too. COSMO–LEPS could outperform other models in areas with clear orographic structure only. This is the strength of COSMO–LEPS and why it has been designed: Provide the forecaster a hint what could happen in these areas in the case of severe weather. COSMO–LEPS has been adjusted to deal with the orography of the Alps and the surrounding mountains of the Mediterranean Sea and not with the highlands over Central Germany. Another point is that COSMO–LEPS is reflecting the weaknesses of the driving ECMWFs EPS and the nested LM. This has been characterized by the problems of

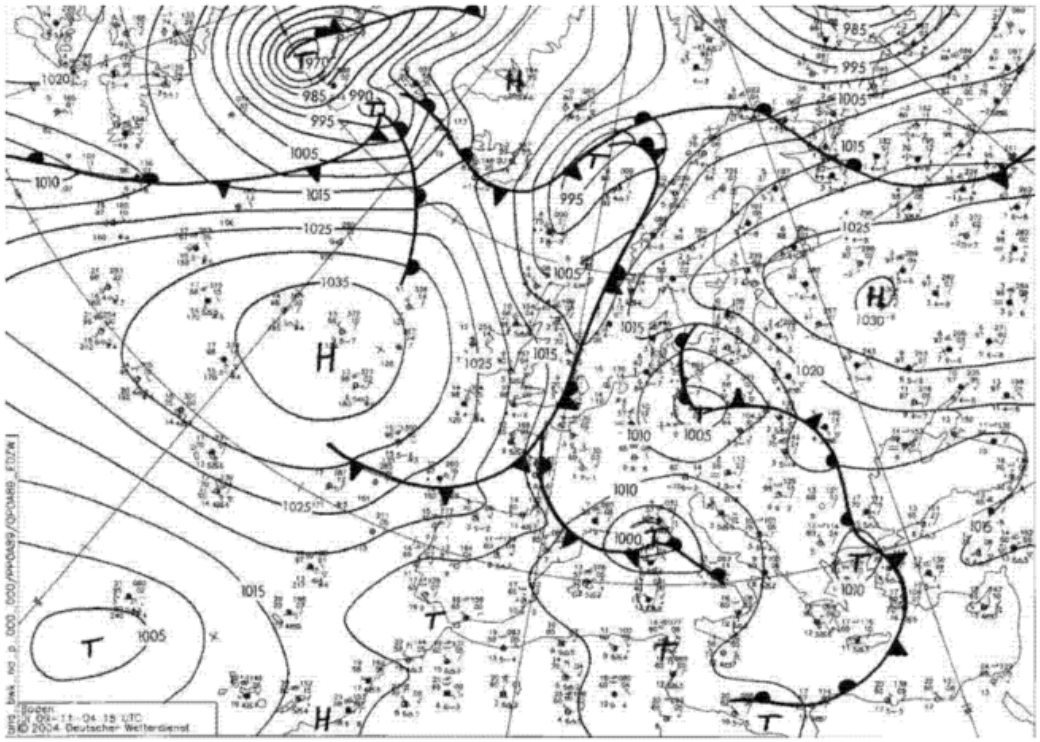

Figure 29: MSLP Analysis, 09 Nov 2004, 18 UTC.

COSMO–LEPS predicting convective gusts and precipitation and due to the poor vertical resolution in the lower troposphere in the forecast of the daily temperature minimum as well as for the temperature maximum in the case of extreme heat waves. Further verification is required to detect changes in the model behavior caused by the variation of the configuration since 06/2004.

7.1 A case study - early winter over Germany (09 Nov, 2004)

The synoptic situation was characterized by a huge cut off-low with embedded centers over the west part of Germany and the southern Adriatic Sea. Crossing the eastern part of the Alps the second center has been induced a cyclogenesis. The resulting low passed the Czech Republic and has been moved over Northeastern Germany (see Fig. 29, SLP Analysis 09 Nov 2004, 18 UTC.). The low caused the first winter outbreak over Germany in 2004/2005. Widespread areas have been covered by fresh fallen snow (Fig. 30, snow cover over Germany in centimeter, 10 Nov 2004, 06 UTC). The early winter outbreak lead to chaotic situations in the traffic including disruptions of streets by broken trees because of wet snow (Fig. 31, impressions from the winter outbreak over central parts of Germany).

How has COSMO–LEPS predicted this winter outbreak? That will be demonstrated by Fig. 32. On the left the probability of exceeding 10 centimeter fresh fallen snow is shown, the right shows the 20 centimeter-threshold. The first row are the 120-hr forecasts verifying on 10 November, 12 UTC. Already during the early medium range COSMO–LEPS has been shown relevant signals. In the highlands over the central part of Germany 10 centimeter fresh fallen snow is likely and up to 20 centimeter is possible. Over the southwestern part of Germany not more than 10 centimeter snow has to be expected. In this situation COSMO–LEPS has provided an "early warning". Therefore it was possible to describe this scenario

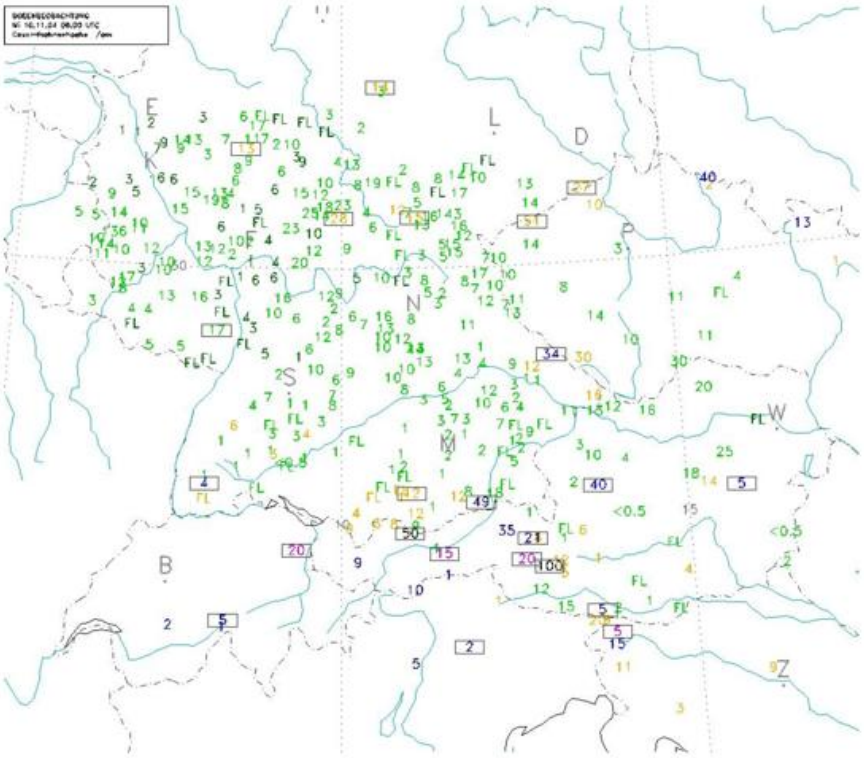

Figure 30: Fresh fallen snow, 10 Nov 2004, 06 UTC

Figure 31: Impressions from the winter outbreak over central parts of Germany 10 Nov, 2004

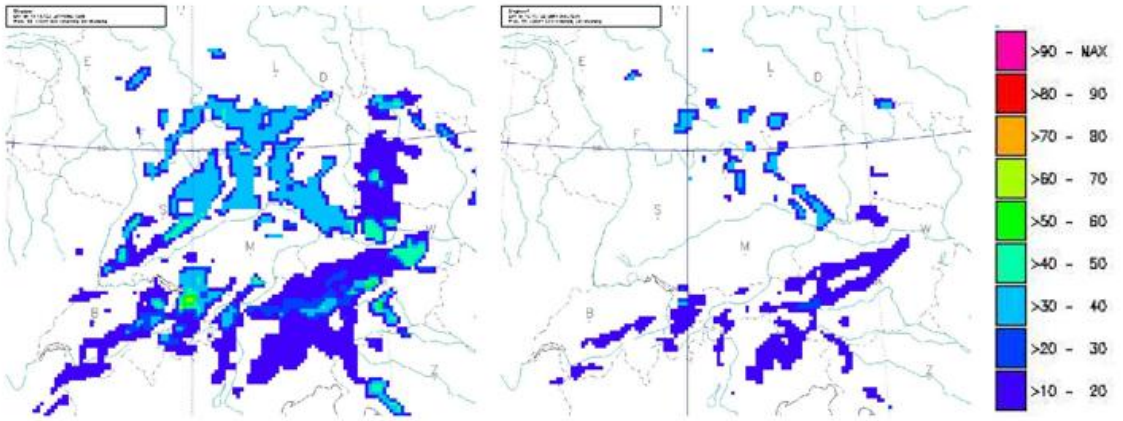

Figure 32: 120 hr-forecast, verifying at the 10 Nov 2004, 12 UTC. Left: Threshold 10 centimeter, right: 20 centimeter fresh fallen snow.

early in the weather reports, from a forecasters point of view this early winter outbreak was not a surprise.

The signal has been developed by the forecasts of the following days (see Fig. 33). The closer the event comes, the more the pattern has been shifted into northwesterly direction. Comparing against observations this was correct. The maximum of snow has been predicted already during the medium range. The orographic representation of the probabilities shown here even allows predictions that in the Upper Rhine valley, the lower-evaluated part of the Rhein-Main-area and the Wetterau snow will be unlikely or the snow depth will not exceed a few centimeter as it has been observed close to the Danube river or in the Hunsrück highlands.

This case study demonstrates a successful forecast of COSMO–LEPS how the system is working and how it could be used to improve the forecasters guidance. During the majority of the severe weather cases the signals provided by COSMO–LEPS were less developed and consequently the forecasts less helpful.

7.2 Conclusions

The COSMO–LEPS system did not always meet forecasters expectations. The guidance provided by COSMO–LEPS to predict the temperature minimum of the day and convective events (related gusts and heavy precipitation) is poor and useful in a few cases only. COSMO–LEPS will add value to the prediction of large scale precipitation and wind gusts if the causing event is a synoptic or larger scale one. The regional assignment is mostly realistic, orographic effects are well represented, weak, but realistic and useful signals often have been shown already during the medium range. The majority of severe weather warnings will be caused by smaller scale events related often with heavy convection. The prediction of such events needs to be improved as well by COSMO–LEPS as by the driving ECMWFs EPS and the nested LM. A small number of cases does not allow final conclusions, further verification (continuous or case-sensitive) is required. A problem is the re-calculation of the COSMO–LEPS forecasts for "historical" weather events again. This might be too expensive. An archiving of the set of derived probability forecasts in the MARS archive of the ECMWF would be helpful.

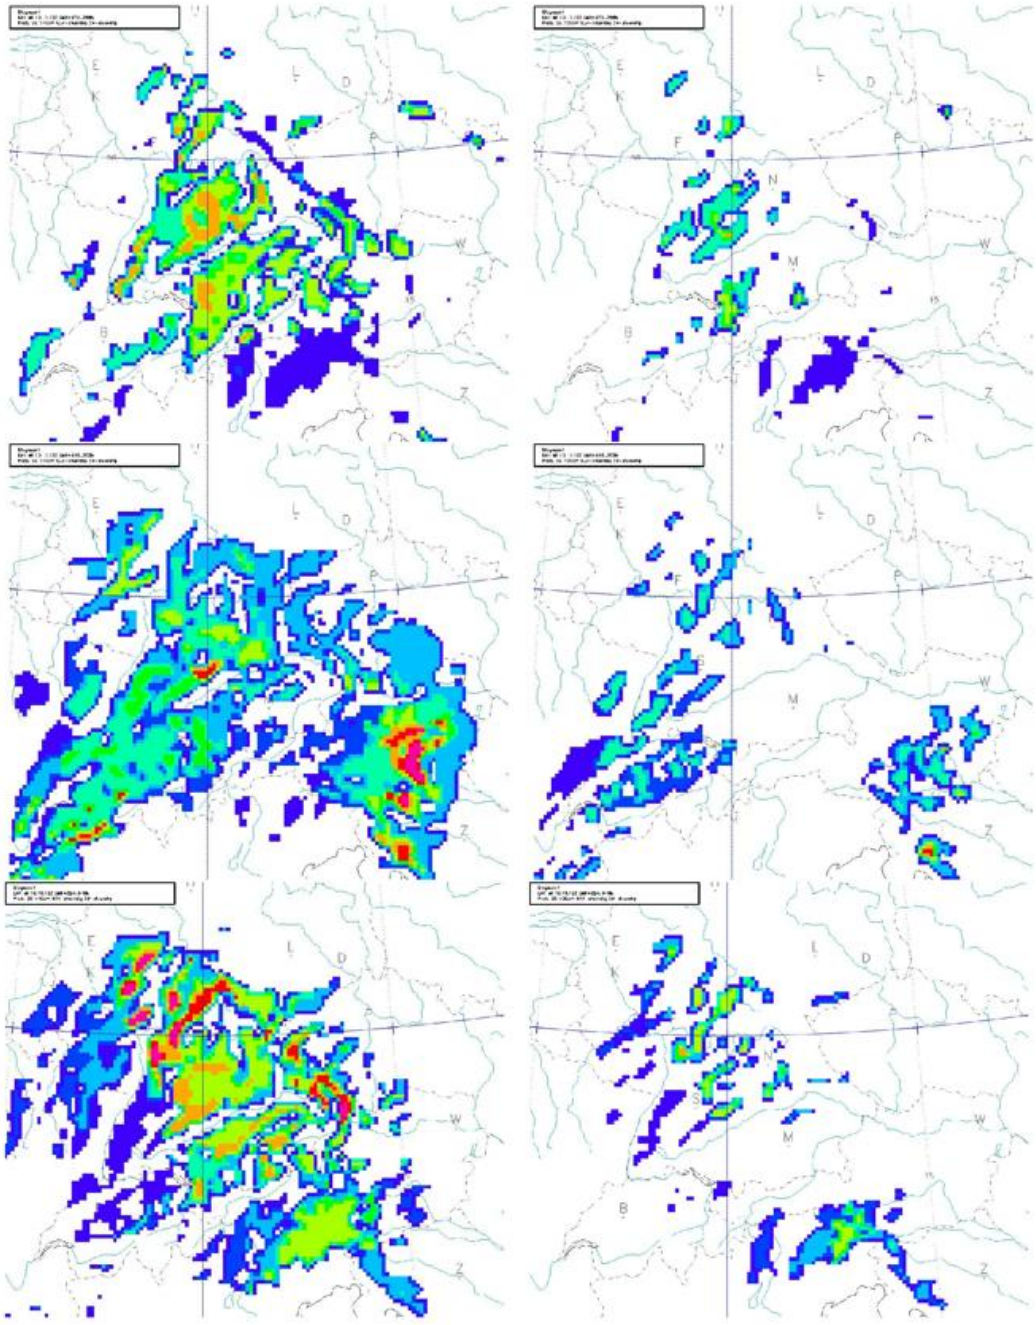

Figure 33: 96 hr-forecast (top), 72 hr-forecast (center) and 48 hr-forecast (bottom) verifying at the 10 Nov 2004, 12 UTC. Left: Threshold 10 centimeter, right: 20 centimeter fresh fallen snow. Color scheme is the same as in Fig. 32.

8 Conclusions

The high–resolution system COSMO–LEPS has been designed as a tool for the prediction of heavy precipitation in a probabilistic perspective. On a case study basis (Montani et al., 2003b and Marsigli et al., 2004), the system has proved to be successful in the prediction of intense rainfall events. An objective probabilistic verification is being carried out at ARPA–SIM so as to assess both the abilities and shortcomings of the system, to address future developments of the system and to provide guidelines to the users. Furthermore, the other COSMO partners have submitted the systems to a careful subjective evaluation, trying to assess the usefulness in a quasi–operational framework.

With regard to the objective verification, in this report the COSMO–LEPS performances in forecasting precipitation has been presented. The period considered is September–November 2003 and forecast precipitation cumulated over 24 hours is compared with observed data.

In order to quantify the added value provided by the mesoscale probabilistic system, COSMO–LEPS has been compared with the ECMWF EPS. To make an appropriate comparison of the two systems, the differences in the number of ensemble members (5 for COSMO–LEPS and 51 for the EPS) and in the horizontal resolution (10 km for COSMO–LEPS and 80 km for the EPS) have been considered. As far as the population of the ensembles is concerned, the reduced EPS made up of the 5 Representative Members has also been analysed, allowing to quantify the impact of the increased resolution alone. On the other hand, the problem of the very different resolutions of the two systems is tackled by upscaling both systems to a lower resolution: the grid point forecasts of both model are aggregated over boxes of 1.5×1.5 degrees. The observations are also aggregated over the same boxes.

A comparison in terms of average precipitation values over 1.5×1.5 degree boxes shows that EPS performs better. Nevertheless, COSMO–LEPS outperforms the reduced EPS composed of the 5 Representative Members in terms of ROC area, in particular showing a higher Hit Rate. When the comparison is carried out in terms of maximum values over boxes of the same size, COSMO–LEPS scores are the highest, in terms of both Brier Skill Score and ROC area. This is due to the capability of the mesoscale system to forecast high precipitation values. The analysis of the ROC Curves shows that this improvement is not associated to a dramatic increase of the false alarms.

Considering average precipitation over a quite large area, EPS is performing better than the mesoscale system. Nevertheless, it is worth noting that meteo–hydrological applications often requires information on a more local scale. The skill of the COSMO–LEPS system in forecasting the occurrence of precipitation maxima is a clear indication of the usefulness of the system in forecasting intense and localized events.

Finally, COSMO–LEPS scores are worsening at the 5 day forecast range, leading to a reduction of the improvement with respect to the global systems. This could be linked to the increase of the limited–area model error, which, at this time range, becomes large enough to overwhelm the improvement produced by LM in terms of predictability of mesoscale structures.

A comparison of the COSMO–LEPS scores with and without the application of the weighted procedure has not been presented in this report. Results (not shown) indicate that no benefit is added by weighting the COSMO–LEPS members according to the cluster population. These results were obtained in terms of precipitation, verified against observations. Nevertheless, a positive impact is evident in the subjective verification performed by ARPAL, where it is shown that weighting the members improves the COSMO–LEPS performances,

both in terms of intensity and localization of the precipitation, especially for moderate and intense precipitation.

An analysis of the COSMO–LEPS methodology, leading to the choice of the Representative Members, has been also shown, addressing the topics of the super–ensemble size (1 EPS, 2 EPS, 3 EPS) and of the number of Representative Members (5 or 10). The analysis has been performed by verifying the precipitation forecast by the reduced EPS made up by the RMs without running the nested LAM. The forecast are compared with ECMWF proxy rain over the same season (Autumn 2003).

We showed that the use of just two EPS in the super–ensemble seems to be a suitable compromise between the need to decrease the percentage of outliers and the need to maintain a high skill. Furthermore, doubling the number of Representative Members (from 5 to 10) produces the greatest improvement of the skill.

These results led to a modification of the COSMO–LEPS methodology at the beginning of June 2004: the super–ensemble has been built by using only the 2 most recent EPS and the number of clusters has been fixed to 10, nesting Lokal Modell on each of the selected 10 RMs. The 10 Lokal Modell runs are performed by using both the Tiedtke and Kain–Fritsch schemes for the parameterization of the convection. The scheme used within each single run is randomly selected. This choice was adopted since we did not see any significant difference when using either the Tiedtke scheme or the Kain–Fritsch scheme.

The new configuration of COSMO–LEPS system is being currently verified and the impact of the modifications on the system performance is addressed. The verification methodology is still under development, focusing on the proper way of performing a probabilistic verification of an high–resolution forecast system.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *Consortium for Small-Scale Modelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (UGM, ARPA-SMR) and Switzerland (MeteoSwiss). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the Lokal-Modell (LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completition of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction

This review aims to discuss the suitability of *particle filtering* as a method of choice for the future COSMO meso-scale data assimilation system.

2 Nonlinear filtering

In this introductory section some basic facts on nonlinear filtering are given in order to facilitate the subsequent discussion of the particle filtering technique.

2.1 Statement of the problem and notation

Let us be interested in the system (atmospheric, oceanic...) state, X, at the time instant t_k, X_k. The information we have on X_k is twofold:

1. We have the deterministic model,

$$X_k^f = \mathcal{M}_{k-1}(X_{k-1}^a), \tag{1}$$

   where the superscript "a" means "analysis" (forecast initial conditions) and "f" forecast.

2. We have observations Y_s, $s = k, k-1, k-2, ...$, which are related to the state in the known way:

$$Y_s = H_s(X_s) + \eta_s, \tag{2}$$

   where η_s is the observation error, which includes both the measurement error and the error in the observation operator H_s (representativeness error).

We assume that the deterministic model, Eq. (1), *approximates* the true system evolution, so that if we substitute, into Eq. (1), the *true system* states (not the *model* states), a discrepancy arises, which is called "model error", ξ:

$$X_k = \mathcal{M}_{k-1}(X_{k-1}) - \xi_{k-1}. \tag{3}$$

We stress that this equation is a stochastic dynamic model for the *true* system state.

In order to properly assimilate the information contained both in the observations and the model, we assume the error sources, η_s and ξ_s ($s = k, k-1, k-2, ...$), to be independent of X and governed by the respective stochastic models, so that their probability distributions are known, $p(\eta_s)$ and $p(\xi_s)$, respectively. For the assimilation to be *sequential*, we require that both η_s and ξ_s are *white* sequences. For simplicity, we also assume that observation errors and model errors are (probabilistically) independent.

2.2 Sequential non-linear filtering

In data assimilation, our goal is the conditional distribution of the state, given all current and past observations (called posterior distribution):

$$p(X_k|Y_{:k}), \tag{4}$$

where " $:k$" means "up to k" (at the time moments $t_k, t_{k-1}, t_{k-2}, ...$).

To develop an assimilation technique, we break up the observations into the present and past batches: $Y_{:k} = (Y_{:k-1}, Y_k)$. Then, we transform Eq. (4) using the Bayes theorem:

$$p(X_k|Y_{:k}) = p(X_k|Y_{:k-1}, Y_k) \propto p(X_k|Y_{:k-1}) \cdot p(Y_k|X_k, Y_{:k-1}). \tag{5}$$

Here, $p(X_k|Y_{:k-1})$ is the *predictive* (prior) distribution (density) and

$$p(Y_k|X_k, Y_{:k-1}) = p(Y_k|X_k) \tag{6}$$

is the likelihood; the equality in Eq. (6) follows from the assumption that the observation error sequence is white.

Thus,

$$p(X_k|Y_{:k}) \propto p(X_k|Y_{:k-1}) \cdot p(Y_k|X_k). \tag{7}$$

The likelihood is assumed to be known (from the observation operator and the observation error probability distribution), so all it remains to be found is the predictive probability density. From Eq. (3), we have:

$$p(X_k|Y_{:k-1}) = p[\mathcal{M}_{k-1}(X_{k-1}) - \xi_{k-1} = X_k|Y_{:k-1}].$$

Here, both X_{k-1} and ξ_{k-1} are random and unknown, so we use the "complete probability rule": $p(X) = \mathbf{E}p(X|\vartheta)$, with ϑ being some random variable (vector):

$$p(X_k|Y_{:k-1}) = \mathbf{E}_{X_{k-1}} p[\xi_{k-1} = \mathcal{M}_{k-1}(X_{k-1}) - X_k|X_{k-1}, Y_{:k-1}] \tag{8}$$

(here the conditional expectation is taken over X_{k-1}). Using the *previous* posterior density, $p(X_{k-1}|Y_{:k-1})$, we obtain from Eq. (8):

$$p(X_k|Y_{:k-1}) = \int p(X_{k-1}|Y_{:k-1}) \cdot p[\xi_{k-1} = \mathcal{M}_{k-1}(X_{k-1}) - X_k] \mathrm{d}X_{k-1}. \tag{9}$$

The fact that the second p.d.f. in the r.h.s. of this equation is unconditional, follows from the assumptions indicated above in the last paragraph of the previous subsection.

Using the explicit transition probability density, $p(X_k|X_{k-1})$, we can rewrite Eq. (9) as

$$p(X_k|Y_{:k-1}) = \int p(X_{k-1}|Y_{:k-1}) \cdot p(X_k|X_{k-1}) \mathrm{d}X_{k-1}. \tag{10}$$

Thus, Eqs. (7) and (9) provide the desired sequential non-linear assimilation algorithm: having the posterior density at time t_{k-1}, $p(X_{k-1}|Y_{:k-1})$, we compute (in theory) the prior density at time t_k (using Eq. (9)) and then update it using current observations, Eq. (7). At the very beginning of the assimilation process, we specify some initial distribution $p_0(X)$.

3 Monte-Carlo filters

For high-dimensional systems like the atmosphere, the above non-linear sequential assimilation technique in its pure and non-approximated form is absolutely unsuitable, mainly, due to the complexity of the integral in Eq. (9) or (10). The analysis (measurement update) step, Eq. (7), may become feasible for high-dimensional systems if the observation operator is only weakly non-linear and the observation-error distribution is multivariate Gaussian (3D-Var). But the forecast step (time update) in its exact form is prohibitively expensive even for linearized (tangent-linear) dynamics and Gaussian model errors, when the Kalman filter is applicable. Simplified Kalman filters have not yet proven to be successful, so we resort to Monte-Carlo methods.

One of such methods, known as the Ensemble Kalman Filter (EnKF), relies on the Gaussian approximation of the predictive distribution (Evensen, 1994 and Houtekamer and Mitchell, 2005). But this approximation may become too restrictive if we attempt to treat highly non-linear atmospheric processes that involve moisture, clouds, precipitation etc. at fine spatial resolution. This leads us to turn our attention to fully non-linear assimilation methods known as "particle filters". The basic particle filter is called the bootstrap or SIR filter. The term SIR means "sequential importance resampling" or "sampling importance resampling".

4 The bootstrap (SIR) filter

The simplest particle filter proposed by Rubin (1987) relies on the *discrete* (point-support) approximation to the probability distributions in question (just like the statistical technique known as bootstrap (Efron and Tibshirani, 1993)). Namely, we proceed as follows

1. At the discrete time moment t_{k-1}, approximate the posterior distribution, $p(X_{k-1}|Y_{:k-1})$, by the *discrete* distribution, so that the whole probability mass is concentrated in N points (particles), $\{X^-_{k-1}(j)\}_{j=1}^N$ (the sign "$-$" means "before sampling from the posterior distribution"):

$$\hat{p}(X_{k-1}|Y_{:k-1}) = \sum_{j=1}^{N} w_{k-1}(j) \cdot \delta[X_k - X^-_{k-1}(j)], \tag{11}$$

   where the hat denotes an estimate and $w_{k-1}(j)$ are the weights.

2. Resampling: draw N samples from this discrete distribution: $\{X^+_{k-1}(j)\}_{j=1}^N$ (the sign "$+$" means "after sampling from the posterior distribution"). Now, all $\{X^+_{k-1}(j)\}$ are independent and identically distributed samples from the approximate posterior density Eq. (11).

3. Feed the time evolution model, Eq. (3), with $X_{k-1} = X^+_{k-1}(j)$, $j = 1, 2, ..., N$, and obtain (as it can be easily seen) a set of N samples from the approximate predictive (prior) distribution:

$$X^-_k(j) = \mathcal{M}_{k-1}[X^+_{k-1}(j)] - \xi_{k-1}(j), \tag{12}$$

   where $\xi_{k-1}(j)$ is the j-th pseudo-random realization of the model error on the (t_{k-1}, t_k) time interval.

4. Regard this sample from the approximate prior distribution as the discrete distribution with equal weights:

$$\hat{p}(X_k|Y_{:k-1}) = \frac{1}{N}\sum_{j=1}^{N}\delta[X_k - X_k^-(j)]. \tag{13}$$

This is a virtual step, nothing is computed here. Actually, we can drop the assumption that the *prior* distribution is approximated by the discrete one, instead, we can derive the SIR equations by considering the analysis step as an importance sampler from the posterior (at time t_k) distribution (Pitt and Shephard, 1999), but we will not elaborate on this.

5. Accomplish the analysis step, Eq. (7), with the point-mass prior distribution, Eq. (13):

$$\hat{p}(X_k|Y_{:k}) \propto \frac{1}{N}\sum p(Y_k|X_k^-(j)) \cdot \delta[X_k - X_k^-(j)].$$

Denoting $p(Y_k|X_k^-(j)) =: w'_k(j)$ and normalizing $w'_k(j)$ (in order to obtain a proper discrete distribution),

$$w_k(j) = \frac{w'_k(j)}{\sum_{i=1}^{N} w'_k(i)}, \tag{14}$$

we get the point-mass approximation to the posterior distribution:

$$\hat{p}(X_k|Y_{:k}) = \sum_{j=1}^{N} w_k(j) \cdot \delta[X_k - X_k^-(j)]. \tag{15}$$

6. Now, we go to step 1 above and the process repeats.

Note that in the resampling step, if, for some j, the respective weight $w_k(j)$ is large, then, likely, this particle will be sampled several times, $N_j > 1$, but if $w_k(j)$ is small, then, likely, $N_j = 0$. So, the least likely (as identified by the likelihoods) particles are killed, whereas the most likely particles multiply ("survival of the fittest").

Finally, we discuss how the ordinary deterministic analysis can be obtained with the particle filtering assimilation scheme. As it can be easily seen from Eq. (15), the mean of the posterior distribution is

$$\hat{X}_k = \int X_k \cdot \hat{p}(X_k|Y_{:k})\mathrm{d}X_k = \sum w_k(j) \cdot X_k^-(j). \tag{16}$$

This mean provides the best estimate, in the mean-square sense, of the current state of the system, given all present and past observations. So, $\hat{X}_k$ can be used as the "analysis".

Eq. (16) implies that the analysis is just a linear combination of an inevitably small number of particles. This has very serious consequences for the applicability of a particle filtering data assimilation scheme for such a highly variable system as the atmosphere (see the discussion below).

5 Inherent advantages and disadvantages of the SIR filter

5.1 Advantages

The advantages of particle filtering include its great simplicity, substantial modularity, generality (no linearity, no Gaussianity needed). These are discussed in the referenced literature, so it is not necessary to dwell on this in the critical review here.

5.2 Disadvantages

In the literature, two main drawbacks of the SIR filter were indicated.

First, an "impoverishment" of the particle swarm is often observed. This effect arises if the predictive density appears to be substantially dissimilar to the likelihood. If this happens, most of the "forecast" particles are rejected, leaving only a small number of heavily weighted "survivors". As a consequence, the diversity of the swarm of particles becomes too weak, the point-mass approximation too poor, the filter ceases to follow the truth (degeneracy of the filter). The above dissimilarity of the predictive density and the likelihood may be a result of either very small model error or very small observational error.

Second, if the posterior distribution has heavy tails (outliers happen), then a very large ensemble size is needed in order to represent these distant areas in phase space. This is because their probability mass, p_{out}, is so small that, in order to obtain a single "representer" of these areas (provided we consider these outliers meteorologically important, say, indicating possible severe weather events), the ensemble size should satisfy the inequality $N \cdot p_{out} > 1$, so $N_{min} = p_{out}^{-1}$, which can be large. It becomes even larger if we wish to have several "representers" in these remote areas in phase space. If, moreover, a *difference* between various outlying areas is of interest to us (which is certainly the case for meso-scale modelling and filtering), p_{out} is divided into several even smaller probabilities, thus making N_{min} further larger.

6 Extensions to the SIR filter

A number of improvements and extensions to the basic bootstrap (SIR) filter have been proposed in order to mitigate the above problems of the basic scheme.

To overcome the "impoverishment" problem Gordon et al. (1993) proposed the technique called jittering. With this technique, one adds small random noise to the posterior sample, thus making coincident particles differ from each other. This introduces the desired diversity in the set ("swarm") of particles.

Another technique (Rubin, 1987), called "particle boosting" consists in multiplying, at the prediction step, the number of particle candidates $N_+ = mN$, where m is an integer. Then, one randomly takes N particles from the set of mN candidates. This also increases the diversity, as desired. But this technique greatly increases the computational cost if the forecast step is expensive (as is the case in the atmospheric data assimilation problem).

Musso et al. (2001) proposed "regularized particle filters", in which the point-mass approximation is replaced by the kernel density approximation, see also the "smooth bootstrap" technique (Stavropoulos and Titterington, 2001). Again, the forecast particles become more

different as a result of kernel smoothing, which can prevent the particles' swarm from "impoverishment" and even degeneracy.

Xiong et al. (2006), similarly, proposed to use a posterior Gaussian resampling technique in order to introduce variability in the ensemble sample (see below).

Liu et al. (2001) discuss reweighting as a means to control the balance between "diversity" and "focus" in the posterior swarm of particles. As a generic choice, they recommend to use

$$\pi_k(j) = \sqrt{w_k(j)} \tag{17}$$

as the probabilities of the particles $X_k(j)$. But then, in the prior discrete distribution, Eq. (13), $1/N$ should be replaced by $(1/N) \cdot w_k(j)/\pi_k(j)$. Using the square root in the definition of the probabilities $\pi_k(j)$, allows us to tolerate, to some extent, low-weight particles (outliers), which enhances diversity. Other than the square root choices are also possible.

So, even if the weights happen to differ considerably one from another, we may sample from a more uniform discrete distribution. This means that for a heavily weighted particle, we may not launch too many forecasts from the same (or similar) initial conditions (which looks as a wasting of computer time, even though model-error perturbations can make these forecasts slightly diverge). Instead, we may just remember that this particle has high weight and use this knowledge in the subsequent analysis. Similarly, we may let "light" particles "live", thus preventing the particles' swarm from collapsing.

Pitt and Shephard (1999) proposed to use a more complex sampling scheme, in which the so-called proposal distribution (importance distribution) for importance sampling from the posterior distribution becomes *dependent on current observations* (in the basic SIR formulation, the proposal distribution is the approximate prior distribution). Introducing current observations into the proposal density can, obviously, decrease the above dissimilarity between $p(X_k|Y_{:k-1})$ and $p(Y_k|X_k)$, thus alleviating the "impoverishment" problem. As they report, using the proposal distribution dependent on current observations significantly increases the efficiency of the sampling scheme (less very-low-probability particles). But their "auxiliary filter" requires multiple *evaluations* of the proposal density and the time transition density, which would be very time consuming in the atmospheric data assimilation context.

A simpler technique to use current observations with the aim to appropriately change the importance sampling distribution is "prior editing" proposed by Gordon et al. (1993). With this technique, one enhances the ensemble size at the prediction step and removes the particles with small likelihoods at the current time step. But, similarly to "particle boosting" (see above), this technique is computationally inefficient in our case in view of the high cost of the forecast.

Another technique to skip hopelessly bad (not supported by observations) particles was developed by Van Leeuwen (2003), see below.

Djuric (2001) proposed to combine the well-known from the seventies (Anderson and Moore, 1979) Gaussian sum filter with the SIR methodology. Such a combination can cope with the outliers problem and the "impoverishment" problem of the SIR technique.

More on different flavors of particle filtering can be found in Farnhead (1998).

The above brief review of the techniques developed to improve the basic SIR formulation demonstrates that there are a number of ways to make the SIR filter more efficient. However, Stavropoulos and Titterington (2001) note that *"in general the more sophisticated methods did not lead to noticeable improvement over the simpler versions of particle filtering"*.

7 Non-meteorological and non-oceanographic applications of particle filtering

In the last 15 years, a substantial literature arose devoted to applications of particle filtering. The main areas of applications include target tracking, navigation, positioning, computer vision, signal processing, financial time series modelling, bio-medical applications etc. The common point of all these papers is the low dimensionality of the dynamical systems under investigation. A few examples follow.

Marss (2001) reported on a successful implementation of a particle filter for a 3-D system. Koller and Lerner (2001) worked on a system with 33,000 discrete states. If we assume that in Euclidean space, about 30 points are enough to represent the function's behavior along each axis, we find that 33,000 points roughly correspond to the 3-D case. McGinnity and Irwin (2001) worked with systems whose dimensionality ranged from 1 to 4. It was not possible to find any high-dimensional (more than 10-D) particle filter applications in the statistical literature among tens of available papers.

For such low-dimensional systems, it is of interest for us to look at the ensemble sizes in use. About 40 papers have been checked and those with practical or near-practical applications have been selected. Then, the ensemble sizes reported by the authors has been indicated. The resulting distribution follows.

50

100

200, 200, 200

400

500, 500, 500

1000, 1000, 1000, 1000, 1000

3000

4000, 4000

5000, 5000, 5000

8000

9000

10000, 10000

50000, 50000

100000

50KF

The median of this distribution is about 3000, which is not encouraging for us. The $N = 50$ case corresponds to a simple 2-D mobile robot localization problem. 50KF means 50 Kalman filters in a mixture Kalman filtering scheme.

A personal interpretation of these results is that the particle filtering technique works if we can really *approximate* (in the weak sense) the true distribution by a point-mass distribution. In our effectively high-dimensional case this is certainly not possible.

8 Applications of particle filtering in meteorology and oceanography

8.1 A meteorological review

In the meteorological literature, the use of particle filters was proposed by Anderson and Anderson (1999), Pham (2001), Kim et al. (2003), Xiong at al. (2006), Eyink and Kim (2006), and Nakano et al. (2007).

Anderson and Anderson (1999) used a kernel smoothing (of the prior density) in a Gaussian sum filter without resampling. They used the three-variable Lorenz model and the ensemble size $N = 40$. They also showed that for a 3000-D global barotropic model in an idealized setting, their kernel filter with $N = 40$ was capable of doing the assimilation job. However, it is difficult to judge the relative merit of their filter as compared with other, more traditional approaches. Anderson and Anderson (1999) argue that a small ensemble size may be sufficient if the system "lives" on a low-dimensional attractor. But on the meso-scale, we hardly can assume that the attractor (if it exists) is low-dimensional — in view of the highly variable and diverse atmospheric behaviour on the meso scale. Besides, at every assimilation time step, observations will inevitably push the system off the attractor.

Pham (2001) proposed to use, in the meteorological and oceanographic context, a SIR filter with kernel smoothing of the posterior density. He applied the filter for the three-variable (just three degrees of freedom) Lorenz system and found that for good performance, 50 particles were needed. This is not a promising result for us because the dimensionality of our phase space is about one million.

Kim et al. (2003) used the SIS (sequential importance sampling) and SIR filters for a one-dimensional non-linear stochastic differential equation. They checked the ensemble sizes of 100 and 10^4 and found that 10^4 particles were needed for SIS and 100 for SIR. Again, this is not a good result for us, in view of the extremely low dimensionality of their phase space, $n = 1$. They also proposed a parametric particle filter, in which the prior density is approximated by a density from the exponential family. In their experiments, they found that this filter performed better than SIR (nothing is said about SIS). The parametrization idea seems fruitful, but in the implementation of their analysis step, only two free parameters of the parametric density were updated, which is not acceptable for us, since we wish to control, in the analysis, many meso-scale features across the domain of interest.

Xiong et al. (2006) proposed to use a posterior Gaussian resampling technique in order to fight "impoverishment" of the ensemble sample. This method is not useful for us because it is the non-Gaussianity that has drawn our attention to particle filtering. Besides, in other respects (especially in the analysis scheme), the technique of Xiong et al. (2006) does not differ from the basic SIR formulation. For the three-variable Lorenz system, the ensemble size in their numerical experiments ranged from 100 to 1000. Again, this is not encouraging for us, because we have to build a hyper-dimensional meso-scale data assimilation system.

Eyink and Kim (2006) proposed several methods based on the maximum entropy principle. The methods were checked on low-dimensional systems, but the authors claimed that they were preparing a paper in which they would report on a successful application of these methods for high-dimensional oceanic thermohaline circulation assimilation.

A device to fight the "impoverishment" problem was proposed by Nakano et al. (2007). Their suggestion is not to kill low-weight particles (thus, reducing the desirable diversity) but to use them in a particle merging scheme. The merging is a linear combination (with

the weights independent of the physical-space coordinates) selected to preserve the first two moments of the multivariate posterior distribution. They tested their merging technique in experiments with the three-variable Lorenz model and the 40-variable Lorenz-96 model. While the merging technique itself does not seem to lead to vital improvements in the meso-scale data assimilation context, their results are interesting for us in the ensemble sizes they used. Namely, for the 40-D case, even as many as 260,000 members were not enough for the performance of their filter to converge (to stop improving). This result, again, indicates that in our 10^{-6}-D case, the ensemble size necessary for a particle filter to properly work will be enormous, thus prohibiting the use of the particle filtering idea for atmospheric data assimilation.

8.2 Work of P. J. Van Leeuwen

In the oceanographic context, Van Leeuwen (2003) tested three formulations of particle filters: first he used the standard SIR (with a slight modification of sampling from the discrete probability distribution), second he proposed the local SIR (LSIR) and third, the guided SIR (GSIR).

He noticed that the SIR analysis is essentially global, so that on one domain's sub-area, one subset of particles appears to be consistent with the observations, whereas in other sub-areas, quite different particles can be supported by observations. In order to let the observations influence not just the global weights but local neighborhoods, he proposed to make the weights spatially variable by performing the SIR analysis step many times for every grid point with local data selection, like in optimum interpolation (OI). This can introduce the necessary locality of the observational usage, but the great problem arises: what should be the posterior particles if at different grid points different particles were selected. Van Leeuwen (2003) used a simple gluing of the particles, which was not successful in his experiments and does not seem to be a suitable approach in meso-scale assimilation for the two following reasons.

1. From a theoretical point of view, this device violates the particle representation, so that we, seemingly, cannot justify how to *change* ("break") the particles at the analysis step. How can we find the posterior distribution if the prior particles are completely destroyed by "gluing" ? If "gluing" is an approximation, a question arises: is there a *proof* that the error of this approximation tends, in some sense, to zero as the ensemble size tends to infinity ? Without mathematically-based answers to these questions, the technique becomes largely *ad hoc*, which should be considered as a serious drawback.

2. From a practical point of view, "gluing", or equivalently, building the new posterior particles of patches from different ensemble members (presumably, as many patches as many different meso-scale features are present across the analysis domain) violates the dynamical and physical balances in the new particles. This will certainly lead to generation of spurious gravity waves (as noted by the author of the technique) and also to spurious fluxes of heat, water, and momentum, giving rise to the well-known "spin-up" phenomenon, which is highly undesirable in the data assimilation context because a *short-* or *very-short-range* forecast is used at the analysis step as a source of a priori information. In addition, like in OI, local data selection will lead to small-scale noise, which can mask important meteorological details on the meso scale.

So, in the present form, the LSIR technique seems to be not suitable for meso-scale data assimilation.

The GSIR technique of Van Leeuwen (2003) aims to reduce the ensemble size by removing "bad" particles at the very early stages of the forecast. This is possible because we can start the ensemble forecast step *after* we receive current observations (although, at the price of some time delay in issuing the analysis, which may be not desirable in the operation context). For meso-scale data assimilation, the GSIR idea can be useful, among others, but GSIR remains a *global* technique (the weights do not vary across the domain), which prohibits its direct use. The reason for this, as explained below, is that in the global ensemble, the number of global particles should be comparable with the number of effective degrees of freedom we wish to control in the analysis. In the meso-scale, the latter can be very large as compared with the affordable ensemble size.

As for the numerical experiments of Van Leeuwen (2003), it is worth noting that his assimilation/forecast results were not compared with observations. There was also no comparison with other assimilation methods. Besides, in his experiments the assimilated fields look smoother than atmospheric meso-scale patterns.

Concerning the applicability of the results obtained for *oceanic* data assimilation to atmospheric problems, it should be mentioned that the atmosphere is much better observed than the ocean. This implies that oceanic forecasts are relatively much worse than the atmospheric ones. As a result of this, oceanic data assimilation works in a rather different "regime" than the atmospheric one, which reduces the applicability of oceanic results to atmospheric data assimilation, in particular, on the meso-scale.

9 Summary of the disadvantages of a hypothetical particle-filtering based meso-scale data assimilation scheme

The main problem: critically insufficient ensemble size to resolve meso-scale details of meteorological fields and to allow efficient observational usage.

1. Mathematically, we cannot even imagine to approximate a million-dimensional density by a handful of phase-space points (particles). This is completely "unmathematical". Even if we take into account that not all of these numerous degrees of freedom are equally important and the effective number of degrees of freedom, n_{eff} is substantially less, n_{eff} remains, as it follows from physical arguments for meso-scale modelling, orders of magnitude larger than any practically imaginable ensemble size.

2. Meteorologically, an inevitably small ensemble size does not allow us to *resolve* small-scale meso-scale details, as discussed below in this section.

3. Practically, a particle filtering based analysis scheme would imply **critically inefficient use of observations** (as compared to OI and Var).

   In a particle-filter atmospheric data assimilation scheme, tens of thousands, and very soon, millions of observations can influence the analysis only through a few (30-50) free parameters, the particle weights (a "bottleneck"). So, information contained in a huge number of observations, before correcting the forecast fields, should be "summarized" in an extremely small number of particle weights. Obviously, such a tremendous "compression" of observational data is impossible without an immense loss of information. But if we waste valuable observational information, we cannot hope to design an efficient assimilation system.

   In other words, in the SIR filter, local corrections due to local observation-minus-forecast differences are virtually impossible because only the *combined* effect of *all*

observations does influence the analysis (through the particle weights), see Eq. (16).

The most severe consequence of the small ensemble size is that the number of degrees of freedom of the meso-scale field we wish to resolve appears to be orders of magnitude larger than the number of adjustable parameters (the particle weights) at the analysis step. Indeed, if we intend, in the analysis, to resolve meteorological details of the size of kilometers, then we have to design an analysis scheme capable of controlling the analysis fields with this granularity. In other words, if in the analysis we admit a feature (say, a cloud system) of the size of 10 km, and observations indicate that we have to correct the forecast in this 10-km area, then the analysis technique should allow this. And this job has to be done simultaneously, in other 10-km "boxes", independently of each other. In a 1000 by 1000 km domain there are 10,000 horizontal "boxes". In the vertical, similarly, if we aim at details, say, 500-m deep, then 10 to 20 vertical "boxes" have to be resolved. Thus, in total, we obtain $10,000 \cdot 20 = 200,000$ 3-D "boxes" or degrees of freedom. But, in the SIR analysis, we have only N (recall, N is the ensemble size) free parameters, with N being about 30–50. Obviously, it is absolutely impossible to control 200,000 degrees of freedom with such a tiny number of adjustable parameters.

Otherwise stated, the SIR analysis equation, Eq. (16), can be viewed as an expansion of the analysis field in the basis functions $X_k^-(j)$, the particles' fields (a kind of *spectral* technique). But the number of the basis functions, N, is so incredibly small as compared to the number of meso-scale details to be resolved, that we have to conclude that the SIR filter is inappropriate with a reasonable (for us) ensemble size. With $N = 50$, only about 50 details over the whole 3-D analysis domain can be resolved, which is far too small for a state-of-the-art and a prospective meso-scale data assimilation system.

The LSIR Ansatz of Van Leeuwen (2003) could be a remedy but it seems to lack mathematical and meteorological justification (see above).

In addition to the above small-ensemble-size issues, the following practical points are worth noting.

1. In 3D and 4D-Var analysis schemes, the very important role of the prior (background) probability distribution (covariances) is well established. To obtain a good analysis, very sophisticated background-error covariance models have been proposed. In particular, control of multivariate covariances, non-separability (vertical by horizontal) of 3-D correlations and other aspects are shown to be of great importance for a successful background-error covariance model. With a particle filter, we do not care about these issues at all, completely relying on the (small) swarm of particles. But particles are selected, to a large extent, at random, so the implied probability distribution is also random (significantly contaminated by sampling noise). Is it good to use this random prior distribution as if it were the true one?

2. As noted by Anderson and Anderson (1999), the SIR filter may fail if the forecast model is *biased*. In this case, all particles can be biased, so that the observations will be not capable of removing this bias at all (because the observation has only "the right" to select from prior particles, which are all biased).

3. The SIR analysis algorithm is so incredibly simple that we may question: why the substantial *simplification* of the analysis technique (from the complicated 3D-Var to the extremely simple SIR) will lead to an improvement? Common practice shows that the converse is almost always the case.

10 Conclusions

The SIR filter is *not* recommended for meso-scale data assimilation because it would imply, for an affordable ensemble size, first, critically inefficient observational usage and second, lack of high-resolution meso-scale fields' analysis corrections.

The LSIR filter is also *not* recommended for meso-scale data assimilation in its present form because of lack of its mathematical and meteorological justification.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIM, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW) and Romania (NMA). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

An Epilogue to Part I **66**

1 Introduction

At the Deutscher Wetterdienst (DWD) an internal project named LITFASS (Lindenberg Inhomogeneous Terrain - Fluxes between Atmosphere and Surface - a long-term Study) was founded (Müller et al. 1995) and is running up to summer 2001. The aim of that project is to determine by measurement and model simulation area-averaged turbulent fluxes of momentum, heat and moisture representative for an inhomogeneous landscape typical of Central Europe and far enough to the south-east of Berlin.

The project takes advantage of the given infra-structure of the Research Division at DWD, where model research capacity is brought together with considerable and very complex measurement capacity at and over a defined area around the Meteorological Observatory Lindenberg (MOL). LITFASS consists of two main components, a measurement/observation component, (cf. Beyrich 2000) and a numerical simulation component, which serves in a judicious and mutual way to finally help improving the parameterization of subgrid-scale fluxes at and near to the underlying surface for the operational NWP-models. For these models at DWD, and for those elsewhere, one is confronted with the notoric problem that parameterization of subgrid-scale turbulent fluxes is far from being completely solved, and so, for instance, the prediction of 2m-parameters often fails to be satisfactory.

At the end of the project time, after a great, joint achievement and with a noticeable research investment the conclusion may be drawn that due to LITFASS a complex long-term validation system could be established from which the above mentioned task can be tackled with a permanently available measurement system and an appropriate and reliable numerical simulation model. The concern of this paper is to present the numerical simulation component of LITFASS. It represents the 'heart' of the project. From utmost importance is that that model is tightly related to the high-resolution part of the new operational NWP-system, namely to the non-hydrostatic 'Lokal-Modell' (LM), which in the present mode is running with a 7 km horizontal gridpoint distance and 35 vertical layers (cf. Doms and Schättler 1999). Since the model presented here is derived from the LM, it will be designated as LITFASS-Lokal-Modell or LES-Lokal-Modell. The generic abbreviation is LLM. The strict relation to the LM is deliberately organized so as to have a high degree of consistency by using a unified program code, having similar dynamics, numerics and therefore a close reference to the LM-validation from the point of view of the LLM over the defined Lindenberg-observational and LLM-simulation area.

The latter aspect is of particular importance, because the LLM is the simulation tool to determine explicitly the relevant turbulence structures in the integration area as 'true' area-averaged fluxes which are then allowed to compare with the corresponding subgrid-scale fluxes of the LM. This is in the narrow sense the main task of the LLM. It is integrated with a very high horizontal and vertical grid resolution. The integration area covers the planetary boundary layer in the vertical. Its horizontal size corresponds to an area of 14×14 km^2 (or even larger: 20×20 km^2) in which the MOL is placed. A detailed physiographic description of the underlying surface is taken into account. In contrast to common LES models (e.g. Mason 1994, Mason and Brown 1999, Chlond 1999, Stevens 2000, Kanak et.al. 2000) which are sophisticated instruments to investigate the energy-relevant turbulence structures under clearly defined and controlled conditions (horizontally homogeneous vertical profile of wind, temperature, water content plus small randomized perturbations defining an initial state, homogeneous properties of the underlying surface with prescribed time-independent surface fluxes, or regular or stylized pattern of surface inhomogeneities, double-periodic lateral continuation of the integration domain etc.), the LLM is designed as a 'real-world'-LES model operating under general meteorological conditions.

Demonstrating the unity with the measurement component of LITFASS, the LLM integration mode is characterized by a time-dependent external forcing at the lateral and upper boundary derived from available time sequences of measured vertical profiles, and also by the physical forcing at the surface deduced from temporally variable ground-based measurements of radiation (supported by satellite data) and precipitation, and by observations describing updated surface parameters (vegetation parameters). All the LLM simulations are mainly related to two intensive measurement campaigns in the Lindenberg field. The first one is the 'LITFASS-98 Experiment' (25 May - 30 June 1998) (cf. Beyrich 2000), and the second one is an experiment named 'LINEX-2000' which took place during August/September 2000.

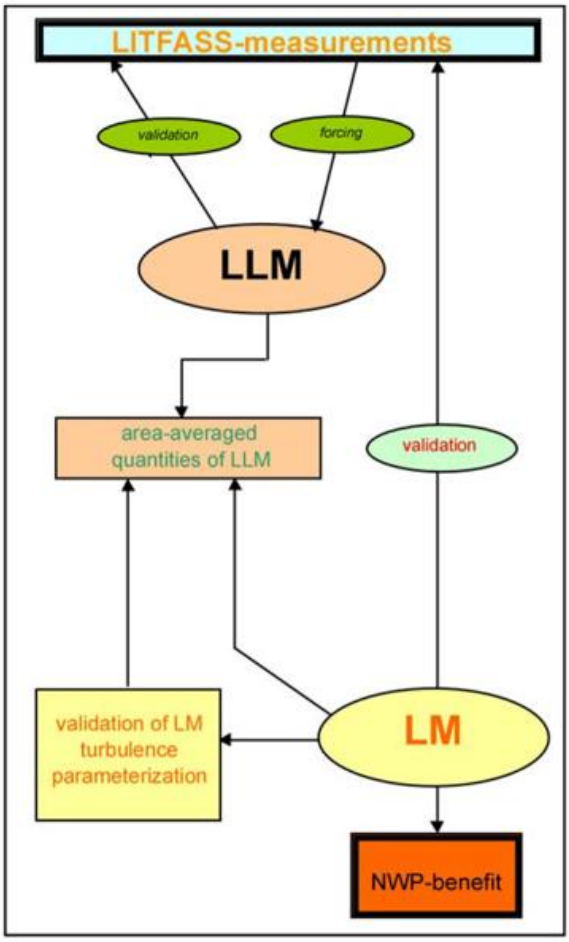

Figure 1.1: The meaning of the DWD project LITFASS from the point of view of bridging observation and simulation by use of the LLM as a tool to validate and help improving NWP models like the LM.

The entire paper is organized as follows. In Chapter 2 the model design is described. It concerns the model equations, the numerics with the vertical and horizontal grid spacing, the specific lateral, upper and lower boundary treatment, a description and explanation of the physics relevant to the LLM integration mode and, finally, the definition and position of the LLM simulation area. Chapter 3 contains a detailed discussion of the LLM-specific incorporation of the three-dimensional subgrid-scale turbulent fluxes concerning both numerical aspects and their parameterization using a prognostic scheme for the turbulent kinetic energy (TKE).

The Chapters 4 and 5 are of particular meaning with respect to the 'real-world' properties of the LLM. Chapter 4 describes how the LLM is externally driven in a lateral and upper boundary zone due to time-sequences of meteorological vertical profiles derived from different measurement sites and vertical sounding systems. In addition to this, the physical forcing of the LLM from the heterogeneous underlying surface is thoroughly discussed in Chapter 5. Here, an important aspect of the LLM integration mode is pointed out. It concerns the careful documentation of the external parameters related to the coupled soil model, and a broader description of methods is given, how to deduce the in homogeneous distribution of surface radiation components and precipitation. The actual time variation of the soil moisture distribution is also taken into account.

In Chapter 6 the model validation is carried out in detail. It reflects the primary claim to have obtained by LITFASS a reliable LLM as a simulation tool on the base of measurements. The following Chapter 7 involves a theoretical consideration. It will be shown in the context of the model equations how area-averaged subgrid- plus grid-scale fluxes are to be formulated in the LLM for referring them to the subgrid-scale fluxes of the LM. As a conclusion, the quantitative comparison of model results from LLM versus LM is particularly demonstrated in Chapter 8. Beyond the given presentation, in an additional Chapter 9 the efforts of programming and program organization on the high-capacity computers at DWD (Cray T3E) and the ECMWF (Fujitsu/VPP 700/116) are dealt with, which have guaranteed the feasibility of the computationally extensive task of LLM simulations. Summing up all partial results, a rather complex and upgraded validation system has been achieved, which makes up the main result of the present state of LLM development. This is shown in Fig. 1.1. It must be understood as a platform ready to start from for systematic and continuous work of NWP activities in the field of parameterization.

The present issue does not contain the entire content listed above, but rather Chapters 1 - 5. These Chapters together built a logical unit. They describe with a fairly completeness the LLM-design including all specific and technical aspects. While writing and preparing the full text we made an incidental decision to publish immediately that part just completed as Part I, before Part II with the following Chapters 6 - 9 will be issued next.

Remark
This paper here submitted to the COSMO community is an improved und updated version of an equally entitled contribution in *Deutscher Wetterdienst, Forschung und Entwicklung, Arbeitsergebnisse Nr.67, Offenbach, Juli 2001.*

2 Model Description

The LLM (LITFASS/LES-Lokal-Modell) is derived from the LM (Lokal-Modell) after having made a deliberate decision in this way. The most important reason for this is obvious, because the LM is the high-resolution model component of the new operational NWP-system at the DWD, and the LITFASS-project was from the very beginning thought to become directly useful to the NWP. As the LM is a nonhydrostatic, compressible model, it is from the point of view of these general properties immediately suitable to be used also as a very high-resolving model within the context of LITFASS. Therefore, the basic equations are, apart from minor modifications, for the LLM identical with the LM equation set. This makes the following model description short enough, where we, however, need the full reference to Doms and Schättler (1999).

2.1 The Model Equations

As discussed above, the LLM equations are borrowed from the LM. We write them here in the following form:

$$\begin{aligned}\frac{\partial u}{\partial t} &= -\frac{1}{\rho}\left(\frac{\partial p'}{\partial x}-\frac{1}{\sqrt{\gamma}}\frac{\partial p_0}{\partial x}\frac{\partial p'}{\partial \zeta}\right)-\left(\frac{\partial K}{\partial x}-vV\right)-\dot{\zeta}\frac{\partial u}{\partial \zeta}-\frac{1}{\rho}\left(\nabla\cdot\underline{\underline{F}}\right)\cdot\underline{e}_1 \\ &\quad + M_u^{LB}+M_u^{UB}+D_u \qquad (1)\end{aligned}$$

$$\begin{aligned}\frac{\partial v}{\partial t} &= -\frac{1}{\rho}\left(\frac{\partial p'}{\partial y}-\frac{1}{\sqrt{\gamma}}\frac{\partial p_0}{\partial y}\frac{\partial p'}{\partial \zeta}\right)-\left(\frac{\partial K}{\partial y}+uV\right)-\dot{\zeta}\frac{\partial v}{\partial \zeta}-\frac{1}{\rho}\left(\nabla\cdot\underline{\underline{F}}\right)\cdot\underline{e}_2 \\ &\quad + M_v^{LB}+M_v^{UB}+D_v \qquad (2)\end{aligned}$$

$$\begin{aligned}\frac{\partial w}{\partial t} &= \frac{g}{\sqrt{\gamma}}\frac{\rho_0}{\rho}\frac{\partial p'}{\partial \zeta}+g\frac{\rho_0}{\rho}\left\{\frac{(T-T_0)}{T}-\frac{T_0 p'}{T p_0}+\left(\frac{R_v}{R_d}-1\right)q^v-q^l\right\} \\ &\quad -\left(u\frac{\partial w}{\partial x}+v\frac{\partial w}{\partial y}\right)-\dot{\zeta}\frac{\partial w}{\partial \zeta}-\frac{1}{\rho}\left(\nabla\cdot\underline{\underline{F}}\right)\cdot\underline{e}_3+M_w^{UB}+D_w \qquad (3)\end{aligned}$$

$$\begin{aligned}\frac{\partial p'}{\partial t} &= g\rho_0 w-\frac{c_{pd}}{c_{vd}}p\left(D_H-\frac{g\rho_0}{\sqrt{\gamma}}\frac{\partial w}{\partial \zeta}\right)-\left(u\frac{\partial p'}{\partial x}+v\frac{\partial p'}{\partial y}\right)-\dot{\zeta}\frac{\partial p'}{\partial \zeta} \\ &\quad +M_{p'}^{LB}+M_{p'}^{UB} \qquad (4)\end{aligned}$$

$$\begin{aligned}\frac{\partial T}{\partial t} &= -\frac{p}{\rho c_{vd}}\left(D_H-\frac{g\rho_0}{\sqrt{\gamma}}\frac{\partial w}{\partial \zeta}\right)-\left(u\frac{\partial T}{\partial x}+v\frac{\partial T}{\partial y}\right)-\dot{\zeta}\frac{\partial T}{\partial \zeta} \\ &\quad +Q_T-\frac{1}{\rho c_{pd}}\nabla\cdot\underline{H}+M_T^{LB}+M_T^{UB}+D_T \qquad (5)\end{aligned}$$

$$\begin{aligned}\frac{\partial q^k}{\partial t} &= -\left(u\frac{\partial q^k}{\partial x}+v\frac{\partial q^k}{\partial y}\right)-\dot{\zeta}\frac{\partial q^k}{\partial \zeta} \\ &\quad +Q_k-\frac{1}{\rho}\nabla\cdot\underline{F}_{q^k}+M_{q^k}^{LB}+M_{q^k}^{UB}+D_{q^k} \qquad (6)\end{aligned}$$

with $k = v, l$ (denoting water vapour or cloud liquid water, respectively) and with the definitions

$$p = \rho R_d \left\{ 1 + (R_v/R_d - 1)q^v - q^l - q^f \right\} T \tag{7}$$

$$\dot{\zeta} = -\frac{1}{\sqrt{\gamma}} \left(u\frac{\partial p_0}{\partial x} + v\frac{\partial p_0}{\partial y} + g\rho_0 w \right) \tag{8}$$

$$D_H = \left(\frac{\partial u}{\partial x} - \frac{1}{\sqrt{\gamma}} \frac{\partial p_0}{\partial x} \frac{\partial u}{\partial \zeta} \right) + \left(\frac{\partial v}{\partial y} - \frac{1}{\sqrt{\gamma}} \frac{\partial p_0}{\partial y} \frac{\partial v}{\partial \zeta} \right) \tag{9}$$

$$K = \frac{1}{2}\left(u^2 + v^2\right), \quad V = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} + f \tag{10}$$

The formulation makes reference to a defined basic state, which is hydrostatic, dry and at rest. For the temperature and the pressure follows $p = p_0(z) + p'$, $T = T_0 + T'$, and the density of the basic state is $\rho_0 = p_0/(R_d T_0)$. Because the LLM integration domain has a rather limited horizontal extension (see below in 2.6), the horizontal partial derivatives are here symbolized in local cartesian coordinates ($\partial x := a\cos\varphi\partial\lambda$, $\partial y = a\partial\varphi$) instead of spherical ones. Spherical metric terms are therefore dropped, and the variation of the Coriolis parameter is neglected. Furthermore, the equations are formulated with a terrain-following vertical coordinate ζ in such a way, that the momentum equations are related to the physical wind components u, v, w. $\dot{\zeta}$ denotes a contravariant vertical velocity which by use of (8) is related to u, v, w.

The factor $\sqrt{\gamma}$ is defined by $\sqrt{\gamma} = \partial p_0/\partial\zeta$, where $\sqrt{\gamma}/(g\rho_0)$ is the Jacobian of the transformation from the z- to the ζ-coordinate. The horizontal wind divergence D_H, the kinetic energy of the horizontal wind K, and the absolute vorticity V are defined by (9) and (10). The equation of state for a mixture of dry air, water vapour and liquid water is given by (7), q^v and q^l denote the specific contents of water vapour and liquid water, respectively. Thus, (6) consists of two equations for both these moisture variables. The ice phase is not taken into account in the LLM. In contrast to the LM, we consider here the turbulent fluxes of momentum, heat and moisture in all three space directions. Therefore, F denotes in (1), (2), (3) the turbulent momentum flux tensor with its 6 components, and H, F_{q^v} and F_{q^l} the three-dimensional turbulent vector fluxes of heat, water vapour and liquid water. In addition, in the prognostic equations (1), (2), (3), (5), (6) a non-physical computational mixing is implied, where a linear fourth-order horizontal diffusion symbolized by the terms D_ψ ($\psi = u, v, w, T, q^v, q^l$) is applied.

The source terms Q_T and Q_{q^k} need also to be explained. Q_T represents the rate of diabatic heating/cooling due to phase changes of water. The atmospheric effect of radiation is deliberately neglected. This will be discussed from the point of view of the external model forcing in Sections 2.5 and Chapters 4 and 5. The terms Q_{q^v} and Q_{q^l} contain the cloud microphysical source and sink terms and the precipitation flux.

In order to complete the formal model description, the terms M_ψ^{LB} and M_ψ^{UB} must be mentioned. They have no physical background. They represent relaxation terms, acting in a *lateral boundary* zone (=superscript LB) and *upper boundary* model layer (=superscript UB), in order to bring the LLM solution within those boundary zones outward to an externally driving state deduced from measured vertical profiles. This aspect is discussed in Section 2.3 and in Chapter 4. For the rest of symbols in the equations above the meteorological standard notion is valid: R_d and R_v are the special gas constant for dry air and water vapour, respectively, g is the gravity constant, and c_{pd} (c_{vd}) denotes the specific heat capacity at constant pressure (volume).

2.2 Numerical Aspects

As argued above in the description of the continuous LLM equations, we can be brief in discussing the numerics of the LLM as far as taken directly from the LM numerical scheme. This concerns horizontal, vertical and time differences. The horizontal gridpoint position of variables is ordered in a C-grid scheme after the well-known Arakawa nomenclature: At a central point of each gridbox almost all scalar variables inclusively w are placed, while horizontal wind components are positioned halfway from that point as normal components with respect to the box sides (u to 'right' and 'left'; v 'above' and 'below'). The vertical grid is a so called Lorenz-grid. Here, most of variables are placed in the middle of each layer, which is at the so called main levels, while the vertical velocity and also the turbulent vertical flux terms are placed at half levels, which are the interfaces between those layers. The fundamentals of the vertical layer structure can easily be characterized from a strict quotation of Doms and Schättler (1999, cf. Subsection 2.5.3 in the LM-Scientific Documentation).

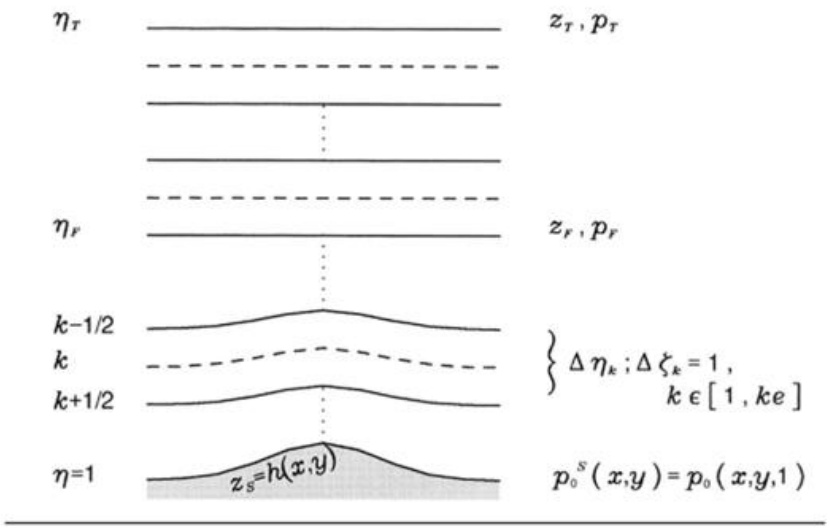

Figure 2.1: Vertical differencing scheme based on the terrain-following hybrid vertical coordinate η with some mapping $\eta = m(\zeta)$ onto the generalized coordinate ζ with the convenient property $\Delta\zeta_k = 1$. The LLM values are $z_T = 3000$ m, $p_T = 693.9075$ hPa, $\eta_T = p_T/p_{SL}$, $p_{SL} = 1000$ hPa, $z_F = 1000$ m, $p_F = 887.27$ hPA and $\eta_F = p_F/p_{SL}$. z_s is the orographic height which is also given by a standard surface pressure distribution $p_0^s(x, y)$ on $\eta = 1$.

An important aspect of the terrain-following vertical coordinate used in the LLM is specified as a pressure-based hybrid coordinate that involves a defined height of $z_F = 1000$ m separating the entire vertical domain into a terrain-following part below and a pure z-coordinate above it (Fig. 2.1). Thus, the lower model boundary is a coordinate surface formed by the highly resolved orography plus a seasonally varying field of the displacement height. The upper boundary is assumed at 3000 m height. This vertical depth of the LLM is divided into 39 layers, where the layers nearest to the lower boundary are very thin. The thickness is spreaded from 4 m to 25 m in the first two-hundred meters with 15 layers. Above, the layer thickness increases gradually up to 100 m at 425 m height where it remains so up to about 1000 m. From there the resolution becomes still coarser with a thickness of 150 m up to model top height (Tab. 2.1).

With a horizontal mesh width of $\Delta \simeq 100$ m the aspect ratio $\alpha = \Delta z/\Delta$ varies between $1/25 \leq \alpha \leq 3/2$. The vertical depth of 3000 m has been fixed after test integrations of a 52-layer model version with a model top height chosen for sake of caution at 5000 m for

Table 2.1: Vertical structure of layers. The index $k \in [1, 40]$ counts the half-levels with associated heights and basic-state pressure values.

a convective case. The outcome has indicated that a 3000 m upper boundary height is sufficient.

The time differencing scheme used for the LLM integration is completely taken from the LM-code as the dominant scheme amongst three options. In brief, we selected the mode-splitting time integration method originally proposed by Klemp and Wilhelmson (1978), refined by Skamarock and Klemp (1992) and completed by further implicit manipulations. In this line the model equations are split up into a slowly varying part and a fast one. The former consists of horizontal advection, vertical advection, turbulent diffusion in all three space directions, horizontal computational mixing and source/sink terms. The water balance equations for vapour and liquid water and the turbulent kinetic energy equation are exclusively slow equations, while the momentum equations for the wind components u, v, w, the temperature equation and the prognostic perturbation pressure equation have also a fast part.

In the slow equations/equation parts different terms are treated differently as follows. The horizontal advection is integrated by use of the leap-frog scheme. The vertical advection and the vertical turbulent flux terms are approximated by an implicit Crank-Nicholson scheme, and the horizontal turbulent flux terms, the computational mixing (fourth-order diffusion), and the source/sink-terms as well, are formulated by a simple forward scheme. The corresponding time step (large time step) is chosen $\Delta t = 2$ s with respect to the horizontal gridpoint distance $\Delta = 96.5$ m. The entire time marching per Δt consists in extrapolating the fast equation part with a small timestep $\Delta\tau$ several times over each time span $2\Delta t$ keeping the before determined slow tendencies fixed over this intervall. The fast-mode part involves, apart from the slow tendencies of momentum, temperature and perturbation pressure, all terms representing inertial-gravity waves and sound-waves. Those terms describing

vertically propagating waves are treated implicitly in order to prevent any dependence on high vertical grid resolution. Thus, the choice of the small time increment $\Delta\tau$ is governed by the linear stability condition $\Delta\tau \leq \Delta/(\sqrt{2}\,c_s)$ with an estimate for the sound speed $c_s = (R_d(c_{pd}/c_{vd}) \times 303K)^{1/2}$. With respect to the relation $\Delta\tau = 2\Delta t$ follows $N = 22$ as the number of small timesteps over twice the large step giving $\Delta\tau = 0.182$ s.

Each time step Δt ends with the application of a Robert-Asselin time filter followed by the upper and lateral boundary relaxation technique in order to match the inner LLM solution with an external forcing. The latter aspect is of special interest for the LLM integration mode and will therefore be discussed separately in the next Section.

Lest we ignore possibly a time integration scheme being less time consuming than the mode splitting scheme, it was mandatory for us to test further options available for the LM. Thomas et al. (1998 a, b) had developed a three-dimensional semi-implicit time integration method suitable for a non-hydrostatic compressible model which they also introduced in the LM program code. Their method rests on a GMRES (General Minimal Residual Krylov Iterative Solver) algorithm and seemed to promise computational advantages. Therefore, rather time-expensive tests of that scheme applied to the LLM have been carried out (Herzog and Fiedler 1999). The computational efficiency of the fully 3D semi-implicit (SI) time-scheme versus the above described split-explicit (SE) scheme has been investigated by comparable real data runs for the 14.06.97 day. Unfortunately, the outcome of these runs was negative. Compared to the SE reference run with the 'slow mode'-time step of $\Delta t = 2$ s the SI runs led to an unexpected computational overhead. The slow convergence rate of the elliptic solver could not be influenced by an enlarged Krylow space dimension and an aspect ratio $\Delta z/\Delta$ chosen always smaller than unity. The conclusion had to be drawn that the SI-scheme cannot compete with the SE-scheme in case of the LLM which simulates the planetary boundary layer with its inherent three-dimensional micro-scale structures. For a comparably larger-scale LM computational problems discussed seem different (Saito et al. 1998).

2.3 Lateral and Upper Boundary Techniques

Integrating a very high-resolving model over a rather limited area like the LLM, one is confronted with an extremly underestimated problem in view of external atmospheric information needed to drive the model via its lateral boundaries and the upper boundary as well. We assume the relatively low-resolved boundary data provided from measurements (cf. Chapter 4) to be in general variable in time. For that reason it is important to have some desirable control of such boundary forcing. Particularly, the effect of local physical forcing in the near-surface Planetary Boundary Layer domain of the LLM should be maintained as far as possible. Trying to find a solution, a pragmatic, engineering strategy is reasonable to be pursued. Unfortunately, there is no standard method that has been demonstrated to be satisfactory for the wide-spread spectrum of atmospheric motions, and so for the LLM problem neither.

In view of this, rather extended numerical experiments have been made both as transparent simplified tests and as complex real-data model runs, in order to come to a decision for an acceptable compromise. Basically, two types of lateral boundary methods have been tested. The first type is the *radiation condition* in its approximate form (Orlanski 1976). The principal difficulty to incorporate a radiation condition into a realistic model is that the speed normal to the boundary is generally unknown. The approach (Miller and Thorpe 1981) locally diagnoses the normal speed component, whereas in Klemp and Wilhelmson (1978) it is specified to be a representative phase speed of internal gravity waves. In each case

tested, the approach remains approximative and is linear. The boundary condition becomes, however, necessarily nonlinear which means that this type of method works successful only when the solution is dominated by a single wave. In all other cases we are mainly interested in, the solution is severely polluted with errors. By the way, there is also no convincing theoretical support for the radiative idea, since the original variables are not characteristic. The outcome of numerous test integrations gave us a sufficient reason to discard this type of lateral boundary technique from further consideration.

The second type uses a certain *adjustment or 'sponge' effect* in a zone next to the lateral boundary (Davies 1976, Perkey and Kreitzberg 1976, Chen 1973, Miyakoda and Rosati 1977 etc.). Our interest is to apply a method of that type which was introduced in a particularly easy and therefore practicable form by Kallberg and Gibson (1977) starting from Davies' original approach. The so called 'Davies-Kallberg'-technique is a preferable method which is always available because of its ease to be used in general situations, where the boundary data are time-dependent. The property of easy use is also a very important aspect in view of parallel programming. Nevertheless, one must not ignore the inevitable shortcomings of the Davies-Kallberg boundary relaxation or blending method from which dynamical imbalances in the relevant boundary adjustment zone may be produced.

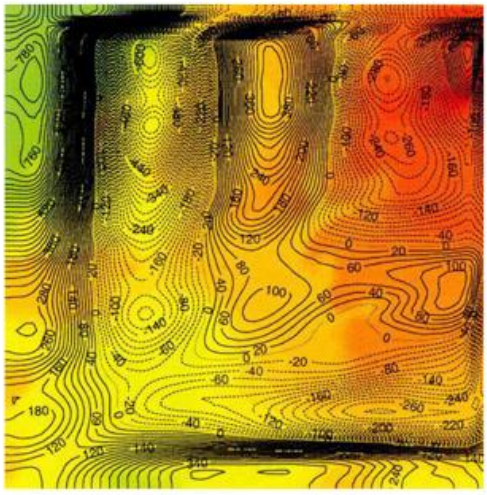
Before we start describing a version of the Davies-Kallberg technique applied to the LLM regime, some remarks concerning a hybrid method are given. The latter one has also been tested because there were arguments in literature (Arakawa 1984) for a pragmatic solution, in which a scheme that is nonreflective – at least for idealized cases – is combined with some adjustments near the boundary. An attempt was therefore made to adapt such a method to the compressible, non-hydrostatic LLM with its specific time-splitting technique. The working hypothesis was to introduce also a mode splitting for the radiative scheme. In doing so, the acoustic-gravity equation part is treated with open boundaries at each short timestep. For the advection part, however, a mixed scheme is applied: At the outflow boundary points a radiative scheme is used again, but now for the advective wind speed, while at outflow points a modified Davies-scheme operates.

In short, this rather sophisticated scheme works well in case of simplified flow situations, where outflow points and inflow points can easily be separated (e. g. the most simple case of a diagonal basic current). In more general cases problems emerge at boundary points, where the relaxation scheme and the radiative scheme influence and conflict with each other in an uncontrolled way. Therefore, this method was also discarded, which has finally led to our choice of a 'pure' Davies-Kallberg technique. That method is applied in the LLM in a modified form.

The prototype for each prognostic LLM equation may be written

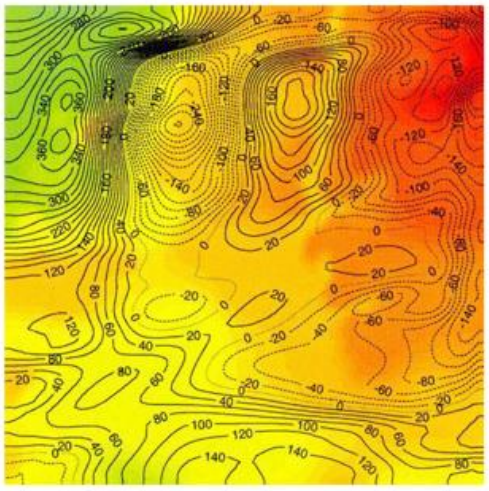
$$\frac{\psi_j^{(\tau+1)} - \psi_j^{(\tau-1)}}{2\Delta t} = RHS_j^{(\tau-1,\tau,\tau+1)} - \mu_j \left(\psi_j - \psi_j^B\right)^{(\tau+1)} . \tag{11}$$

In a more symbolized form the tendency is approximated by a centered time difference with $2\Delta t$. In $RHS_j^{(\tau-1,\tau,\tau+1)}$ all terms of each equation are absorbed, and the second term on the r. h. s. represents the lateral boundary relaxation term of interest. Towards the boundary the inner LLM solution is forced to become equal to the external solution represented by the boundary data ψ_j^B. The index j numbers the gridpoints of a grid row inwards and normal to the boundary point $j = 0$.



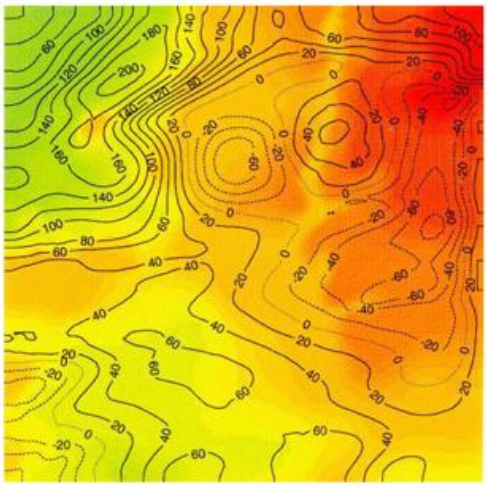
In line with the philosophy of that relaxation term, abbreviated by M_ψ^{LB} in the model equations, the relaxation coefficient μ_j is a prescribed function of distance of an inner gridpoint

j to the boundary point. At the boundary the coefficient becomes infinity and it approaches to zero in the inner region defining so the prescribed width of the lateral boundary relaxation zone. The time levels $\tau - 1$, τ, $\tau + 1$ in (11) indicate in a common way of notation the different time difference approximations (leap-frog centered, forward and implicit treatment of involved terms) in the prototype equation. As known from many descriptions of Kallberg's approach, the equation type (11) can be brought into an astonishing simple linear form



$$\psi_j \;=\; (1 - \alpha_j)\, \psi_j^{LLM} + \alpha_j \psi_j^B \;, \tag{12}$$

where the internal LLM data ψ_j^{LLM} – not influenced by the relaxation term M_ψ^{LB} – are linearly combined with the external driving boundary data ψ_j^B to produce per timestep the boundary data adjustment of the inner solution in terms of ψ_j. Far from being ideal the simple procedure is thought to avoid most of dangerous reflections and contaminations originating from overestimated and generally unfitted boundary data. The blending weights α_j are related to the relaxation coefficients μ_j by



$$\alpha_j \;=\; \frac{2\Delta t \mu_j}{1 + 2\Delta t \mu_j} \;. \tag{13}$$

a=0.5, max = 884mm/s, min = -675mm/s

a=0.25, max = 388mm/s, min = -302mm/s

a=0.125, max = 206 mm/s, min = -86 mm/s

Figure 2.2: Horizontal section of vertical velocity w at altitude z = 1500 m after an one-hour integration over a LLM subdomain of 81 × 81 gridpoints assuming a basic flow over the real orography with U = 10 m/s. The w-field is shown for three values of the Kallberg-parameter a. Top left: a = 0.5, top right: a = 0.25, bottom left: a = 0.125.

For the α_j-weights follows $0 \leq \alpha_j \leq 1$ with $\alpha_{j=0} = 1$. Formula (13) is, however, unpractical to be used. Since Kallberg (1977) it is common practice to apply an ad hoc formula

$$\alpha_j = 1 - \tanh(aj); \quad j = 0, 1, 2, ..., \tag{14}$$

which describes a damping curve like (13). The parameter a determines the essential decrease of that curve because of $(\partial\alpha/\partial j)_{j=0} = -a$. In many limited area models (e.g. EM, DM, LM) the value $a = 0.5$ has shown to be sufficient. To find out an appropriate steepness of the α_j-curve for the LLM with its significantly higher grid resolution, some numerical experimentation was carried out starting from the default value $a = 0.5$. The result is shown in Fig. 2.2. It suggests an α_j-curve with a sufficiently weaker slope. Thus, $a = 0.125$ is chosen further on instead of 0.25 or 0.5. Fig. 2.3 demonstrates the weight curves (14) for those three slope values.

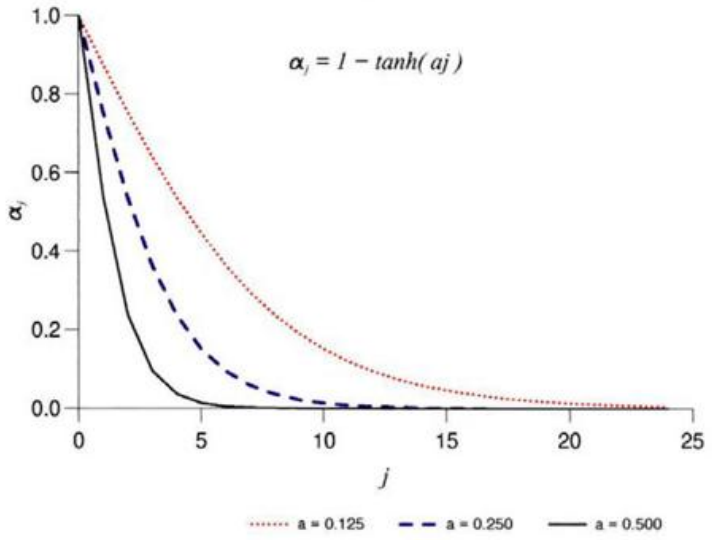


Figure 2.3: Boundary weight curve (Equation (14), see text) as a function of distance of an inner gridpoint j to the boundary point $j = 0$ for three different slope parameters a = 0.5, 0.25, 0.125.

In order to obtain more insight from the result shown in Fig. 2.2, it is illuminating to take into account also the first and second derivative of relation (12):

$$\frac{\partial\psi}{\partial x} = (1-\alpha)\frac{\partial\psi^{LLM}}{\partial x} + \alpha\frac{\partial\psi^{B}}{\partial x} - \frac{\partial\alpha}{\partial x}(\psi^{LLM} - \psi^{B}), \tag{15}$$

$$\frac{\partial^2\psi}{\partial x^2} = (1-\alpha)\frac{\partial^2\psi^{LLM}}{\partial x^2} + \alpha\frac{\partial^2\psi^{B}}{\partial x^2} - 2\frac{\partial\alpha}{\partial x}\left(\frac{\partial\psi^{LLM}}{\partial x} - \frac{\partial\psi^{B}}{\partial x}\right) - \frac{\partial^2\alpha}{\partial x^2}(\psi^{LLM} - \psi^{B}). \tag{16}$$

x is a continuous coordinate measured in grid distance units. While the blending formula (12) is actually applied per timestep for prognostic variables ψ $(= u, v, T, p)$, one obtains, in effect, due to (15) and (16), no similar blending of $\partial\psi/\partial x$ (which, for instance, is related to the horizontal wind divergence and vorticity) and $\partial^2\psi/\partial x^2$ (related to the horizontal gradient of vertical motion, respectively). It can be seen that the dissimilarity is fundamentally marked by the always existing difference between inner solution (ψ^{LLM}, $\partial\psi^{LLM}/\partial x$) and the external one ($\psi^{B}$, $\partial\psi^{B}/\partial x$). (15) and (16) tell us furthermore that the significant

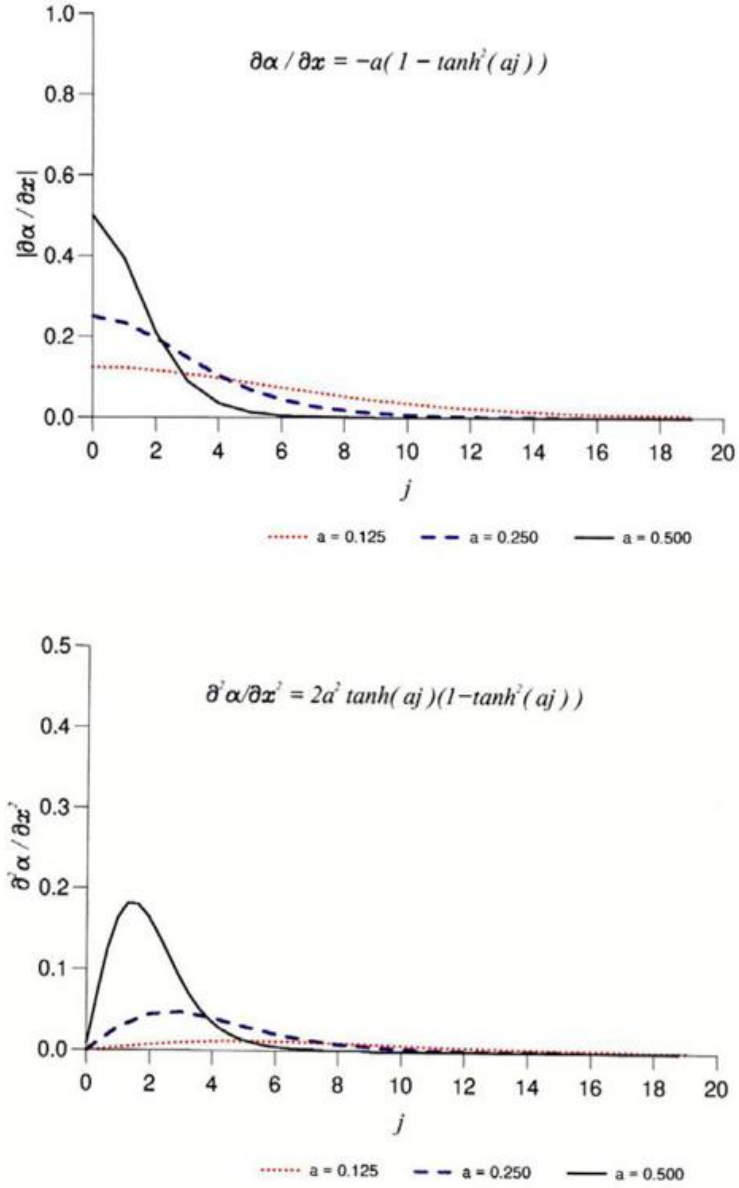

Figure 2.4: The first (top) and second (bottom) derivatives of the Kallberg boundary weight function α (x is measured in grid distance units) for $a = 0.5, 0.25, 0.125$.

difference is multiplied by $\partial\alpha/\partial x$ and $\partial^2\alpha/\partial x^2$. By an appropriate choice of the weights α we are, however, able to keep the unwanted effect due to those terms rather small. This depends obviously on the choice of the parameter a. Fig. 2.4 shows in addition to Fig. 2.3 the functions

$$\frac{\partial\alpha}{\partial x} = -a(1 - \tanh\{ax\}), \quad \frac{\partial^2\alpha}{\partial x^2} = 2a^2 \tanh\{ax\}(1 - \tanh^2\{ax\}) . \tag{17}$$

The conclusion from Fig. 2.3 together with Fig. 2.4 is that $a = 0.125$ is the best value to be used in case of the LLM. The strong gradient of w in a short distance from the boundary, as shown in Fig. 2.2 for $a = 0.5$, may be explained by use of the continuity equation summing up the gradient of the horizontal wind divergence from the earth surface to the height z.

In this way the vertically accumulated effect of the $\partial\alpha/\partial x$ and $\partial^2\alpha/\partial x^2$-terms in (16) is involved. It is not demonstrated here from the background experiment of Fig. 2.2 that the near-boundary gradient of vertical motion shown for $a = 0.5$ is actually not observed on the lowest model levels but will be formed and amplified with increasing height. All our experimentation with numerous real data cases so far have indicated that with $a = 0.125$ the unwanted gradients discussed do vanish.

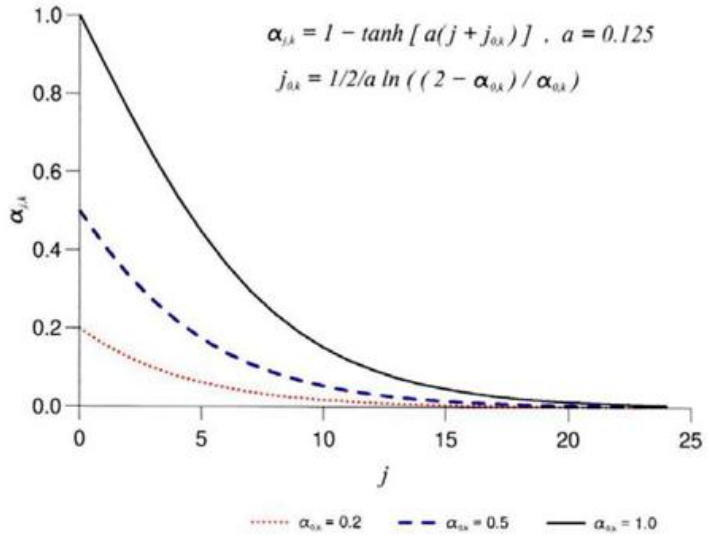

Figure 2.5: Plot of vertically varying weight function $\alpha_{j,k}$ showing how in the LLM the external boundary data influence is reduced downwards by using a phase parameter $\alpha_{0,k}$ in the intervall $0.2 \leq \alpha_{0.k} \leq 1$ (see text).

In order to complete the description of the LLM-specific lateral boundary technique another engineering component is added to the original Kallberg approach. The motivation follows from the decision to use the weight curve parameter $a = 0.125$. Though necessary, some nuisance might come from the relatively far inward reaching influence of boundary data information connected with a low-steepness curve. To alleviate possible problems from this, the following vertically varying weight functions differing from (14) are introduced:

$$\alpha_{j,k} = 1 - \tanh\left[a(j + j_{0,k})\right] , \tag{18}$$

with a phase parameter

$$j_{0,k} = \frac{1}{2a} \ln\left(\frac{2 - \alpha_{0,k}}{\alpha_{0,k}}\right) .$$

k is the vertical model level index, and a is always equal to 0.125 (Fig. 2.5). The new parameters $\alpha_{0,k}$ are user-prescribed values, which for the lowest LLM levels $14 \leq k \leq 39$ (cf. Tab.2.1) are linearly distributed in the range $0.2 \leq \alpha_{0,k} \leq 1$ by $\alpha_{0,k} = 1 - 0.8(k-14)/39-14)$. This empirical operation, entirely determined from experimentation, makes sure that the influence of the always not exactly adapted boundary data is in the planetary boundary layer towards the earth surface gradually diminished, where, however, the near-surface turbulent fluxes produced in the LLM are allowed to remain dominating. Instead of (12) a similar blending formula, now also depending on k, must be applied, which evaluates the above described weights (18) instead of (14),

$$\psi_{j,k} = (1 - \alpha_{j,k})\, \psi^{LLM}_{j,k} + \alpha_{j,k} \psi^{B}_{j,k} . \tag{19}$$

It follows from this philosophy that in any case of $\alpha_{0,k} < 1$ also internal LLM information is needed at the boundary points which from the numerical integration is not directly available. Therefore, a simple linear extrapolation as computational boundary condition is additionally applied.

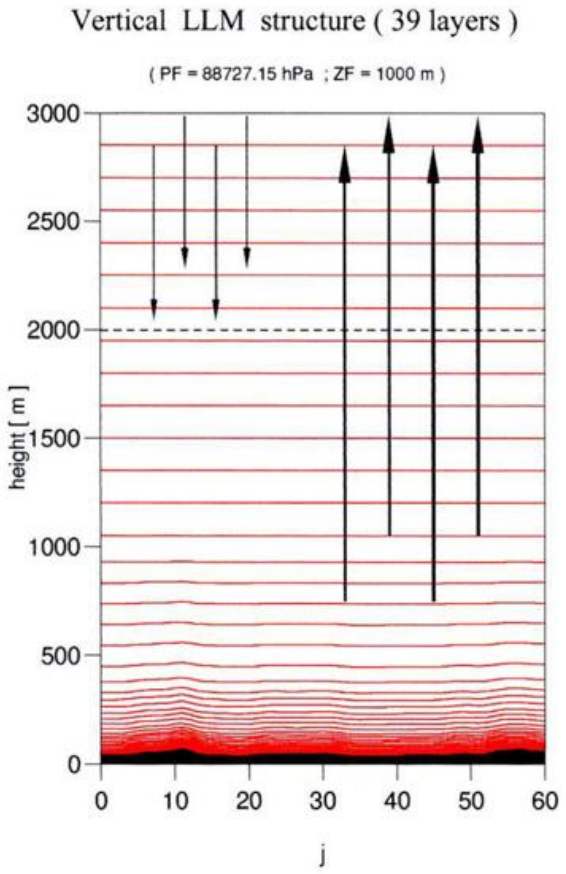

Figure 2.6: Position of the Rayleigh damping layer connected with vertical layering of the LLM.

In the following the *upper boundary technique* will be explained. It is directly adopted from the LM-scheme. The method is similar to the lateral boundary technique, which is a Rayleigh-damping mechanism. In the model equations (1) - (6) this is symbolized by the terms M_ψ^{UB}. Here, the vertical motion w is included. The original motivation for that sort of upper boundary relaxation is to allow an upper lid condition $w = 0$ at the top of the model, from which artificial gravity wave reflection can take place. The Rayleigh damping method prevents that by absorption of energy of those waves penetrating upward through an upper absorption zone before arriving the top elevation. In case of the LLM, the purpose of that method is, however, twofold. In addition, the technique is thought to be an adaptation method as at the lateral boundary in order to match the inner solution also in an upper boundary zone with an outer solution which serves as a driver from measured data in the free atmosphere (cf. Chapter 4). Similar to equation (11) the mechanism rests here on a prognostic equation like that

$$\frac{\psi_k^{(\tau+1)} - \psi_k^{(\tau-1)}}{2\Delta t} = \cdots - \nu_k^{rd} \left(\psi_k - \psi_k^B\right)^{(\tau+1)} . \tag{20}$$

In (20) only a relaxation term M_ψ^{UB} is of interest. The vertical model level index k emphasizes its operation in vertical direction. ν_k^{rd} is a relaxation coefficient corresponding to a reciprocal relaxation time. After Ikawa and Saito (1991) it is assumed to have the form

$$\nu_k^{rd} = \frac{1}{2N_{rd}\Delta t}\left[1 - \cos\left(\pi\frac{z_k - z_{rd}}{z_T - z_{rd}}\right)\right] . \tag{21}$$

The parameters in formula (21) are specified as follows: $\Delta t = 2$ s, $N_{rd} = 10$, $z_T = 3000$ m and $z_{rd} = 2000$ m. They define a Rayleigh damping layer being 1000 meters thick and resolved by the 7 uppermost layers, $k \in [1, 7]$ (Fig. 2.6). From the cosine-profile function follows an increasing absorption effect towards the model top. There, the damping effect reaches its maximum. The parameter $N_{rd} = 10$ means, that the perturbation $(\psi - \psi^B)$ will be reduced to its e^{-1}-th part at the top height $z_T = 3000$ m after 10 large LLM timesteps. For levels below 2000 meters the method is ineffective. The practical execution of the Rayleigh damping is similar to the lateral boundary technique, where a blending like (11) or (19) is applied. The associated weight function is here $\alpha_k = 2\Delta t\nu_k^{rd}/(1 + 2\Delta t\nu_k^{rd})$.

A radiative scheme instead of the presently applied method is still under development. The hydrostatic radiation condition after Klemp and Durran (1983) and Bougeault (1983) successfully introduced in the former DM/HRM (Herzog 1995, Binder and Herzog 1995), seems not directly suited in the non-hydrostatic and compressible world of LM/LLM.

2.4 Lower Boundary Condition and Forcings

For the sake of completeness, the lower boundary condition/treatment must be added here after having described the LLM-specific lateral and upper boundary technique in the previous Section. Because the lower bounding surface is the earth surface (without deeper thinking how it is defined from the point of view of modelling), it is assumed rigid. Frictional forces are important at that surface. Therefore, the classical adherence condition or non-slip condition holds there. Consequently, the horizontal wind components u and v vanish at the surface. Since the contravariant vertical motion $\dot{\zeta}$ in the LM/LLM-equations always vanishes then, it follows from equation (8) a vanishing physical vertical velocity, that is $w = 0$.

The boundary layer processes are of vital interest in LLM modelling. Thus, the turbulent fluxes of momentum, heat and moisture at the surface must be available as exact as possible. For their determination the surface temperature and moisture must be known. These parameters again are determined from an LLM-coupled prognostic soil model 'terra'. That model is also incorporated in the present operational LM version and was already operating in the former DWD-models EM and DM/HRM (Jacobsen and Heise 1982). Intensive work is underway to insert for the thermal part, still being an 'extended force-restore' method, a higher resolved heat conduction equation.

All the external parameters needed have been derived in case of the LLM problem from a detailed physiographic description of the landscape around Lindenberg. Furthermore, horizontally distributed, time-varying fields of precipitation and short-wave plus long-wave radiation balance at the earth surface determined from measurements constitute the physical forcing of LLM from the underlying surface. This aspect is of greatest importance for reasonable and successful LLM simulations. Therefore, the LLM forcing from the earth surface is the matter of thorough discussion in Chapter 5.

2.5 Model Physics Different to LM

In view of the fact that near-surface turbulent fluxes are very sensitive to forcing from the underlying surface, that process must be kept as close as possible to reality. This will be achieved by using real surface precipitation and radiation balance fields for that forcing as mentioned above in Section 2.4. The consequence is, however, to make an operation in both the cloud-precipitation scheme and the radiation parameterization scheme as they are originally available from the LM.

In contrast to well-defined LES studies taking into account cloud-radiation interaction and a precipitation scheme, the LLM real-case simulations cannot operate with that philosophy. Although forming of clouds and precipitation is in the LLM allowed, the precipitation flux reaching the earth is ignored and replaced by a real-data precipitation field. Furthermore, the radiation scheme available from the LM is even completely discarded. The radiative long- and short-wave balance field at the surface is exclusively deduced from measurements and supported by satellite information (cf. Chapter 5). The input-frequency of the radiation balance and of the surface precipitation field amounts to 10 minutes. In this way the ground surface and therefore the soil model 'terra' perceives radiation and precipitation as would be obtained from properly simulated atmospheric conditions like cloudiness and radiation in and over the LLM integration domain.

A weak point of this strategy might be the omission of any radiation scheme in the atmospheric part of the LLM. This is just taken into the bargain in order to avoid an erroneous radiative heating/cooling from insufficient simulations of all conditions influencing the radiation processes. To keep on the right way, it is tacitly assumed that the long-wave radiative effect on the temperature field is implied in the measured vertical profiles from which the LLM is driven from outside with an 1 hour-updating frequency. Summing up that, the reduction in the precipitation and radiation parameterization in case of LLM studies is believed to be compensated by sets of real forcing data where these processes are implicitly contained.

In the LLM also the soil model 'terra' (already commented in Section 2.4) is incorporated, which is directly taken from the LM system. For a detailed description we refer to the LM Scientific Documentation (Doms and Schättler 1999, Chapter 10). Its use in the LLM and minor adjustments are detailed in Chapter 5, where the forcing of LLM will be discussed thoroughly.

The most important sub-grid parameterization in the LLM is undoubtedly an adequate turbulence scheme. Because this physical component has been developed as a primary task of the LLM-development, it deserves to be documented in the present report in the following Chapter 3.

2.6 Specification of the Horizontal Integration Area

This Section deals with a technical issue concerning the exact size and placement of the horizontal grid net . Its fixation must be explained from a historical situation when the 'Deutschland-Modell' (DM) was in operational use. At the beginning of the LITFASS-project there was a common agreement to think of an integration area for the LLM having exactly the size of a DM-gridbox. The gridbox selected encloses the location of the Lindenberg Observatory and contains almost all measurement places in it (Beyrich 2000). The size of that gridbox (so called 'Lindenberg gridbox') is defined by a mesh width of the DM which is $(\Delta\lambda')_{DM} = (\Delta\varphi')_{DM} = 0.125^\circ$ defining an area of about 14×14 km^2. The primes refer

to a rotated latitude-longitude coordinate system (λ', φ') with its rotated north pole at a location $\lambda = 170.0^\circ W$, $\varphi = 32.5^\circ N$ given in geographical coordinates.The same rotated system is valid for the LM (cf. Doms et al. 1999, Chapter 4; Schättler and Doms 1998, p. 27), and so for the LLM. The DM-gridpoint is positioned exactly in the centre of the Lindenberg gridbox. It coincides with an LM-gridpoint and an LLM-gridpoint as well. In terms of a C-grid valid for DM, LM and LLM this gridpoint is a so called 'mass'-point, where almost all model variables and parameters but the horizontal wind components are placed. (We tacitly make the agreement that all gridpoints considered are the mass-points of a C-grid where the places of u and v are automatically related to.)

The coordinates of the central gridpoint are given by $\lambda' = 2.5^\circ$ and $\varphi' = -5.25^\circ$, corresponding to $\lambda = 14.0617^\circ W$ and $\varphi = 52.1752^\circ N$. For the transformation $(\lambda', \varphi') \leftrightarrow (\lambda, \varphi)$ we refer to Schrodin (1995). The size of the standard LLM integration area is shown in Fig. 2.7 a,b. It is a square having 145×145 gridpoints. Therefore, the LLM mesh width can be found from $(\Delta\varphi)_{DM}/144 = (\Delta\varphi)_{LLM} = (\Delta\varphi)_{LLM} \simeq 96.53$ m (assuming $a = 6371229$ m for the earth radius and 111.19892 km for a 1°-distance on a great circle). With a gridpoint indexing $i \in [1, 145]$ in west-east direction and $j \in [1, 145]$ in south-north direction, the central point is determined by $(i, j) = (73, 73)$. In the following the coordinates of the four corner points are noted.

LLM domain corners	λ' (°)	ϕ' (°)	λ ($^\circ E$)	ϕ ($^\circ N$)
lower left $(i = 1, j = 1)$	2.4375	- 5.3125	13.9544	52.1165
upper left $(i = 1, j = 145)$	2.4375	- 5.1875	13.9663	52.2413
lower right $(i = 145, j = 1)$	2.5625	- 5.3125	14.1567	52.1091
upper right $(i = 145, j = 145)$	2.5625	- 5.1875	14.1692	52.2339

Besides this standard area another option of integration area has been agreed with the people of the measurement branch, which is the so called 'extended Lindenberg' - area having all local measurement points enclosed and more possibilities of testing the LLM. Compared to the standard area it is extended about 2km to south and north and 4km to north and west. The total is about 20×20 km^2 covered by 199×199 gridpoints. It corresponds to the entire area shown in Fig. 2.7. In order to note at least the relative placement of that 'extended area', the corner points of the 'standard area' are to be noted in terms of the 'extended area' indices $i_{ext} \in [1, 199]$ and $j_{ext} \in [1, 199]$:

$$\begin{aligned} (1,1) &= (37,19)_{ext} \\ (1,145) &= (37,163)_{ext} \\ (145,1) &= (181,19)_{ext} \\ (145,145) &= (181,163)_{ext} \end{aligned}$$

Finally, the location of the corner points of the central LM-gridbox ($\simeq 7 \times 7$ km^2) is given in terms of the 'standard area' gridpoint indices $i \in [1, 145]$ and $j \in [1, 145]$: (37,37), (37,109), (109,37) and (109,109).

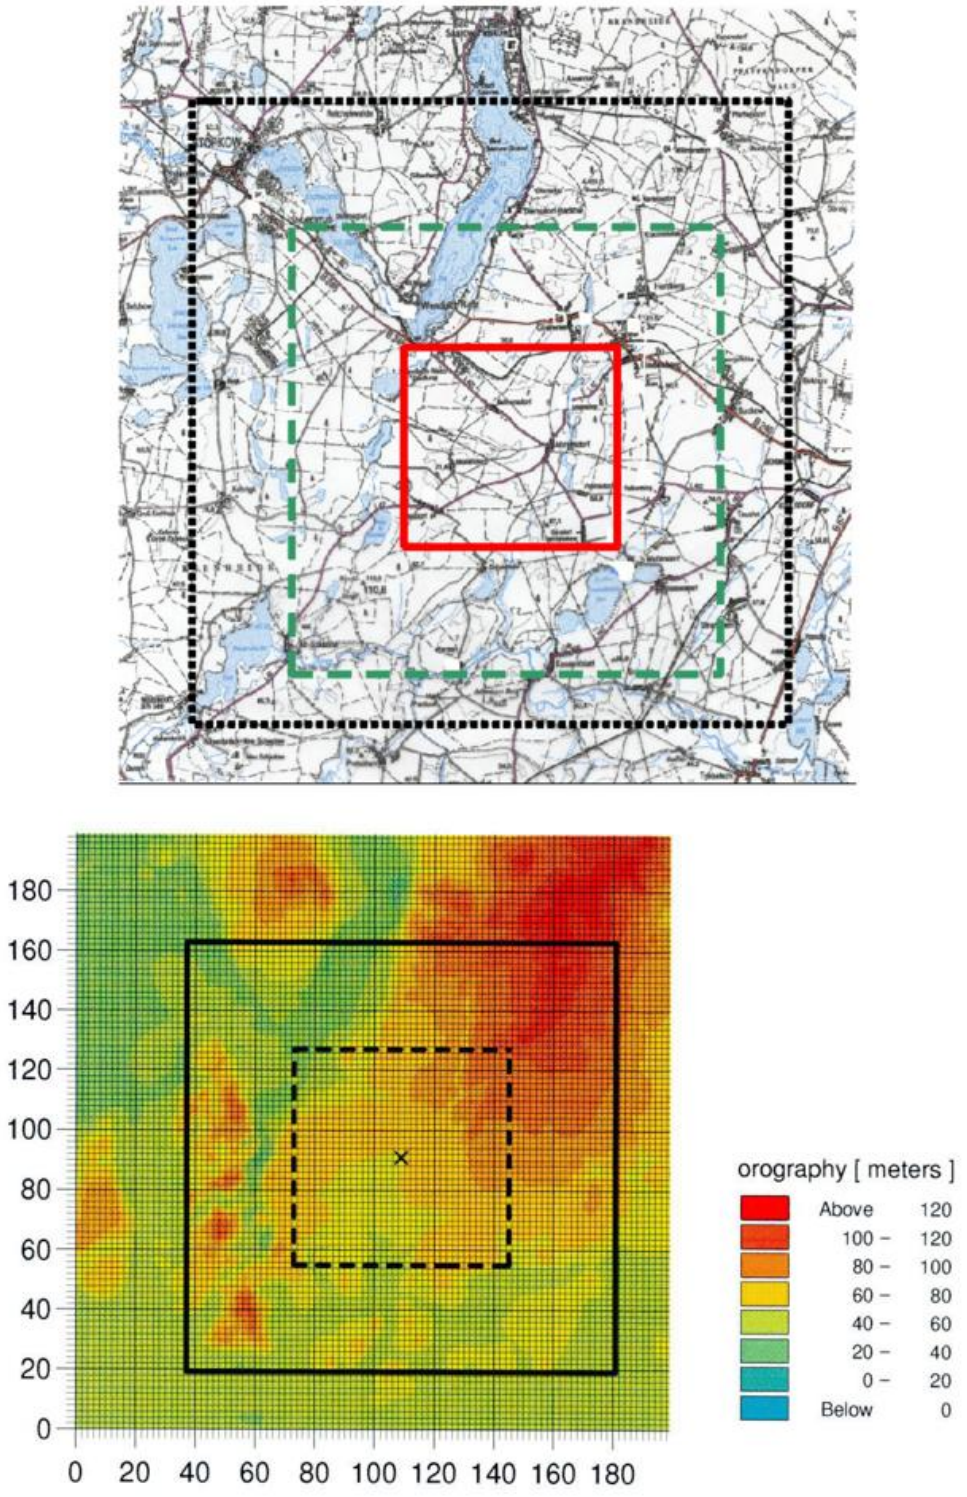

Figure 2.7: Position of the LLM integration area laid over a map of Lindenberg (top) and over a grid net with twice the mesh width and underlaying orography.

Top: Black broken line – boundary of the extended area ($\sim 20 \times 20$ km^2, 199×199 gridpoints). Green dashed line – boundary of standard area ($\sim 14 \times 14$ km^2, 145×145 gridpoints). Red full line – boundary of centered LM grid box ($\sim 7 \times 7$ km^2).

Bottom: Whole area corresponding to the extended area, with standard area (black line) and LM grid box (dashed line) in it. The cross point marks the central LM gridpoint.

3 Parameterization of Subgrid-Scale Turbulence

The parameterization of subgrid-scale (actually subfilter) turbulent processes, also called a subgrid-scale (SGS) model, is of particular meaning for the LES-like LLM. Because such an SGS model was not available from the LM system, we had to do an extra development. For this, a completely three-dimensional flux scheme was necessary to implement instead of only vertical turbulent flux terms as included in the given LM scheme. This part of work was with considerable effort an extension of the original LM code. In a further step, the SGS model itself, which must be written as function of the resolved scales (unaffected by a filter application), seems to be easier for the LLM compared to LM. Namely, in the latter the parameterization embraces more complex processes than in case of the LLM. The SGS model we decided to use is a prognostic turbulent kinetic energy (TKE) scheme taking into account the three space directions. This is documented in the following. In a first step, the SGS model is described, while in the following step the numerical incorporation is exactly demonstrated for the first time.

3.1 The SGS - TKE Model

We start from the LLM equation set (1)-(3), (5), (6) (see Section 2.1), which is rewritten here, emphasizing the turbulent flux terms:

$$\begin{aligned}
\frac{\partial u}{\partial t} &= \ldots - \frac{1}{\rho}\left(\nabla \cdot \underline{\underline{F}}\right) \cdot \underline{e}_1 \\
\frac{\partial v}{\partial t} &= \ldots - \frac{1}{\rho}\left(\nabla \cdot \underline{\underline{F}}\right) \cdot \underline{e}_2 \\
\frac{\partial w}{\partial t} &= \ldots - \frac{1}{\rho}\left(\nabla \cdot \underline{\underline{F}}\right) \cdot \underline{e}_3 \\
\frac{\partial T}{\partial t} &= \ldots - \frac{1}{\rho c_{pd}} \nabla \cdot \underline{H} \\
\frac{\partial q^k}{\partial t} &= \ldots - \frac{1}{\rho} \nabla \cdot \underline{F}_{q^k}
\end{aligned}$$

For the following the three-dimensionality of those terms is completely retained. $\underline{\underline{F}}$ denotes the turbulent momentum flux tensor with its 6 independent components τ_{ij} $(i, j = 1,2,3)$, and $\underline{H}$ and $\underline{F}_{q^k}$ are the vector fluxes of heat and water components. From these fragments of equations we change, as often usual, to the more convenient tensor notation:

$$\frac{\partial u_i}{\partial t} = \cdots - \frac{1}{\rho} \frac{\partial \tau_{ij}}{\partial x_j}\,, \tag{22}$$

$$\frac{\partial X^n}{\partial t} = \cdots - \frac{1}{\rho} \frac{\partial Y_j^n}{\partial x_j}\,, \tag{23}$$

where there is $(u_i) = (u, v, w)$, $(\tau_{ij}) = \underline{\underline{F}}$, $(X^1, X^2) = (T, q^k)$, $(Y_j^1) = \underline{H}$ and $(Y_j^1) = \underline{F}_{q^k}$ for $i = 1,\ 2,\ 3$ and $j = 1,\ 2,\ 3$. The fluxes are specified by use of a first-order closure assumption. It means that the fluxes are set proportional to the local gradient multiplied by a local turbulence coefficient:

$$\tau_{ij} = -\rho K_m \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i} \right)\,, \tag{24}$$

$$Y_j^1 = -c_p \pi \rho K_h \frac{\partial \Theta_v}{\partial x_j}, \qquad Y_j^2 = -\rho K_h \frac{\partial q^k}{\partial x_j}. \tag{25}$$

For this specification we refer, for instance, to Mason (1994), and Mason and Brown (1999). There, a distinction is drawn between a turbulence coefficient for momentum, K_m, and heat, K_h, respectively. Here, ρ is density, Θ_v denotes virtual potential temperature and π is the Exner function. The SGS-TKE model is determined by specifying the turbulence coefficients after Prandtl and Kolmogorov:

$$K_m = \phi_m \Lambda \sqrt{\overline{e}}, \qquad K_h = \phi_h \Lambda \sqrt{\overline{e}}. \tag{26}$$

Apart from having still undetermined factors ϕ_m, ϕ_h, that $K_{m,h}$-specification needs the knowledge of turbulent kinetic energy, $\overline{e}$, and some assumption, how to set the turbulence length scale Λ. In order to come to a closure of the system, we need a relation/equation, which allows the calculation of TKE from the resolved/filtered fluid regime. For that purpose we invoke the prognostic TKE-equation which may be written

$$\frac{\partial \overline{e}}{\partial t} + u_j \frac{\partial \overline{e}}{\partial x_j} = \delta_{i3} \frac{g}{\overline{\Theta}_v} (\overline{u_i' \Theta_v'}) - \overline{u_i' u_j'} \frac{\partial \overline{u_i}}{\partial x_j} - \frac{\partial (\overline{u_j' e})}{\partial x_j} - \frac{1}{\rho} \frac{\partial (\overline{u_i' p'})}{\partial x_i} - \varepsilon. \tag{27}$$

Here, the TKE is defined by

$$\overline{e} = \frac{1}{2} (\overline{u_i' u_i'}) \tag{28}$$

and $e = u_i' u_i'/2$. We quote Stull (1988, p. 152) for the derivation of that TKE-equation (27). The physical meaning of all terms, and so the definition of variables in it, can also be found in Stull's bible of turbulence quoted. It is important to note here that the derivation of (27) implies the Boussinesq-approximation, the hypothesis of Reynolds averaging and the assumption of incompressibility and shallow convection. This is not strictly in agreement with the more general LM/LLM-equations and, we may think that it does not need so. Here, we remind of experiences that errors in the parameterization of SGS processes in case of an LLM-like resolution do not influence the resolved scales in a significant manner. In view of determining K_m and K_h according to (26a,b), one needs in a further step suitable parameterizations in (27). Here, the 'flux-gradient' specification, like (24) and (25), is also used,

$$\overline{u_i' u_j'} = -K_m \left(\frac{\partial u_j}{\partial x_i} + \frac{\partial u_i}{\partial x_j} \right) \tag{29}$$

$$\overline{u_i' \Theta_v'} = -K_h \frac{\partial \Theta_v}{\partial x_i} \tag{30}$$

in order to make the buoyant production term and the shear production term applicable. The term describing the turbulent transport of TKE and the pressure correlation term are collected,

$$\frac{\partial (\overline{u_j' e})}{\partial x_j} + \frac{1}{\rho} \frac{\partial (\overline{u_j' p'})}{\partial x_j} \simeq \frac{\partial}{\partial x_j} \left(\overline{u_j' e + \frac{u_j' p'}{\rho}} \right), \tag{31}$$

in order to parameterize the resulting flux also in accordance with a gradient specification:

$$\overline{u_j' \left(e + \frac{p'}{\rho} \right)} = -2 K_m \frac{\partial \overline{e}}{\partial x_j}. \tag{32}$$

For the latter we refer to Stevens et al. (1999). Finally, as usual the dissipation term is set equal to

$$\varepsilon \;=\; c_\varepsilon \frac{(\overline{e})^{3/2}}{\Lambda}\,. \tag{33}$$

The length scale Λ will be defined later. The value of c_ε is assumed different in literature. Here, we adopt $c_\varepsilon = 0.93$ (Stevens et al. 1999). In that way the following TKE-equation is found to be useful for our purpose:

$$\frac{\partial \overline{e}}{\partial t} + u_j \frac{\partial \overline{e}}{\partial x_j} \;=\; -K_h N^2 + K_m S^2 + 2\frac{\partial}{\partial x_j}\left(K_m \frac{\partial \overline{e}}{\partial x_j}\right) - c_\varepsilon \frac{(\overline{e})^{3/2}}{\Lambda}\,. \tag{34}$$

(The tacit change of denotation for the resolved/filtered variables must be noted, that is $\overline{u}_j = u_j$, $\overline{\Theta}_v = \Theta_v$, etc.) There we have introduced the Brunt-Väisälä frequency squared

$$N^2 \;=\; \frac{g}{\Theta_v}\frac{\partial \Theta_v}{\partial z}\,, \tag{35}$$

and the definition

$$S^2 \;=\; 2S_{ij}S_{ij} \;=\; \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)\frac{\partial u_i}{\partial x_j} \;=\; \frac{1}{2}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)^2\,, \tag{36}$$

where S_{ij} is the strain tensor and S^2 the deformation squared.

By solving the TKE from the prognostic equation (34), we would be able to determine K_m, K_h according to (26a,b), provided the coefficients ϕ_m and ϕ_h are known. Therefore, we think about these factors how to determine them as some reasonable functions of stability and having then a stability-dependent Prandtl-number

$$Pr \;=\; \frac{K_m}{K_h} \;=\; \frac{\phi_m}{\phi_h}\,. \tag{37}$$

In order to come to a reasonable solution, we start as an interlude from another more simple SGS-model, that is the extension of the Smagorinsky (1963) model presented by Brown et al. (1994) (cf. also Mason and Brown 1999). We call it, in brief, a Smagorinsky-SGS-model. It is characterized by the following K_m-, K_h-specification:

$$K_m \;=\; \lambda^2 S F_m(Ri)\,, \quad K_h \;=\; \lambda^2 S F_h(Ri)\,. \tag{38}$$

The stability dependence is imposed through the functions F_m and F_h. These functions are based on observations which are loosely the 'Kansas data'. S is defined in (36), and λ is the length scale in the Smagorinsky model. That length scale may be rewritten

$$\lambda \;=\; c_s \Lambda \tag{39}$$

defining the constant c_s. We assume here $c_s = 0.25$. Λ is a length scale closely related to the grid spacing as a measure of the numerical resolution envisaged and may be identical with the length scale Λ in the Prandtl-Kolmogorov specification (26). Following Brown et al. (1994) the stability functions F_m and F_h are specified as separate functions for statically unstable conditions and statically stable conditions, and it is ensured that these functions match in value (not in gradient) at $Ri = 0$. Anticipating our three-dimensional TKE-model, the local Richardson number may be defined as

$$Ri \;=\; \frac{N^2}{S^2} \tag{40}$$

with reference to (35) and (36).

For the unstable case, $Ri < 0$, one assumes

$$F_m = (1 - 16Ri)^{1/2}\,, \quad F_h = (1 - 40Ri)^{1/2} Pr_N^{-1}\,, \tag{41}$$

while in case of stability, $0 \leq Ri \leq Ri_c$,

$$F_m = (1 - Ri/Ri_c)^4\,, \quad F_h = (1 - Ri/Ri_c)^4(1 - 1.2Ri) Pr_N^{-1} \tag{42}$$

is used. The critical value of Ri is taken $Ri_c = 0.25$. The value $Pr_N^{-1} = 0.7$ which is the Prandtl number in neutral condition is chosen consistent with the Kansas data and LES experiments. In order to specify the length scale Λ we deviate from Brown et al. (1994) and introduce

$$\Lambda = (\Delta x \Delta y \Delta z)^{1/3} f(a_1, a_2)\,. \tag{43}$$

The function $f(a_1, a_2)$ serves as a corrective factor in case of an anisotropic grid and has been proposed by Scotti et al. (1993, 1997). If $\Delta_1, \Delta_2, \Delta_3$ are the dimensions of a grid box, where we can always assume $\Delta_1 \leq \Delta_2 \leq \Delta_3$, the two aspect ratios of the given grid are defined as

$$a_1 = \frac{\Delta_1}{\Delta_3}\,, \quad a_2 = \frac{\Delta_2}{\Delta_3}\,. \tag{44}$$

For the present LLM grid configuration (cf. Section 2.2) the relevant aspect ratio $\Delta z/\Delta$ (with $\Delta x = \Delta y = \Delta$ and $(\Delta x \Delta y \Delta z)^{1/3} = \Delta^{2/3}\Delta z^{1/3}$) ranges from 1/25 to 3/2. Thus, we meet with a 'pancake-like' grid ($\Delta z/\Delta \leq 1$) and a 'pencil-like' grid ($\Delta z/\Delta > 1$). Scotti et al. (1993) have shown on the base of theoretical arguments for isotropic turbulence that there exists an estimate for the grid anisotropy function as follows

$$f(a_1, a_2) \simeq \cosh\left[\frac{4}{27}(\ln^2 a_1 - \ln a_1 \ln a_2 + \ln^2 a_2)\right]^{1/2}\,. \tag{45}$$

In case of $\Delta z/\Delta \leq 1$ ($\Delta_1 = \Delta z, \Delta_2 = \Delta_3 = \Delta$):

$$\begin{aligned} a_1 &= \Delta z/\Delta \leq 1 \quad a_2 = 1 \\ f(a_1, a_2) &= f(\Delta z/\Delta) = \cosh(0.3849 \ln[\Delta z/\Delta])\,. \end{aligned} \tag{46}$$

In case of $\Delta z/\Delta > 1$ ($\Delta_1 = \Delta_2 = \Delta, \Delta_3 = \Delta z$):

$$\begin{aligned} a_1 &= \Delta/\Delta z = a_2 \\ f(a_1, a_2) &= f(\Delta/\Delta z) = \cosh(0.3849 \ln[\Delta/\Delta z])\,. \end{aligned} \tag{47}$$

In case of grid isotropy we have $f = 1$, of course. By now, our Smagorinsky SGS model is sufficiently described. In passing, it was the first SGS model we had incorporated in the LLM scheme. Here it serves as a special case of the general TKE model, in order to deduce the specifications of ϕ_m and ϕ_h in (26) from that. In this line, we recall the Smagorinsky model to be the equilibrium limit of the prognostic TKE equation (34). It can actually be shown the equivalence of the K_m-, K_h-specifications (38) and (26), provided that the equilibrium TKE equation

$$K_m S^2 - K_h N^2 - c_\varepsilon \frac{(\overline{e})^{3/2}}{\Lambda} = 0 \tag{48}$$

is valid. From that special case the equality

$$K_m = \phi_m \Lambda \sqrt{\overline{e}} = c_s^2 \Lambda^2 S F_m(Ri)\,, \quad K_h = \phi_h \Lambda \sqrt{\overline{e}} = c_s^2 \Lambda^2 S F_h(Ri)\,, \tag{49}$$

is used to find the TKE

$$\overline{e} = \phi_m c_\varepsilon^{-1} \Lambda^2 S^2 \left(1 - Pr^{-1} Ri\right)\,, \tag{50}$$

which is, therefore associated to the Smagorinsky model. The Prandtl-number is

$$Pr = \frac{\phi_m}{\phi_h} = \frac{F_m}{F_h}\,. \tag{51}$$

With $-\infty \leq Ri \leq Ri_c = 0.25$ and $Pr = Pr_N = 0.7$ for $Ri = 0$ it follows the stability dependence of Pr in a range

$$0.4427 \leq Pr \leq 1 \tag{52}$$

in accordance with the Kansas data-fitted stability functions F_m and F_h. By inserting (50) in (49), an expression for ϕ_m is then easily found:

$$\phi_m = c_s^{4/3} c_\varepsilon^{1/3} F_m^{2/3}(Ri) \left(1 - Pr^{-1} Ri\right)^{-1/3}\,. \tag{53}$$

That result is now used to be valid in specifying ϕ_m in (26) for the general problem to solve the prognostic TKE equation (34). ϕ_h follows by use of (51) from the known functions F_m and F_h. The grid scale length is found to be

$$\Lambda = \Delta^{2/3} \Delta z^{1/3} \begin{cases} \cosh[0.3849 \ln(\Delta z/\Delta)]\,, & \Delta z/\Delta \leq 1\,, \\ \cosh[0.3849 \ln(\Delta/\Delta z)]\,, & \Delta/\Delta z < 1\,. \end{cases} \tag{54}$$

3.2 Numerical Treatment

We focus our attention first on the incorporation of the three-dimensional 'divergence of turbulent flux'-terms in the given numerical LM-scheme. For this reason, we write down the discretized form of those terms as parts of the momentum, heat and moisture transport equations. For the momentum equations we have

$$\left(\frac{\partial u}{\partial t}\right)^{(n)} = \cdots - \frac{1}{\overline{\rho^{(n)}}^{\lambda} a \cos\varphi} \left(\delta_\lambda \tau_{11} + \cos\varphi \delta_\varphi \tau_{12}\right)^{(n,n-1)} + \frac{g}{\overline{\sqrt{\gamma}}^{\lambda}} \overline{\left(\frac{\rho_0}{\rho^{(n)}}\right)}^{\lambda} \left(\delta_\zeta \tau_{13}\right)^{(n-1,n,n+1)} \tag{55}$$

$$\left(\frac{\partial v}{\partial t}\right)^{(n)} = \cdots - \frac{1}{\overline{\rho^{(n)}}^{\varphi} a \cos\varphi} \left(\delta_\lambda \tau_{12} + \cos\varphi \delta_\varphi \tau_{22}\right)^{(n,n-1)} + \frac{g}{\overline{\sqrt{\gamma}}^{\varphi}} \overline{\left(\frac{\rho_0}{\rho^{(n)}}\right)}^{\varphi} \left(\delta_\zeta \tau_{23}\right)^{(n-1,n,n+1)} \tag{56}$$

$$\left(\frac{\partial w}{\partial t}\right)^{(n)} = \cdots - \frac{1}{\overline{\rho^{(n)}}^{\zeta} a \cos\varphi} \left(\delta_\lambda \tau_{13} + \cos\varphi \delta_\varphi \tau_{23}\right)^{(n,n-1)} + \frac{g}{\overline{\sqrt{\gamma}}^{\zeta}} \overline{\left(\frac{\rho_0}{\rho^{(n)}}\right)}^{\zeta} \left(\delta_\zeta \tau_{33}\right)^{(n-1,n,n+1)} \tag{57}$$

Here, the slow tendencies are approximated as

$$\left(\frac{\partial\psi}{\partial t}\right)^{(n)} = \frac{\psi^{(n+1)} - \psi^{(n-1)}}{2\Delta t}\,, \quad \psi = (u, v, w, T, q^k)\,. \tag{58}$$

Δt is the 'large' timestep. For the 6 turbulent stress components we assume

$$\tau_{11} = -\frac{\left(\rho\overline{K}_m^{\varphi}\right)^{(n)}}{a\cos\varphi} 2\delta_\lambda u^{(n-1)} \tag{59}$$

$$\tau_{12} = -\frac{\left(\overline{\rho K}_m^{\lambda,\varphi}\right)^{(n)}}{a\cos\varphi}\left(\delta_\lambda v^{(n-1)} + \cos\varphi\delta_\varphi u\right)^{(n-1)} \tag{60}$$

$$\tau_{13} = -\frac{\left(\overline{\rho K}_m^{\lambda}\right)^{(n)}}{a\cos\varphi}\delta_\lambda w^{(n-1)} + g\overline{\left(\overline{\left[\frac{\rho_0\rho^{(n)}}{\sqrt{\gamma}}\right]}^{\zeta} K_m^{(n)}\right)}^{\lambda}\left(\beta_d^+\delta_\zeta u^{(n+1)} + \beta_d^-\delta_\zeta u^{(n-1)}\right) \tag{61}$$

$$\tau_{23} = -\frac{\left(\rho\overline{K}_m^{\varphi}\right)^{(n)}}{a}\delta_\varphi w^{(n-1)} + g\overline{\left(\overline{\left[\frac{\rho_0\rho^{(n)}}{\sqrt{\gamma}}\right]}^{\zeta} K_m^{(n)}\right)}^{\varphi}\left(\beta_d^+\delta_\zeta v^{(n+1)} + \beta_d^-\delta_\zeta v^{(n-1)}\right) \tag{62}$$

$$\tau_{22} = -\frac{\left(\rho\overline{K}_m^{\zeta}\right)^{(n)}}{a} 2\delta_\varphi v^{(n-1)} \tag{63}$$

$$\tau_{33} = g\overline{\left(\overline{\left[\frac{\rho_0\rho^{(n)}}{\sqrt{\gamma}}\right]}^{\zeta} K_m^{(n)}\right)}^{\zeta} 2\left(\overline{\beta_d^+}^{\zeta}\delta_\zeta w^{(n+1)} + \overline{\beta_d^-}^{\zeta}\delta_\zeta w^{(n-1)}\right) \tag{64}$$

We have strictly adopted here and in the following formulae all the rules and definitions of differencing and averaging operators applied in the LM numerics as documented in the work of Doms and Schättler (1999). In a similar way the turbulent fluxes of sensible heat and moisture are considered in the following approximations.

$$\left(\frac{\partial T}{\partial t}\right)^{(n)} = \cdots - \frac{1}{\rho^{(n)} a\cos\varphi}\left(\delta_\lambda h_1 + \cos\varphi\delta_\varphi h_2\right)^{(n,n-1)} + \frac{g}{\sqrt{\gamma}}\left(\frac{\rho_0}{\rho^{(n)}}\right)\left(\delta_\zeta h_3\right)^{(n-1,n,n+1)} \tag{65}$$

$$h_1 = -\frac{\left(\overline{\pi\rho K}_h^{\lambda}\right)^{(n)}}{a\cos\varphi}\delta_\lambda\left(T/\pi\right)^{(n-1)} \tag{66}$$

$$h_2 = -\frac{\left(\overline{\pi\rho K}_h^{\varphi}\right)^{(n)}}{a}\delta_\varphi\left(T/\pi\right)^{(n-1)} \tag{67}$$

$$h_3 = g\left(\overline{\left[\frac{\pi\rho_0\rho^{(n)}}{\sqrt{\gamma}}\right]}^{\zeta} K_h^{(n)}\right)\left(\beta_d^+\delta_\zeta(T/\pi)^{(n+1)} + \beta_d^-\delta_\zeta(T/\pi)^{(n-1)}\right) \tag{68}$$

$$\left(\frac{\partial q^k}{\partial t}\right)^{(n)} = \cdots - \frac{1}{\rho^{(n)} a\cos\varphi}\left(\delta_\lambda F_1^k + \cos\varphi\delta_\varphi F_2^k\right)^{(n,n-1)} + \frac{g}{\sqrt{\gamma}}\left(\frac{\rho_0}{\rho^{(n)}}\right)\left(\delta_\zeta F_3^k\right)^{(n-1,n,n+1)} \tag{69}$$

$$F_1^k = -\frac{\left(\overline{\rho K}_h^{\lambda}\right)^{(n)}}{a\cos\varphi}\delta_\lambda(q^k)^{(n-1)} \tag{70}$$

$$F_2^k = -\frac{\left(\overline{\rho K}_h^{\varphi}\right)^{(n)}}{a}\delta_\varphi(q^k)^{(n-1)} \tag{71}$$

$$F_3^k = g\left(\overline{\left[\frac{\rho_0\rho^{(n)}}{\sqrt{\gamma}}\right]}^{\zeta} K_h^{(n)}\right)\left(\beta_d^+\delta_\zeta(q^k)^{(n+1)} + \beta_d^-\delta_\zeta(q^k)^{(n-1)}\right) \tag{72}$$

In these terms of interest, metrical simplifications are implied, that is, metrical terms both related to spherical coordinates and the generalized, terrain-following vertical coordinate are dropped. As can be seen, all horizontal turbulent diffusion terms are treated by forward-in-time differences, and so those terms of vertical momentum fluxes arising from the consideration of horizontal inhomogeneities. The rest of vertical diffusion terms is treated partially implicit by a Crank-Nicholson scheme. This leads together with the vertical advection terms to a tridiagonal vertical structure equation to be solved by a Gaussian elimination procedure as provided from the LM code. In case of the LLM the given method has also been applied due to the τ_{33}-term in the w-equation (57).

On this level the numerical treatment considered is independent of any specified SGS model. With the preparations shown the numerics of the SGS-TKE model must now be put forward. Therefore, we start from the TKE equation (34), which is here rewritten in spherical coordinates neglecting metrical terms and by use of the LM-specific vertical coordinate. We have instead of (34)

$$\begin{aligned}\frac{\partial\overline{e}}{\partial t} = & -\frac{1}{a\cos\varphi}\left(u\frac{\partial\overline{e}}{\partial\lambda} + v\cos\varphi\frac{\partial\overline{e}}{\partial\varphi}\right) - \dot{\zeta}\frac{\partial\overline{e}}{\partial\zeta} - K_h N^2 + K_m S^2 - c_\varepsilon\frac{(\overline{e})^{3/2}}{\Lambda} \\ & + \frac{1}{a\cos\varphi}\frac{\partial}{\partial\lambda}\left(2K_m\frac{\partial\overline{e}}{a\cos\varphi\partial\lambda}\right) + \frac{1}{a}\frac{\partial}{\partial\varphi}\left(2K_m\frac{\partial\overline{e}}{a\partial\varphi}\right) \\ & + \frac{g\rho_0}{\sqrt{\gamma}}\frac{\partial}{\partial\zeta}\left(\frac{g\rho_0}{\sqrt{\gamma}}2K_m\frac{\partial\overline{e}}{\partial\zeta}\right),\end{aligned} \tag{73}$$

where

$$N^2 = \frac{g}{\Theta_v}\frac{\partial\Theta_v}{\partial z}, \tag{74}$$

and

$$\begin{aligned}S^2 = & 2\left[\left(\frac{\partial u}{a\cos\varphi\partial\lambda}\right)^2 + \left(\frac{\partial v}{a\partial\varphi}\right)^2 + \left(\frac{g\rho_0}{\sqrt{\gamma}}\frac{\partial w}{\partial\zeta}\right)^2\right] \\ & + \left(\frac{\partial u}{a\partial\varphi} + \frac{\partial v}{a\cos\varphi\partial\lambda}\right)^2 + \left(\frac{\partial w}{a\cos\varphi\partial\lambda} - \frac{g\rho_0}{\sqrt{\gamma}}\frac{\partial u}{\partial\zeta}\right)^2 \\ & + \left(\frac{\partial w}{a\partial\varphi} - \frac{g\rho_0}{\sqrt{\gamma}}\frac{\partial v}{\partial\zeta}\right)^2.\end{aligned} \tag{75}$$

Next, the differencing in space and time must be carried out. This has to be made also by strict adaptation to the LM numerics. In detail, the C-grid in the horizontal and the Lorenz-grid in the vertical is mandatory to be used inclusively the appropriate differencing and averaging. Concerning the time difference scheme a 'mixed' scheme is applied: horizontal advection is approximated by a leap-frog scheme, for vertical advection plus vertical diffusion

a partially implicit Crank-Nicholson scheme is applied, and horizontal diffusion as well as source/sink-terms like shear production, buoyant production/consumption, dissipation are treated by a time-forward scheme. In effect, by use of a Gaussian elimination algorithm a tridiagonal form for solving the slow-mode regime of the LLM will be found. The resulting $\overline{e}^{(n+1)}$ is then available to specify K_m and K_h. Here we skip the rather lengthy derivation of that tridiagonal form from the discretized TKE-equation. It may suffice to write down the relevant result. In order to support the following notation of differencing, averaging and the definition of the placement of variables on different gridpoints we refer to Figure 3.1 and Figure 3.2.

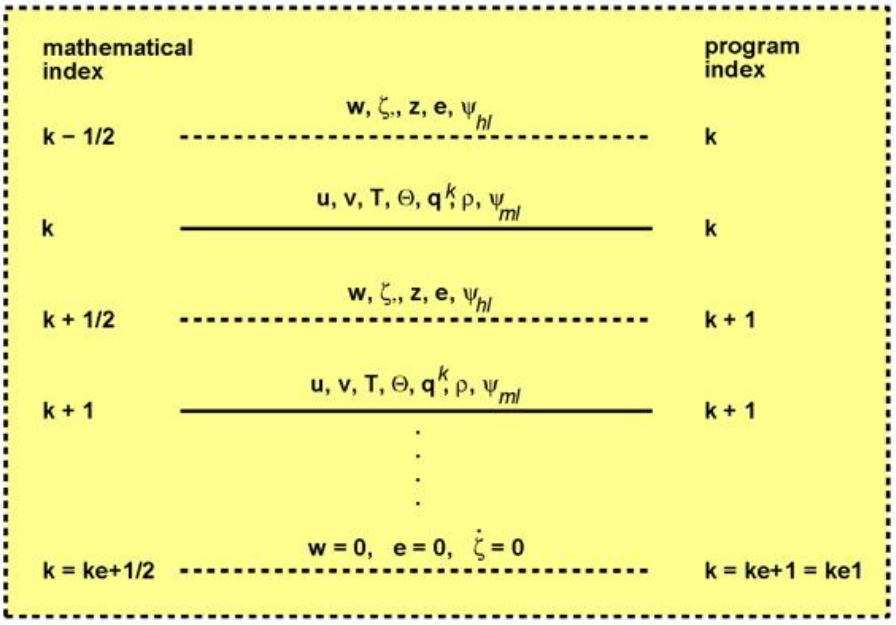

Figure 3.1: Vertical grid scheme (Lorenz-grid) with placement of variables at half-levels (dashed lines) and main levels (black lines). Further half-level variables (ψ_{hl}) and main-level variables (ψ_{ml}) are:
$\psi_{hl} = (\tau_{13}, \tau_{23}, h_3, F_3, K_m, K_h, S, N^2, Ri, \beta_v^{+,-}, \beta_d^{+,-})$,
$\psi_{ml} = (\tau_{11}, \tau_{12}, \tau_{22}, \tau_{33}, h_1, h_2, F_1, F_2, \sqrt{\gamma}, p_0, \rho_0)$.

The tridiagonal structural equation for determining $\overline{e}^{(n+1)}$, which is TKE at vertical half-level k (in accordance with program code indexing) and time level $n+1$, may be written

$$\begin{aligned} B_2\overline{e}_2^{(n+1)} + C_2\overline{e}_3^{(n+1)} &= D_2^{(n,n-1)} \\ A_k\overline{e}_{k-1}^{(n+1)} + B_k\overline{e}_k^{(n+1)} + C_k\overline{e}_{k+1}^{(n+1)} &= D_k^{(n,n-1)} \quad (k \in [3, ke-1]) \\ A_{ke}\overline{e}_{ke-1}^{(n+1)} + B_{ke}\overline{e}_{ke}^{(n+1)} &= D_{ke}^{(n,n-1)} \end{aligned} \tag{76}$$

The functions $D_k^{(n,n-1)}$ for $k \in [2, ke]$ in (76) are known. They contain only variables at the present and previous time level. The same is valid for the coefficients A_k, B_k, C_k. By use of the Gaussian elimination procedure the $\overline{e}_k^{(n+1)}$ follow by assuming the boundary condition $\overline{e}_1 = \overline{e}_{ke1} = 0$. For the coefficients A_k, B_k, C_k and D_k we find:

$$
\begin{aligned}
A_k &= \beta_v^+ A_k^v + \overline{\beta_d^+}^{\,\zeta} A_k^d \\
A_k^v &= -\frac{(\sqrt{\gamma})_k \overline{(W^c)}^{\zeta}_{k-1}}{\overline{(\sqrt{\gamma})}^{\zeta}_k \left((\sqrt{\gamma})_k + (\sqrt{\gamma})_{k-1}\right)}, \quad A_k^d = -\frac{2g^2 \overline{(\rho_o)}^{\zeta}_k}{\overline{(\sqrt{\gamma})}^{\zeta}_k} \overline{\left(\frac{\overline{(\rho_o)}^{\zeta}}{\overline{(\sqrt{\gamma})}^{\zeta}} K_m^{(n)} \right)}^{\zeta}_{k-1} \\
B_k &= \frac{1}{2\Delta t} - A_k - C_k \\
C_k &= \beta_v^+ C_k^v + \overline{\beta_d^+}^{\,\zeta} C_k^d \qquad (77) \\
C_k^v &= \frac{(\sqrt{\gamma})_{k-1} \overline{(W^c)}^{\zeta}_k}{\overline{(\sqrt{\gamma})}^{\zeta}_k \left((\sqrt{\gamma})_k + (\sqrt{\gamma})_{k-1}\right)}, \quad C_k^d = -\frac{2g^2 \overline{(\rho_o)}^{\zeta}_k}{\overline{(\sqrt{\gamma})}^{\zeta}_k} \overline{\left(\frac{\overline{(\rho_o)}^{\zeta}}{\overline{(\sqrt{\gamma})}^{\zeta}} K_m^{(n)} \right)}^{\zeta}_{k} \\
D_k &= \frac{1}{2\Delta t} \overline{e}_k^{(n-1)} + \Sigma_k^{(n,n-1)} + (\beta_v^- A_k^v + \overline{\beta_d^-}^{\,\zeta} A_k^d)(\overline{e}_k^{(n-1)} - \overline{e}_{k-1}^{(n-1)}) \\
&\quad - (\beta_v^- C_k^v + \overline{\beta_d^-}^{\,\zeta} C_k^d)(\overline{e}_{k+1}^{(n-1)} - \overline{e}_k^{(n-1)})
\end{aligned}
$$

with the further definition

$$
W_k^c = \overline{(\sqrt{\gamma})}^{\zeta}_k \dot{\zeta}_k \,. \qquad (78)
$$

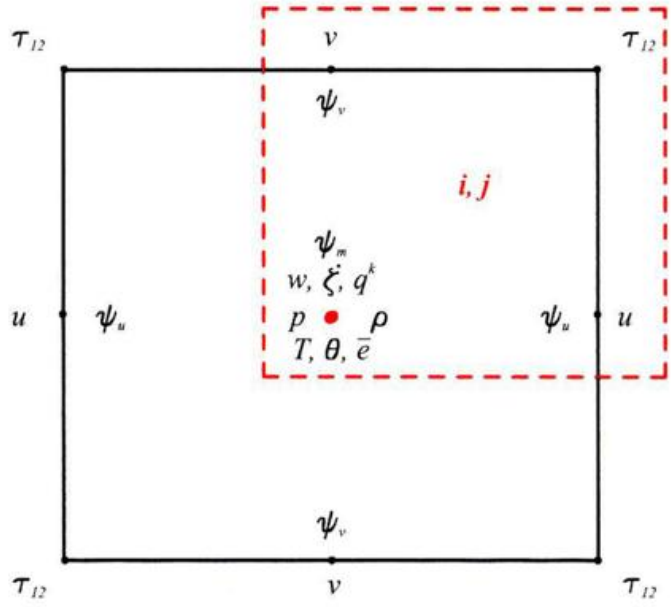

Figure 3.2: Position of variables in the horizontal grid (C-grid). Dashed-line square embraces a cluster of variables having the same horizontal program index pair i, j. Further variables at mass point (ψ_m), u-point (ψ_u) and v-point (ψ_v) are:
$\psi_m = (\tau_{11}, \tau_{22}, \tau_{33}, h_3, F_3, K_m, K_h, S, N^2, Ri, \sqrt{\gamma}, p_0, \rho_0)$,
$\psi_u = (\tau_{13}, h_1, F_1)$, $\psi_v = (\tau_{23}, h_2, F_2)$.

The auxiliary variable $\Sigma_k^{(n,n-1)}$, emerging in the expression for D_k, implies horizontal advection and turbulent horizontal diffusion of TKE as well as source/sink-terms as follows:

$$\begin{aligned}
\Sigma_k^{(n,n-1)} &= -\frac{1}{\overline{\sqrt{\gamma}}^{\zeta} a\cos\varphi}\left[\left(\overline{\overline{\sqrt{\gamma}}^{\zeta} u}^{\zeta}\,\delta_\lambda \overline{e}\right)^{\lambda} + \left(\overline{\overline{\sqrt{\gamma}}^{\zeta} v}^{\zeta}\cos\varphi\,\delta_\varphi \overline{e}\right)^{\varphi}\right] \\
&\quad + \frac{1}{a\cos\varphi}\delta_\lambda\left(2(\overline{K_m}^{\lambda})^{(n)}\frac{\delta_\lambda(\overline{e})^{(n-1)}}{a\cos\varphi}\right) + \frac{1}{a}\delta_\varphi\left(2(\overline{K_m}^{\varphi})^{(n)}\frac{\delta_\varphi(\overline{e})^{(n-1)}}{a}\right) \\
&\quad - K_h^{(n)}(N^2)^{(n-1)} + K_m^{(n)}(S^2)^{(n-1)} - c_\varepsilon\frac{((\overline{e})^{3/2})^{(n-1)}}{\Lambda}\,.
\end{aligned} \tag{79}$$

To complete the description of the tridiagonal form, we need finally the difference approximation of S^2 and Ri. For the deformation squared we have

$$\begin{aligned}
S^2 &= 2\left[\left(\frac{\overline{\delta_\lambda u}^{\zeta}}{a\cos\varphi}\right)^2 + \left(\frac{\overline{\delta_\varphi v}^{\zeta}}{a}\right)^2 + \left(\frac{g\overline{\rho_0}^{\zeta}}{\overline{\sqrt{\gamma}}^{\zeta}}\delta_{2\zeta} w\right)^2\right] \\
&\quad + \left(\frac{\delta_\varphi \overline{\overline{u}^{\lambda,\varphi}}^{\zeta}}{a} + \frac{\partial\overline{\overline{v}^{\lambda,\varphi}}^{\zeta}}{a\cos\varphi}\right)^2 + \left(\frac{\delta_\lambda \overline{w}^{\lambda}}{a\cos\varphi} - \frac{g\overline{\rho_0}^{\zeta}}{\overline{\sqrt{\gamma}}^{\zeta}}\delta_\zeta \overline{u}^{\lambda}\right)^2 \\
&\quad + \left(\frac{\delta_\varphi \overline{w}^{\varphi}}{a} - \frac{g\overline{\rho_0}^{\zeta}}{\overline{\sqrt{\gamma}}^{\zeta}}\delta_\varphi \overline{v}^{\varphi}\right)^2
\end{aligned} \tag{80}$$

and the local Richardson number is written

$$Ri = 2g\frac{(\Theta_{v,k} - \Theta_{v,k-1})\left(\sqrt{\gamma}_{k-1} + \sqrt{\gamma}_k\right)}{(z_{k+1} - z_{k-1})\left(\sqrt{\gamma}_{k-1}\Theta_{v,k} + \sqrt{\gamma}_k\Theta_{v,k-1}\right) S^2} \tag{81}$$

provided $S^2 > S^2_{min} > 0$. The equilibrium case (50) is used to determine an initial value of $\overline{e}_k$. A final remark is made concerning the incorporation of the turbulent surface fluxes. They are determined just as in the LM (cf. Doms and Schättler 1999, Chapter 6). A stability and roughness-length dependent formulation is used, which is based on modified Businger relations. As known, the approach makes use of a drag-law relation

$$F^{\psi}_{sfc} = -\rho\, C^d_{\psi}\,|\vec{v}_h|\,(\psi - \psi_{sfc}) \tag{82}$$

specified for $\psi = (u, v, T, q^k)$. The surface flux F^{ψ}_{sfc} follows then according to (82), provided the drag coefficient is given by a parameterization

$$C^d_{\psi} = \frac{\chi^2}{[\ln(h/z_0)]^2}\, f_\psi(Ri_B, h/z_0) \tag{83}$$

dependent on the bulk Richardson number

$$Ri_B = g\frac{(\Theta - \Theta_{sfc})\,(h - z_0)}{\Theta_{sfc}(u^2 + v^2)} \tag{84}$$

as a measure of stability. With given surface values ψ_{sfc}, Θ_{sfc}, provided from the soil model 'terra', the surface flux will be determined using atmospheric values ψ, Θ and $|\vec{v}_h|$ at the

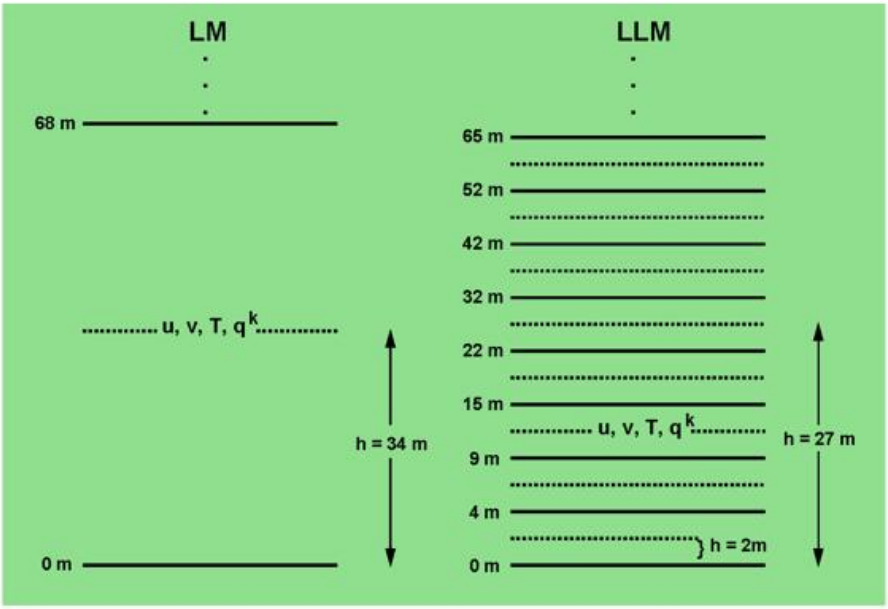

Figure 3.3: Different vertical resolution of the Prandtl-layer in LM (left) and in LLM (right). Further explanation see text.

model altitude h within the Prandtl-layer. In case of the LM this altitude is assumed to be placed at the lowest main-level being $h = 34$ m (Fig 3.3, left). By direct use of that LM-algorithm in case of the LLM the height h would also be positioned at the lowest model main-level, which is only about 2 meters above ground. In order to avoid a value of h too near to the roughness-length z_0, it has been set sufficiently higher than z_0 (Fig 3.3, right). Consequently, some more involved manipulations in the given LM-numerics not mentioned in detail were necessary to be done for that kind of LLM adaptation.

4 External Forcing at the Lateral and Upper Boundary

Since the LLM is thought to be a 'real-world' - LES model with its declared bridge-function in the scope of an observation-simulation conception, it must externally be driven somehow by real-world time-dependent states of the boundary layer atmosphere and the underlying surface. The initial state must also be a realistic one to start the LLM simulation from. While the physical forcing from the underlying surface will be treated in the following Chapter 5, we are dealing here with the atmospheric part of forcing the LLM.

4.1 Method

Before we describe some technical details, how lateral and upper boundary data, and initial data as well, are organized by use of time sequences of measured vertical profiles available, some general remarks about the strategy of an external LLM-driving are necessary. In contrast to 'pure' LES studies the LLM simulations have been planned to cover a wide range of real meteorological weather situations. This needs a more general approach not limited to special cases. This statement does not deny the general virtue of large eddy simulations which by fortunate circumstances can investigate general problems from simplified modelling, e.g. by ignoring the lateral limitation of the integration area. In our case a limited area integration mode must be accepted, and the technique to handle that problem had to be borrowed from the field of NWP. The method of interest has been described in Section 2.3. As explained there, the boundary technique is chosen in such a way that it anticipates the specific problem of application. From the point of view of information content of measured data we meet with a very underestimated problem for providing the LLM with initial and boundary data. In Fig. 4.1 the following argumentation is to be supported. In that manner we are forced to assume only one measured vertical profile for each relevant LLM variable like horizontal wind, temperature and moisture.

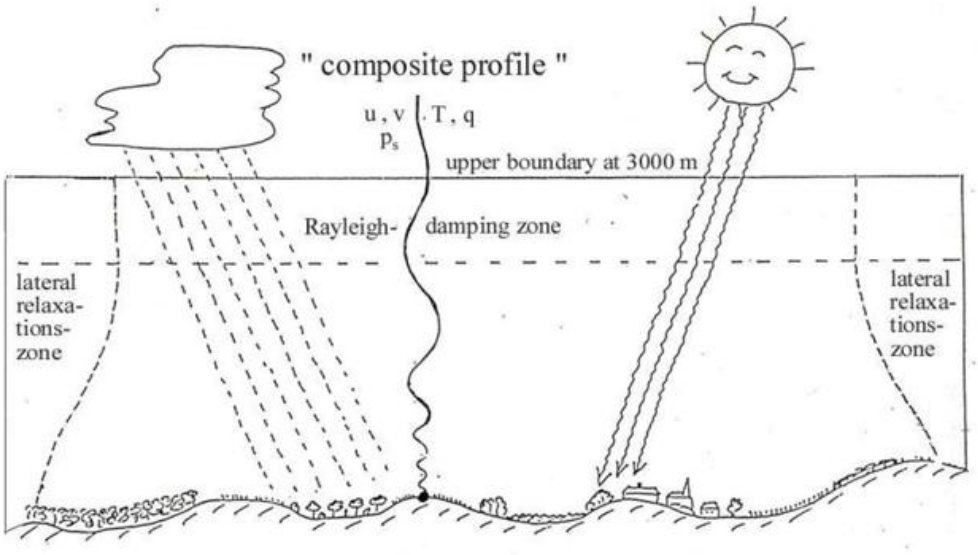

Figure 4.1: A sketch showing how the LLM is externally driven by taking into account a detailed physiographic description of the underlying surface plus surface measurements of precipitation and radiation and by use of a driving composite profile which operates through a vertical and lateral transmission zone.

We call it a 'composite profile' (CP), because it is deduced from vertical profiles of different sounding systems available at and around the MOL (Görsdorf et al. 2000), and it may be available at a time frequency of say, one hour. This CP is assumed to be associated to a distinct location laying in the interior of the LLM integration area. Further, the CP gives the only base of temporally and vertically distributed information for constructing the three-dimensional initial and boundary data due to a quasi-horizontal distribution of that given vertical profiles. How this is carried out will be shown in the next section.

Here some arguments to support this approach will be given. By horizontally distributing the CP we make use of the 'hypothesis of fast local adaptation', provided that the physical forcing from the underlying surface works well (cf. Sections 2.4, 2.5, Chapter 5 and Fig. 4.1). Therefore, the near-surface information of a CP is unsuitable at other places than the original location which is assumed to be assimilated by the LLM very fast and in case of boundary data in a rather short distance from the boundary. The mechanism of dominating near-surface turbulent fluxes, essentially coined by carefully treated lower boundary properties, makes thus the CP-data model-friendly and brings them automatically into a 'ready-to-eat' form. From the point of view of the lateral boundary technique this kind of near-surface adaptation is deliberately supported by reduced boundary weights. Towards higher levels of the LLM the CP information approaches to larger scales and even to scales governing the free atmosphere up to 3 kilometers. Because the essential integration mode of the LLM is given by a non-stationary boundary data forcing, the time-dependent boundary data rely on time series of CPs with an up-dating frequency of 1 hour with a linear time interpolation onto every 2-second timestep.

It is important to note that by use of that CP sequence the LLM perceives relevant large-scale information in an implicit way. That is, changes of the temperature profile imply realistic effects of large scale warm/cold air advection, changes of stability indicating large-

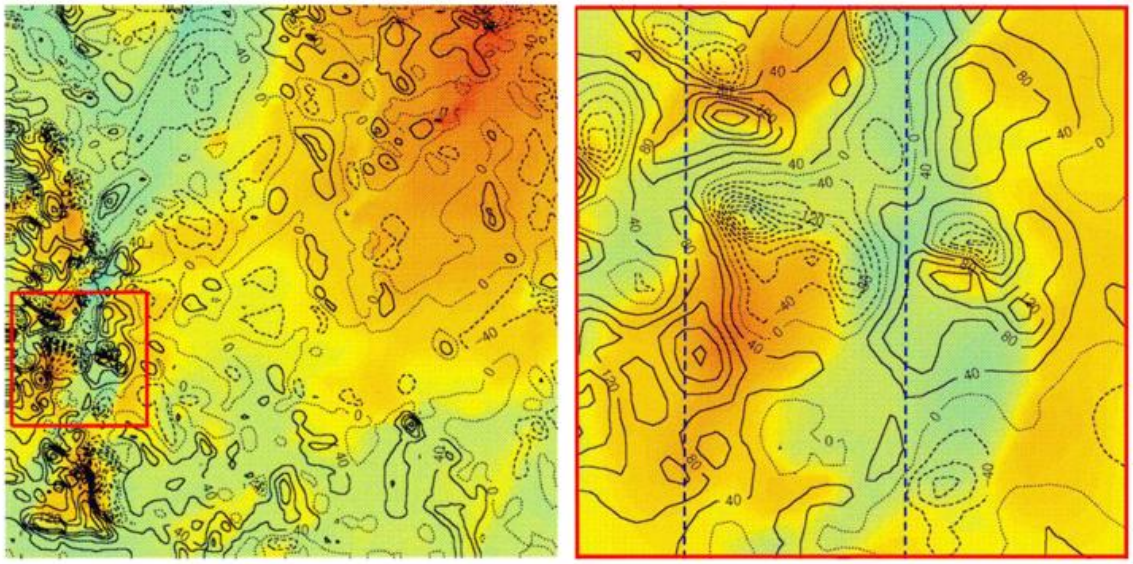

Figure 4.2a: Results from a 24-h integration after 12 hours, on 14 June 1997 at noon, for vertical motion w. Left: in a horizontal section over the whole 145 × 145 gridpoint area at a model level about 100 m above ground. Right: enlargement for the red-marked 3.5 × 3.5 km^2 sub-area, where the vertical velocity varies in an interval -310 mm/s $\leq w \leq$ 277 mm/s. Cross sections along the two dashed lines are shown in Fig. 4.2b.

scale divergence and so subsidence, and also effects of radiative warming/cooling. From each profile an estimate of the geostrophic wind and so the large-scale pressure gradient is derived for determining the pressure field of the initial and boundary data.

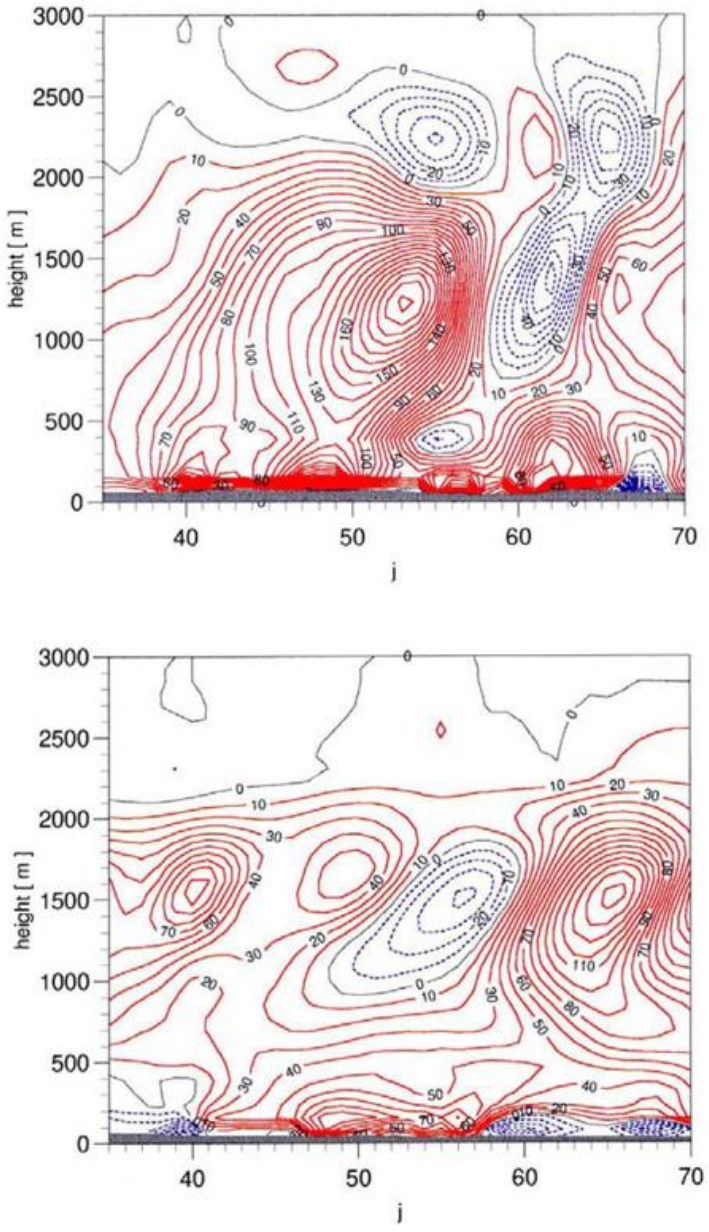

Figure 4.2b: South-north vertical cross sections of vertical velocity (isolines in mm/s, negative values dashed) along the two dashed lines in Fig 4.a. Top: Cross section referring to the left dashed line in Fig. 4.2a. Bottom: Cross section referring to the right dashed line in Fig.4.2a.

Concerning the ability of local adaptation even in the very proximity of the lateral boundary, an example is shown in Figs. 4.2a and 4.2b, where the fine-scale structures are obviously established against the external influence of the boundary data derived from CP's. The example of a 24-hour simulation has been carried out on 14 June 1997. The vertical motion is shown in a horizontal section covering the whole area of 145 × 145 gridpoints, after a 12-

hour integration time, at noon (Fig. 4.2a, left). By zooming over an indicated 3.5×3.5 km^2 sub-area (Fig. 4.2a, right) and by further inspection from two selected south-north-vertical cross sections coherent w-structures related to local orographic structures are observed (Fig. 4.2b). With that case a rather involved synoptic situation has been chosen by chance. The basic current at noon was directed from WSW.

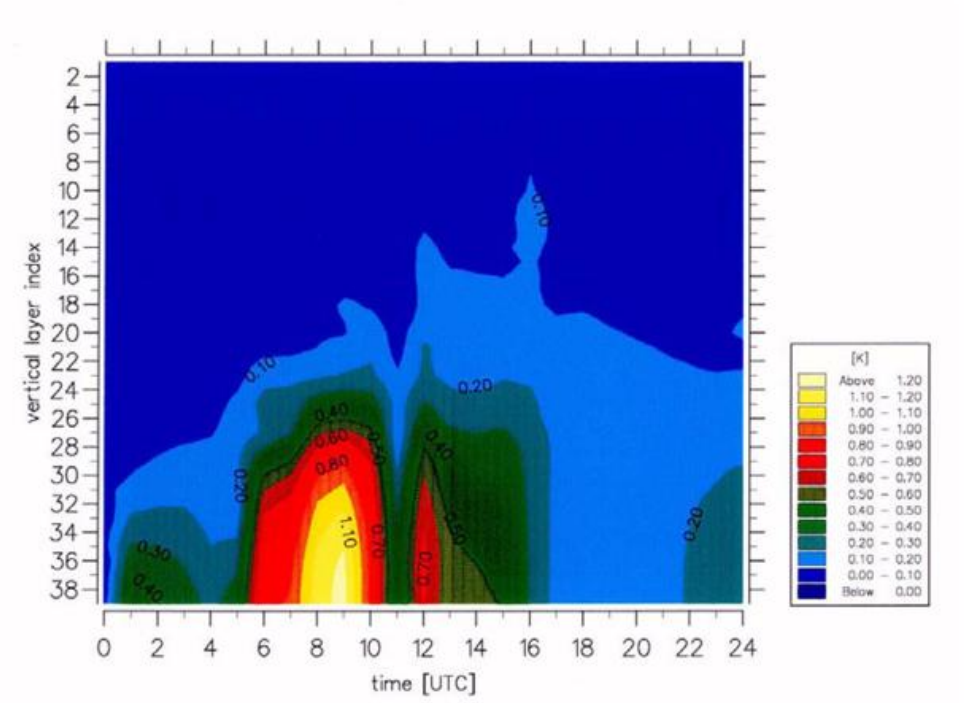

Figure 4.3: The standard deviation of temperature as a function of height and time for the LITFASS day 1 June 1998.

For another 'non-textbook case' (1 June 1998, arbitrarily selected from the LITFASS '98 period) the standard deviation of temperature deduced from the standard LLM integration domain with its variation in time and along the vertical is shown in Fig. 4.3. It demonstrates here in a more qualitative manner the local forcing by the inhomogeneities of the underlying surface: Though the standard deviation is not too large for such a case in June, it shows a rather changable variation over the day with convective intervals in the morning and significant rainfall in the late afternoon and evening.

4.2 Technical Approach

Assuming given vertical profiles of horizontal wind, temperature and moisture as a Composite Profile (CP) constructed from different measurement systems at MOL (Görsdorf et al. 2000, Beyrich 2000) and from the Falkenberg measurement site ('Gemeinsames Messfeld' = GM), the specific task is to determine the initial field and the boundary data fields from that information by use of a reasonable extrapolation approach with the above mentioned philosophy behind. As a matter of fact, those profiles are from technical reasons hourly available, which defines the updating frequency of boundary data for the LLM. By an agreement the CP provides u^M, v^M, T^M and the specific humidity q^M at all LLM-main levels along a vertical gridpoint column (the superscript M denotes a measured value). The surface pressure p_s^M is also assumed to be known.

The location of this vertical profile is given at the horizontal gridpoint i=118, j=67 with respect to the LLM standard grid net (cf. Section 2.6). As a first step, the variables u^M, v^M, T^M are horizontally distributed on (terrain-following) model levels. Due to a lack of more information this procedure has to be tolerated having in mind that the orography in the LLM area is formed by a gently undulating earth surface with surface heights in between about 40 and 120 meters above sea level. Above 1000 meters the model levels are genuinely horizontal (cf. Section 2.2). In mountainous regions this method seems insufficient. Here, the surface pressure field p_s is calculated on the base of p_s^M using T_{ke}^v and the given orographic height values z_s:

$$p_s = p_s^M \exp\left[-\frac{g(z_s - z_s^M)}{RT_{ke}^v}\right] . \tag{86}$$

T_{ke}^v is the virtual temperature at the lowest main level ($ke = 39$). In a further step the large-scale pressure gradient is determined from averaging the five uppermost wind values of the CP which are assumed to be representative for the free atmosphere. From this gradient assuming barotropy a pressure correction is added to the ps-field. In the following step the perturbation pressure field $p'_{ke} = p - p_0(z)$ is calculated for each vertical gridpoint column using p_s and a first guess value of virtual temperature T_{ke}^v. For the present we obtain

$$p'_{ke} = p_s \exp\left[-\frac{g(z_{ke} - z_s)}{RT_{ke}^v}\right] - p_{0,ke} . \tag{87}$$

Next, the p'_{ke} for $k < ke$ can be determined upwards by a recurrent formula following from the hydrostatic equation, which is here the LM-consistent differencing analogue of a balance equation with the first three terms on the r.h.s. of equation (3) (these are vertical pressure gradient -, buoyant- and water loading term). A more detailed description of that hydrostatic approach with an iterative improvement of T^v is given in Doms and Schättler (1999).

Normally, the given CP information consists of a synthesis of measured data from radiosonde, wind profiler, RASS, microwave profiler and 100m-mast. In a program module src_obsdata.f90 that CP estimate is used to construct both the initial field and the hourly boundary data fields as described above. As an important generalization the latest completion in this program module is the possibility to use a pseudo-CP having data exclusively from an LM-profile over the central gridpoint (i,j) = (73,73). In parallel to genuine CP-driven runs some selected 24h-runs with LM-profile forcing from the LITFASS '98 episode have been successfully carried out (cf. Chapter 6). The option of an LM-profile forcing is seen to be a necessary step for integrating the LLM off from Lindenberg over a transportable area imbedded in the LM integration domain. Moreover, that kind of forcing is of interest for a broader LM validation by use of the LLM as the declared validation tool.

In view of the following Chapter 5, where the physical forcing from the surface is dealt with, we add some further functions of the mentioned module src_obsdata.f90 providing the LLM with inhomogeneous fields of soil parameters. These are: land/water fraction per gridbox and soil typ as time-fixed values; all other parameters are in principle temporally variabel due to the annual vegetation cycle: orographic plus displacement height, roughness length, root depth, leaf-area index, degree of plant covering. Finally, two-dimensional fields of the water content of the upper (0-10cm) and medium (10-100cm) soil layer of the soil model 'terra', following from a homogeneous distribution of measured values or a longer series of precursory LLM runs with the desired effect of an inhomogeneous soil moisture spin-up, are read for starting the actual run. All these values have to be distributed among all computing processors.

5 Physical Forcing at the Lower Boundary

As already outlined, the most important forcing of the LLM is caused from the underlying surface with its natural inhomogeneities. In contrast to the lateral and upper boundary, the lower one is a physical interface, where the exchange of energy and water between atmosphere and soil takes place. These processes are characterized by the presence of turbulent near-surface fluxes of momentum, heat and moisture. In a complex way these fluxes depend strongly on physical conditions as e.g. local soil properties, soil moisture, radiation received at the surface, specific land use and realistic orography. In order to have a local forcing from below as exact as possible in the sense of 'real-world' - simulations with the LLM, the careful treatment of the mentioned physical properties is found to be a main task of the LLM development.

In that way, the detailed physiographic description of the underlying surface consists in deriving external parameters which are the key parameters of the coupled soil model to describe the dominating processes of soil, surface and vegetation with them. These parameters will be described in Section 5.1. To determine the relevant energetic processes at the bounding surface, it is important to know the short- and long-wave radiation balance there as well as the precipitation flux reaching the earth surface. These fields are derived from all the surface radiation and precipitation measurements available over the Lindenberg area. This is shown in detail in the following Sections 5.2 and 5.3. Since realistic LLM simulations are strongly dependent on a proper soil moisture distribution in connection with the given soil model, but soil moisture measurements are extremely sparse, an empirical adaptation method by using the LLM system itself is carried out and described in Section 5.4.

5.1 External Parameters

The kind and number of external parameters depend on the soil model in the LLM. Apart from minor changes, the soil model, which is the program module 'terra', is identically taken from the LM. In order to determine the appropriate external parameters over the high-resolving LLM grid, a comprehensive physiographic data set has been made available. It consists of orography data, of actualized airborne land use information (Zimmermann 1994a, b) and of soil property data (Hierold et al., 1997). All these data were provided in a vectorized form and had been transformed to LLM gridpoint data by Rosenow (1998).

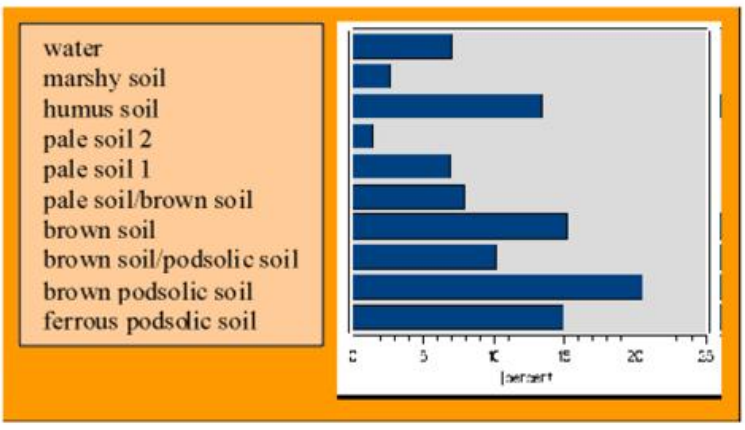

Figure 5.1: Soil type cover in percent of the total LLM area.

In the following a short description is given how the external parameters of interest are deduced from these data. According to a given soil map having 27 different soil types in the LLM simulation area, these types had to be reduced and fitted to only 9 types distinguished in the soil model. Fig 5.1 shows a histogram with the coverage of relevant soil types in percent of the total area of 199 × 199 gridpoints (see Section 2.6). The most frequent soils are brown-podsolic soil (20.5%), brown soil (15.2%) and ferrous podsolic soil (14.9%), while the coverage of water amounts to 7%.

In Fig. 5.2 the areal distribution of soil types is shown indicating the predominance of brown soils in the eastern part, whereas ferrous podsolic soils are found in the west. At some locations in the southern part and also in the proximity of lakes marshy soils sometimes prevail.

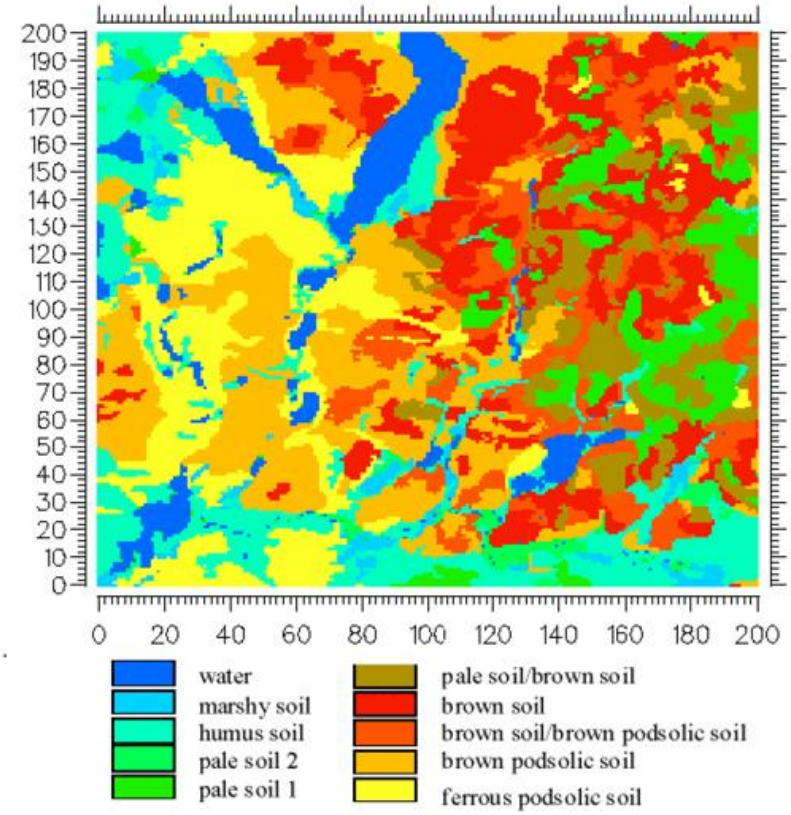

Figure 5.2: Distribution of soil types over the LLM area.

In the following Fig 5.3 topographic information is compiled showing e.g. the placement of important settlements, roads and lakes, and indicating specific locations associated to horizontal gridpoint indices. To add still more information, Tab. 5.1 provides a list of local soil parameters as valid in 'terra'. These parameters are additionally put in relation to processes like water storage, vertical water transfer within the soil, transpiration of plants and radiation near the surface. In order to demonstrate the horizontal heterogeneity of soil parameters, in Figs. 5.4 and 5.5 are shown the patterns of field capacity (a measure of maximal ability to store water in a soil layer) and soil heat capacity, respectively. Comparing both fields, it can be seen that podsolic soils in the west are able to store somewhat more of water and have a larger thermal inertia than brown soils in the eastern part. In contrast, marshy soils indicate a relatively high field capacity, but a relatively low soil heat capacity.

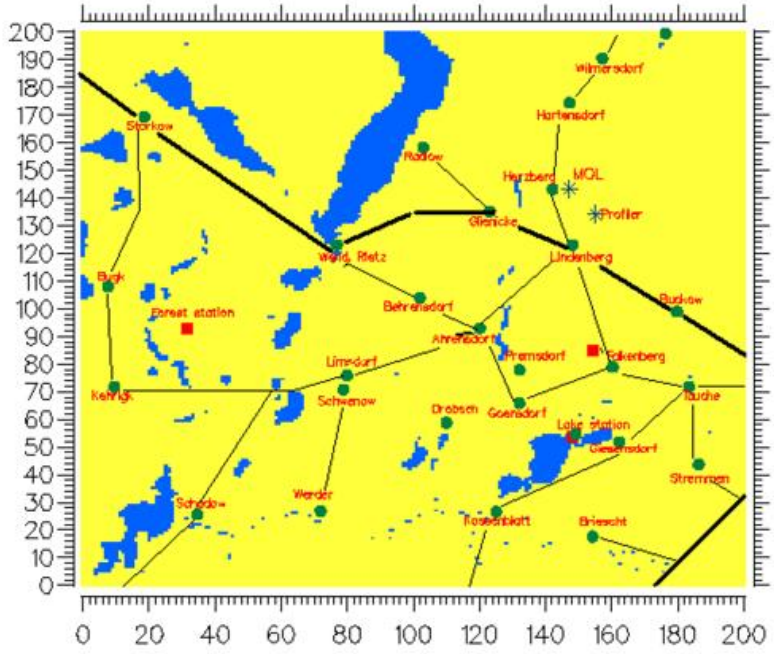

Figure 5.3: Map of local topographic information.

soil parameter	interval	dimension	main impact on
field capacity	0.11 - 0.75	fraction of volume	maximal soil water storage
pore volume	0.36 - 0.90	fraction of volume	infiltration and soil water storage
minimal infiltration rate	0.0002 - 0.0032	kg/(s*m²)	water influx into soil and surface runoff
plant wilting point	0.05 - 0.26	fraction of volume	transpiration
air dryness point	0.012 - 0.098	fraction of volume	transpiration
parameter to determine the hydraulical diffusivity *cdw0* *)	106 - 18400	10^{-9}m²/s	vertical soil water transfer
hydraulical conductivity *ckw0* *)	58 - 47900	10^{-9}m²/s	vertical soil water transfer
soil heat capacity *crhoc* *)	0.58+6 - 1.35+6	J/(K*m³)	thermal inertia of soil
albedo	0.10 - 0.35	fraction of 1	solar energy balance at surface
emissivity	0.90 - 0.98	fraction of 1	emission of IR-radiation from the ground

*) detailed description cf. LM-documentation (Doms and Schättler, 1999)

Table 5.1: Local soil parameters used in LLM.

Another sort of external parameters concerning the simulation of effects related to the coupled surface-vegetation system must be derived from the given land use data. The original data set comprises 35 biotopes resolving details smaller than the LLM grid mesh distance of about 100m. In view of the limited vegetation parameterization model the number of biotopes had to be reduced to 13 main types with water included. The resulting parameters distinguish between vegetation with constant height and a monthly varying leaf area index (e.g. forest, grass- and greenland as well as fen) and those having even daily variations (agricultural plants).

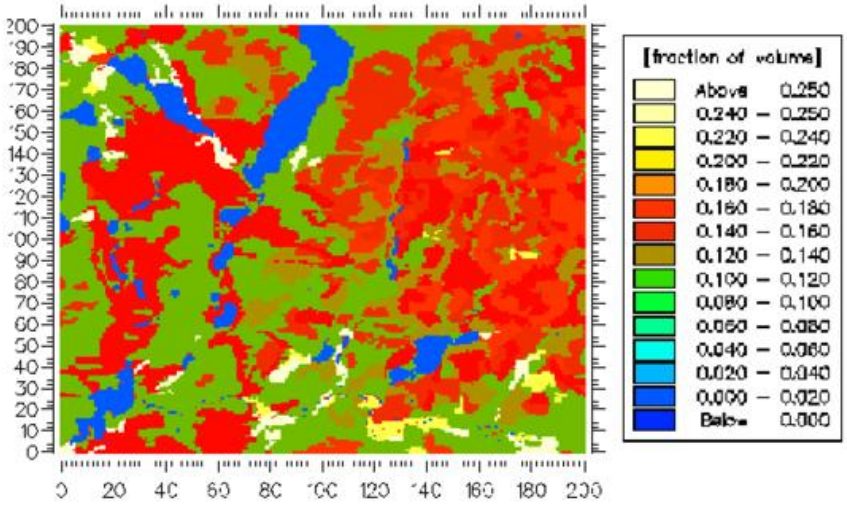

Figure 5.4: Field capacity distribution of the relevant soil types.

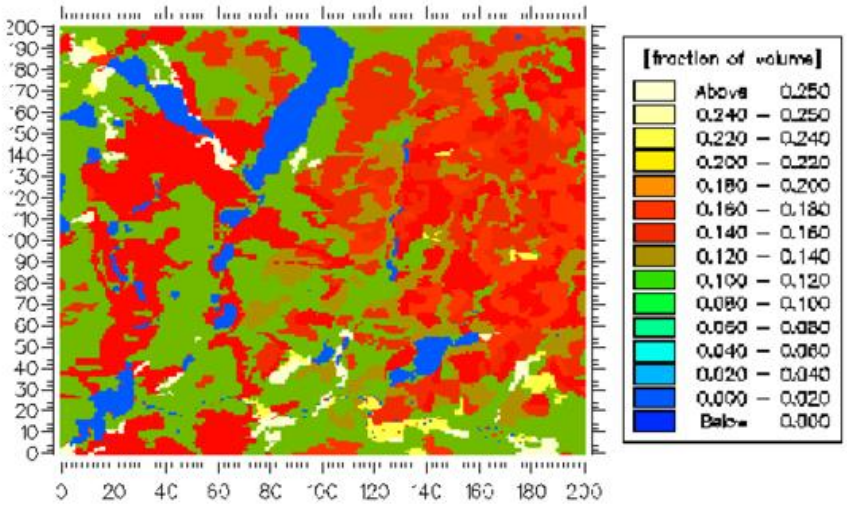

Figure 5.5: Distriubution of soil heat capacity.

As can be seen in Tab. 5.2 the predominant land use pattern is significantly influenced by human activity. The result is a high amount of coniferous forest (40.5%) and farmland (27.5%), while forest of deciduous trees has a portion of 8%. Greenland (here defined as fallow land, covered by several uncultured plants differing from forest) covers 14.5% of the total area.

Forests and fields are unequally distributed over the whole integration domain. According to the land use map shown in Fig. 5.6, forest prevails in the south-west while farmland dominates in the north-eastern part of the region. The most important agricultural plants are triticale, maize and rape. The variety seen in the actual land use map of June 1998 is largely determined from the different sorts of agricultural plants growing in that season. This concerns our simulation period for the LITFASS-98 experiment. In order to adapt the associated parameter distribution to the LINEX-2000 experiment (August-September 2000), the agricultural areas are assumed to be covered by grass after the harvest. That amounts to be an area portion of 28.6% for grassland compared to only 1.1% during June 1998.

Type of land use	coverage during LITFASS-98 [percent]	coverage during LINEX-2000 [percent]
water (lake, river)	7.0	7.0
coniferious forest	40.5	40.5
deciduous forest and settlements	8.0	8.0
triticale	17.2	-
maize	4.4	-
rape	2.8	-
barlay	1.6	-
lucern	0.5	-
sunflowers	0.5	-
wheat	0.5	-
greenland	14.9	14.9
grassland	1.1	28.6
marshland	0.9	0.9

Table 5.2: Land use cover in percent for the campaigns LITFASS-98 and LINEX-2000.

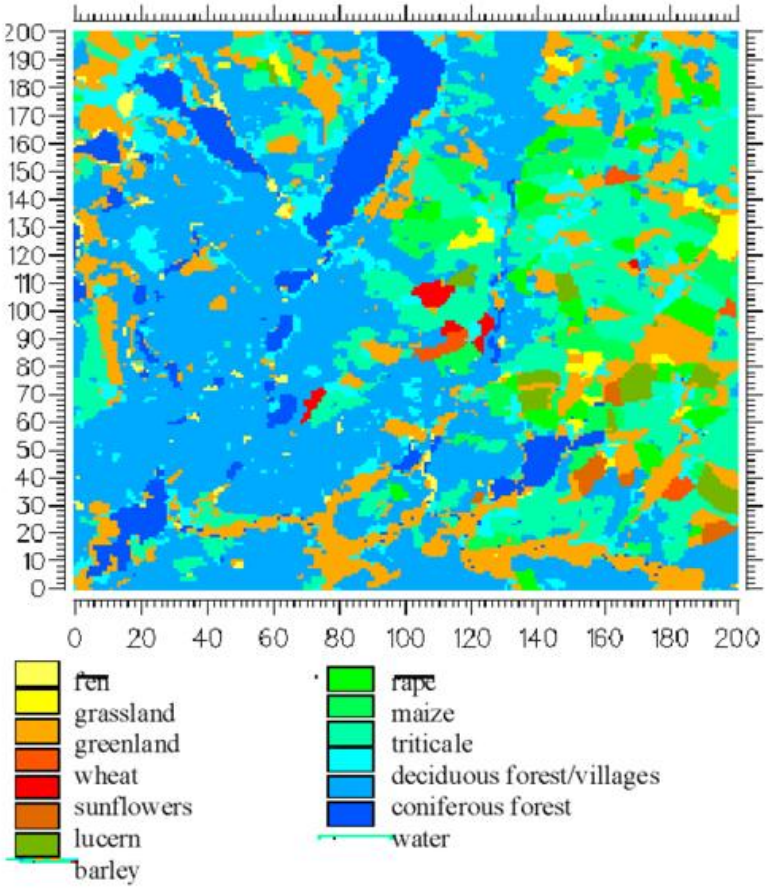

Figure 5.6: Land use cover (see text).

The external parameter set required for the LLM simulations is eventually listed in Tab. 5.3. In addition, the relevant land-surface processes playing a major role in driving the LLM from below are noted in that table.

Among all parameter maps, the landpoint mask can be obtained immediately from the map of soil types indicating where areas of water are located. Considering the fine grid resolution, it suffices to entirely assume a grid point to be either water or land. Concerning the specification of the root depth parameter, it is necessary to accept facts given by the present soil model. With respect to the hydrological part this model is assumed to have two active vertical layers, from 0 - 10 cm and 10 cm - 1 m depth. Therefore, in case of forest and greenland a constant root depth of 0.5 m has been chosen, while the root depth of farm- and grassland as well as fen is taken 0.05 m.

Some more effort is needed to determine the other external parameters mentioned in Tab. 5.3, since they depend explicitly on the type of vegetation. For the sake of convenience they have been estimated separately for vegetation and bare soil, before the final fields are determined by averaging both components with weights of the given degree of plant covering. This approach seems to be valid for the surface roughness length and the displacement height.

external parameter	interval	dimension	main impact on
landpoint mask	0 or 1		distribution of land and water gridpoints
roughness length	0.0002 - 1.52	m	vertical wind profile
displacement length	0 - 12	m	vertical wind profile
leaf area index	0 - 8	m^2/m^2	transpiration of plants
fractional plant cover	0 - 0.99	fraction	vegetation and bare soil components of the external parameters
root depth	0.05 or 0.50	m	transpiration of plants
albedo	0.10 - 0.35	fraction	solar energy balance at surface
emissivity	0.90 - 0.98	fraction	emission of IR-radiation from the ground

Table 5.3: Local external parameters used in the soil/vegetation module of LLM.

land use type	vegetation height [m]	LAI-variation in the annual course
coniferious forest	~15	8.0
deciduous forest	10	0.1 - 8.0
grassland	0.15	0.2 - 1.4
greenland	4	0.1 - 4.0
marshland	1	0.1 - 4.0

Table 5.4: Vegetation heights and LAI-values for some land use types.

In case of vegetation these values depend on the actual height of plants and the leaf area index. For some sorts of vegetation it is sufficient to use fixed plant heights, which are given in Tab. 5.4. Based on observational data from Lindenberg area a forest of coniferous trees is, on average, assumed to have a height of 15 m with a random variation superimposed within an intervall of ± 5 m. Only in case of agricultural plants the vegetation height is assumed time-variable.

For agricultural plants the time-variation of the plant height h_v and the LAI is considered over the vegetation period until the harvest using simple formulae proposed by Vogelgesang (1993) and Jürrens, respectively. For both parameters $\psi = (h_v, LAI)$ a linear time-interpolation formula is applied, where n counts the Julian days during the annual course:

$$\psi = \begin{cases} \psi_s & , n \leq n_s \\ \psi_s + \frac{\psi_z - \psi_s}{n_z - n_s}(n - n_s) & , n_z < n \leq n_s \\ \psi_s + \frac{\psi_{max} - \psi_z}{n_{max} - n_z}(n - n_z) & , n_{max} < n \leq n_e \\ \psi_s & , n_e < n \end{cases} \tag{88}$$

$\psi_s, \psi_z, \psi_{max}$ denote the values of parameters at selected Julian days n_s, n_z and n_{max}, where n_s is a Julian day at the very beginning after the seed-time, n_z marks a day characterizing a particular change of the plant property in order to ameliorate the linear approach due to a nonlinear growth in reality, and n_{max} denotes a day when the plant has obtained its maximal height, n_e is the day of the harvest.

Thus, both key parameters indicate the progress of plant growth and the degree of maturity (cf. Tab's. 5.5 and 5.6). In Fig. 5.7 the time-variation of the plant height as used in the LLM is shown in comparison to some measured heights (triangles), where these measurements are used to derive the parameters in (88). In view of these curves the model-relevant time of the LITFASS-98 experiment (1-20 June 1998) can be characterized by the end of a rapid growth, with exception of maize. Most of plants have obtained their maturity stage. In the following Fig. 5.8 a time-averaged field of LAI over the same LITFASS-98 period is depicted illustrating the typical physiographic structure of the Lindenberg simulation area. High LAI-values of about 8 are found in the south-west, while values of about 2 - 4 can be found in the eastern part of the area. The minimum value is found to be not below 0.7.

Table 5.6: LAI-values and typical vegetation heights.

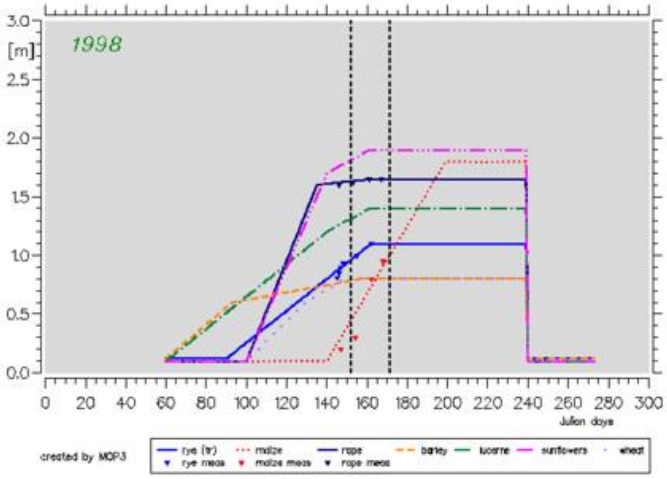

Figure 5.7: Time-variation of the plant height (see text).

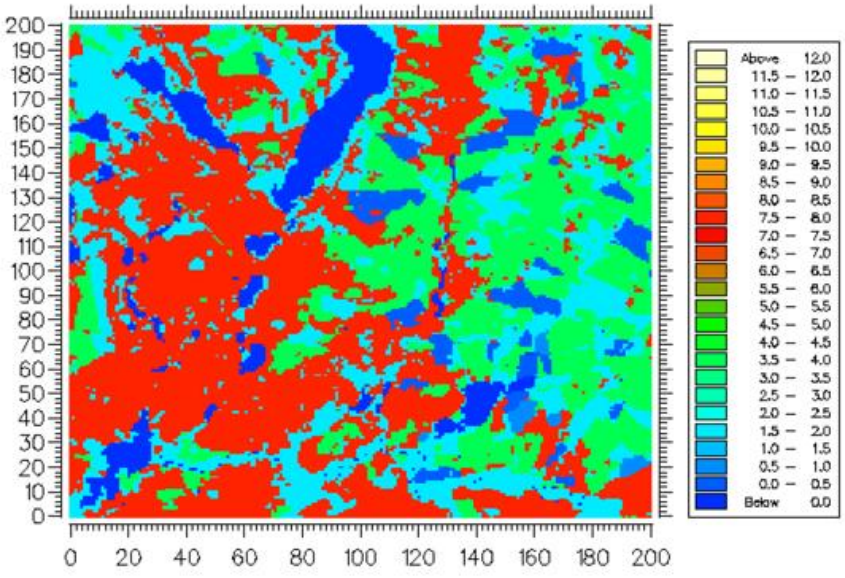

Figure 5.8: Time-averaged field of LAI over the LITFASS-98 simulation period.

In a following step it is necessary to determine the roughness length z_{0v} [m] and the displacement height d_v [m] over vegetation in dependence of the plant height h_v and LAI. In case of a forest with conifers and/or deciduous trees we use formulae by Brücher (1997):

$$z_{0v} = 0.1 h_v \,, \quad d_v = 0.67 h_v \,. \tag{89}$$

Having green- or grassland, fen or agricultural plants, an approach of Bailey and Davies (1980) is taken instead, where the LAI is also involved:

$$z_{0v} = 0.0275 + 0.281 h_v - 0.028 LAI \,, \quad d_v = 0.245 h_v + 0.091 LAI \,. \tag{90}$$

The only exception is made for z_{0v} in case of maize, where the LAI is not taken into account (Uchijima 1976):

$$z_{0v} = 0.062 h_v^{1.08} \tag{91}$$

We use the fractional plant cover expressed as a function of the LAI (Vogelgesang 1993),

$$f_p = 1.0 - \exp\left(-0.4\, LAI\right) . \tag{92}$$

Gridpoint values of the roughness length and of the displacement height over a gridbox area are weighted averages from the partial areas with vegetation and bare soil:

$$\begin{aligned} z_0 &= (1.0 - f_p)\, z_{0,surf} + f_p\, z_{0,v} \,, \\ d &= (1.0 - f_p)\, d_{surf} + f_p\, d_v \,. \end{aligned} \tag{93}$$

In the case of bare soil we assume $z_{0,surf} = 0.01$ m and $d_{surf} = 0$ m. For a water surface, $z_{0,surf} = 0.0002$ m is taken. Any dependence on the wind speed is ignored. By z_0 a roughness length $z_{0,M}$ is actually meant, which is defined for momentum fluxes. For latent and sensible heat fluxes we assume a similar length defined as

$$z_{0,H} = 0.1\, z_{0,M} \tag{94}$$

which is taken from Jürrens (1996). The surface heterogeneity is demonstrated for the LITFASS-98 period in terms of time-averaged fractional plant cover f_p and roughness length

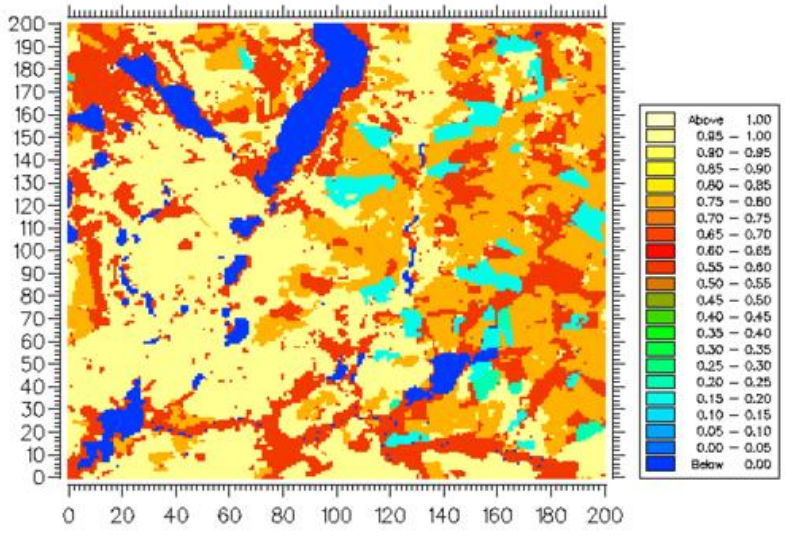

Figure 5.9: Time-averaged field of plant cover (%) over the LITFASS-98 simulation period.

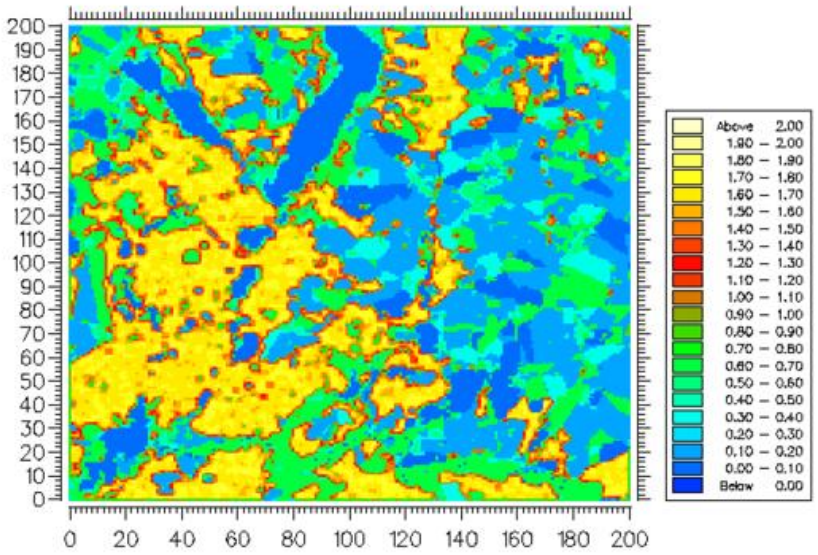

Figure 5.10: Time-averaged field of surface roughness over the LITFASS-98 simulation period.

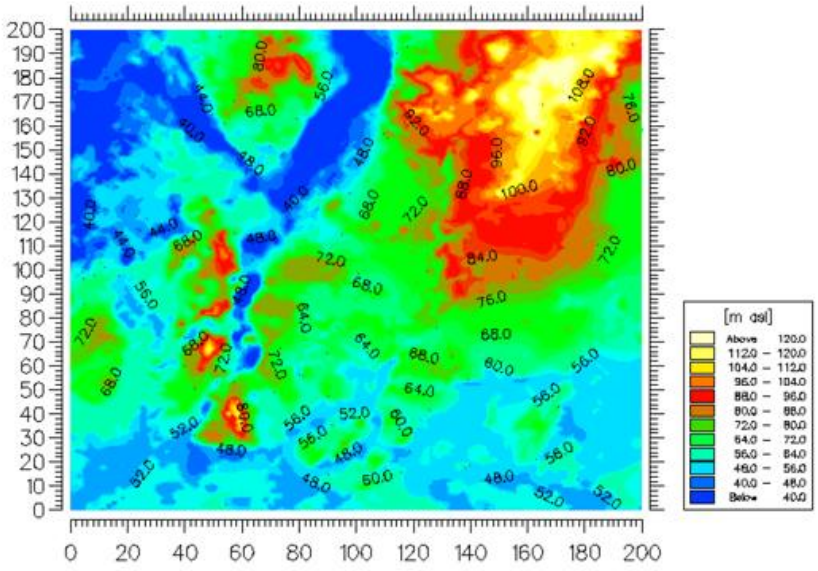

Figure 5.11: Orography plus time-averaged field of displacement height over the LITFASS-98 simulation period.

$z_{0,M}$ in Fig's. 5.9 and 5.10. For the sake of practical convenience the actual field of the displacement height is always added to the time-fixed orography (cf. Fig 2.7b) to have actually a time-variable orography field. That field averaged over the relevant period of LITFASS-98 is shown in Fig. 5.11.

A further group of external parameters immediately relevant to the radiative processes at the surface is related to the reflection of incoming solar radiation and to emission of infrared radiation from the ground. These parameters are albedo and emissivity. They were provided separately for vegetation and bare soil. The influence of precipitation on those parameters will be considered in the following Section 5.2 where the radiation balance components will

be deduced from measurements. Here, the values of albedo for vegetation are differently updated (daily or monthly) in dependence of the average growth rate of each plant type. The corresponding data source has been extracted from a VDI Guideline (1994). Finally, we show as examples the distribution of the 'dry' albedo over the total LLM-integration area in Fig. 5.12 and the 'dry' emissivity of vegetation (Fig. 5.13) indicating the specific heterogeneity from this point of view. These values are also averaged in time over the LITFASS-98 period.

5.2 Radiative Forcing

The task we describe here consists in determining the radiation components of the energy balance at the surface by use of all radiation measurements available in and around the LLM integration area. Satellite information is also taken into account. All these different data sources relevant for our purpose to derive the radiative forcing are compiled in Tab. 5.7. The ground-based radiation measurements are of greatest importance. They are recorded, first of all, at the BSRN-station near the MOL, serving as the reference station, at the radiation measurement site Falkenberg, and at other Energy Balance Stations (EBS) (Lake Kossenblatt, in a pine forest near Storkow, and two special measurement places, in a barley and a triticale field). The latter were only available over the LITFASS-98 period.

Beyond this measurement campaign, further Global Radiation measurement stations have been added since summer 2000 to have meanwhile 8 of them. In Fig. 5.14 the net of radiation measurement points from these different sites is shown, where the mean local METEOSAT pixel positions relevant to our approach are also depicted. As one can see, the area of interest

Data sources available for the radiative forcing of the LLM

■ Satellite-based radiation data	{derived by PODLASLY und BERGER et al. (1999)}
Global Radiation	based on NOAA-measurements (25.05.-30.09.1998) area resolution 1 x 1 km, Northeastern Germany once or twice per day
Temperature planetary albedo	based on METEOSAT data (25.05. - 30.09.1998) area-resolution 7 x 7 km², Northeastern Germany (half-)hourly
■ Ground-based radiation measurements	
Global Radiation Reflected Solar Radiation Diffuse Solar Radiation Direct-beam Solar Radiation	BSRN-station
Global Radiation at horizontal surface Reflected Solar Radiation Thermal Radiation of the atmosphere Emitted thermal radiation from ground	Measurement site Falkenberg
Global Radiation Thermal Radiation of the atmosphere Radiation balance	Forest site Storkow Lake site Kossenblatt measurements at special sites (barley, triticale) [Global radiation network since 2000 (8 sites)]
■ Meteorological data	
precipitation temperature (2m) water vapour pressure (2m)	LITFASS-network (21 sites) Energy balance stations and special sites

Table 5.7: Data base available for radiative forcing.

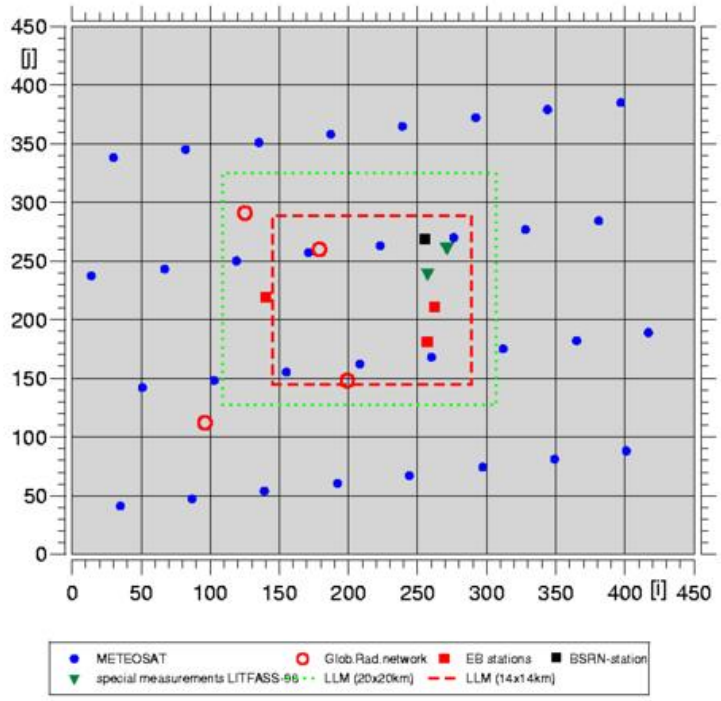

Figure 5.14: Placement of measurement sites recording radiation data.

is chosen considerably larger than the local LLM integration area to be able in any case to apply an interpolation method. In the background NOAA-data are also exploited in order to support the METEOSAT information with its coarser horizontal and spectral resolution. Normal meteorological information, like precipitation, 2m-temperature and water vapour pressure is also involved (Tab. 5.7). These data are provided from a special LITFASS precipitation network with 21 measurement points (see Section 5.3). For further explanation of the instrumental design concerning the radiation measurements during the LITFASS-98 main experimental phase we refer to Beyrich (2000).

For our purpose the satellite data have been made available by Podlasly and Berger (1999). They provided us with a comprehensive data set of METEOSAT and NOAA measurements over the period 25 May - 30 September 1998 with our LITFASS simulation time interval embedded. The METEOSAT data consist of temperature and planetary albedo, while the Global Radiation was derived directly from the NOAA satellite. In the latter case the radiation data have a high resolution of about 1×1 km^2 which would be appropriate for LLM. Unfortunately, these data are available only once ore twice a day over the area of interest. In contrast, the METEOSAT information can be obtained in a relatively high time-resolution, that is every 30 minutes, but due to its poor spectral resolution the Global Radiation data cannot be similarly derived (cf. Podlasly and Berger 1999).

This dilemma of different shortcomings of the two available satellite data sources can be reduced by a method to combine both. In effect, our approach rests on deducing a Global Radiation field from these satellite data by combining the available information with the ground-based measurements of Global Radiation as the key radiation component relevant to the LLM forcing. For the LITFASS-98 period the method cannot do without satellite information due to the small number of ground-based radiation stations inside the LLM

integration area. The following approach may be characterized as some calibration of the available METEOSAT information of temperature and planetary albedo by the Global Radiation field, derived from NOAA data at METEOSAT pixels.

The area of satellite data shown in Fig. 5.15, which covers Northeast Germany with the LLM-area as a tiny sub-area in the eastern part in it. In this figure the 18 June 1998 at 12.30 UTC is chosen, when the NOAA data coincide almost exactly in time with the METEOSAT information. At first glance, the Global Radiation from NOAA data (Fig.5.15a) seems to be not highly correlated neither to the temperature (Fig. 5.15b) nor to the albedo (Fig. 5.15c). Here, qualitative arguments might be helpful to put forward the matter. In this line, we generally expect a significant relation between cloudiness on the one hand and temperature and albedo on the other hand. In case of compact clouds the satellite measures deeper temperatures together with a higher albedo, which must be correlated with a correspondingly reduced Global Radiation at the ground. Inversely, one expects in cloudless areas with relatively high values of temperature and smaller values of albedo increased values of Global Radiation at the ground.

This leads us to the definition of an Insolation parameter s, which is an appropriate combination of albedo *and* temperature, as available from METEOSAT data, in such a way that

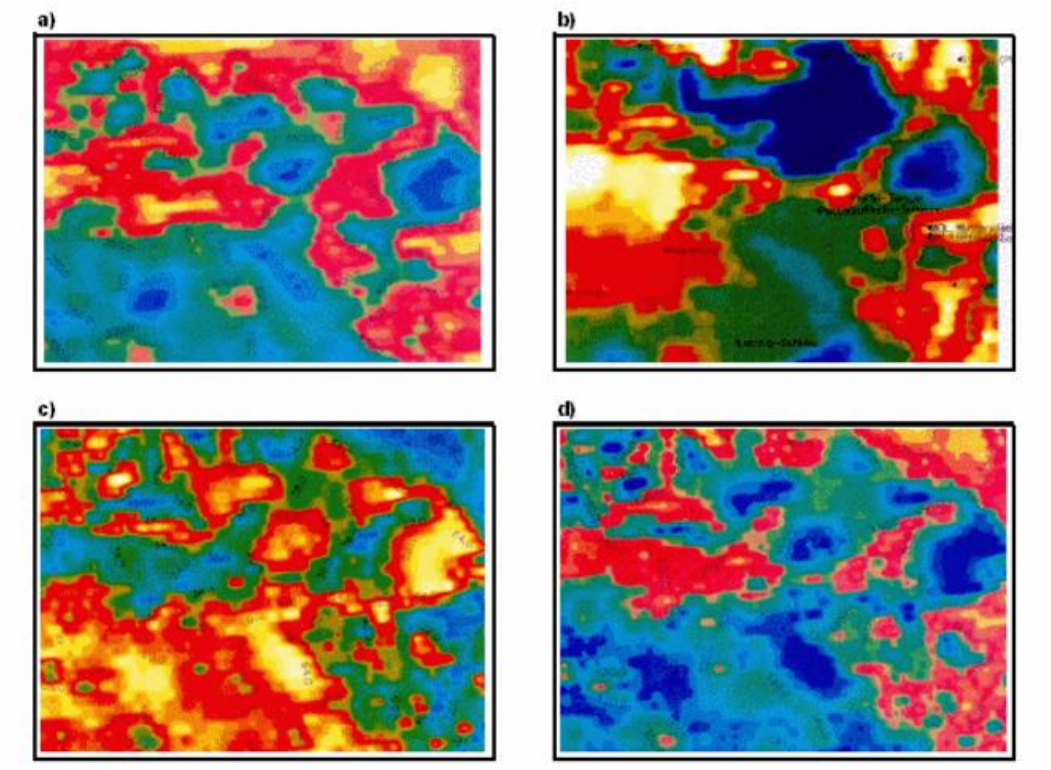

Figure 5.15:
a) Field of Global Radiation derived from NOAA data and adapted to the coarser METEOSAT resolution.
b) Temperature field based on METEOSAT data.
c) Field of Planetary albedo based on METEOSAT data.
d) Field of Insolation parameter.
All fields refer to north-east Germany (18 June 1998, 12:30 UTC).

it has a significantly high correlation to the known Global Radiation fields directly gained from the NOAA satellite. A comparison of the s-field in Fig. 5.15d with the NOAA Global Radiation field in Fig. 5.15a demonstrates such a desired correlation. By use of all available NOAA- and METEOSAT data taken out of the entire data set the Insolation parameter has been found as a result of statistics:

$$s = a_s T\,(1.0 - 0.01\alpha_p) + b_s\,. \tag{95}$$

α_p is the planetary albedo [%] and T [K] the temperature from METEOSAT, the constants are found to be $a_s = 0.0053K^{-1}$ and $b_s = 0.0227$. After deriving relation (95) from NOAA Global Radiation data, it can now be used to determine from the METEOSAT information (from T and α_p) the Insolation parameter field s every 30 minutes.

In the next step a local fitting of the s-field to the Global Radiation measurements at the ground is performed such that the s-field is slightly shifted in the horizontal until a measure of distance to the Global Radiation values at the given 5 measurement points becomes minimal. In Fig. 5.16 the s-field is shown for the same selected time as in Fig. 5.15 after the operations just described. Although this field has a relatively coarse structure due to the METEOSAT-pixel resolution and a 30 minutes-resolution in time, compared to the LLM-scale resolution, the s-field serves as a necessary background information towards a horizontally inhomogeneous and time-variable Global Radiation field at the surface. Thus, at measurement points associated Global Radiation (G-) and s-values are used to deduce a linear s, G-relation. In such a way we obtain all s-values available as G-values which are finally exploited as additional information to the genuine surface measurements in a horizontal interpolation onto the LLM-gridpoints.

Since the ground-based measured values are delivered every 10 minutes, a further time-interpolation from 30 down to 10 minutes is carried out to obtain finally a surface Global Radiation field G over the 20×20 km^2 LLM integration domain with 199×199 gridpoints and a 10-minute input frequency. As can be seen from Fig. 5.17, the method described above is able to provide the LLM with a horizontally inhomogeneous G-field, where real

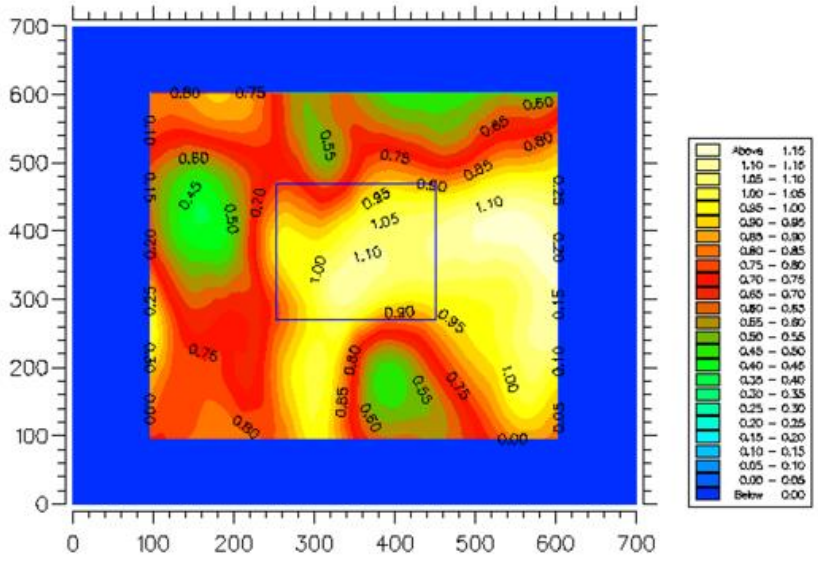

Figure 5.16: Distribution of Insolation parameter for 18 June 1998, 12:30 UTC. The LLM area is embedded in the centre.

cloudiness is involved. This approach has been used for all LLM integrations over our LITFASS-98 simulation period (1 June-20 June 1998). As mentioned above, the number of Global Radiation recording stations was only extended after this period, in summer 2000. In order to demonstrate the additional gain of information from this further technical effort, Fig. 5.18 shows the sequence of G in 10minute-time intervals over the LLM-area with rapid time-changes of that radiation pattern accompanied with rather sharp gradients.

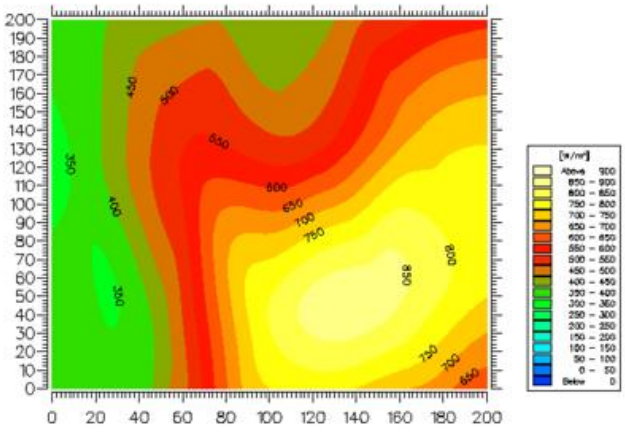

Figure 5.17: Global Radiation field in the LLM area for 18 June 1998, 12:30 UTC (see text).

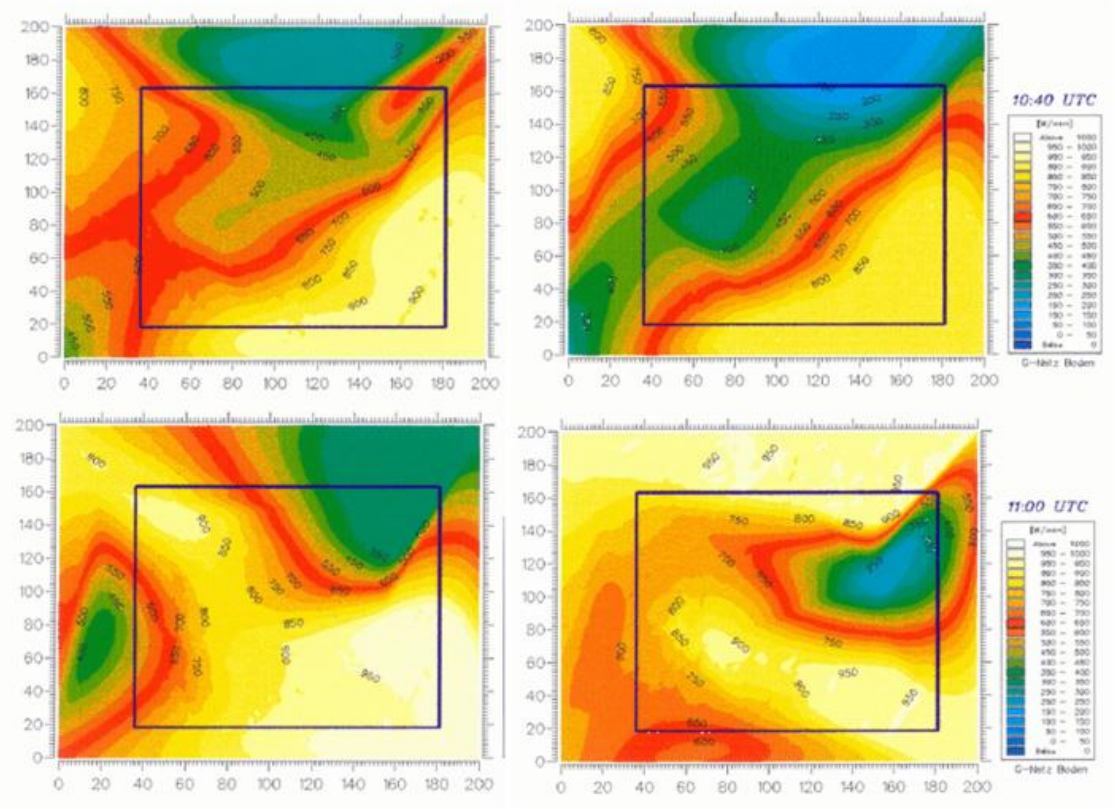

Figure 5.18: Time sequence of Global Radiation fields deduced every 10 minutes from an extended surface network on 21 June 2000. Top left: 10:30 UTC; top right: 10:40 UTC; bottom left: 10:50 UTC; bottom right: 11:00 UTC.

The Global Radiation G found in this way is, however, not the final result. To make the incoming solar radiation flux still more realistic, the inclination of the natural surface has to be taken into account. The corresponding correction necessary is, however, effective only to the Direct-beam Solar Radiation I. For that purpose we need an approach to split up G into its components I plus Diffuse Solar Radiation D, that is $G = I + D$. Assuming that this splitting has been carried out, the correction of I due to the orographic inclination can be performed. All details of that operation including the derivation of the inclination angle from the given orography up to the determination of the modified solar height (depending on the varying sun position over the day and the season) will be dropped here. This method is standard.

The splitting procedure needs, however, further explanation, and for that purpose we introduce a Global Radiation Reduction factor R_s, which may be defined with reference to Davies et al. (1975) as

$$G = G_0 R_s \,. \tag{96}$$

This relation separates the Global Radiation at the ground, G, into a Global Radiation component of the cloudless case G_0 multiplied by a Reduction factor R_s. The latter describes the reducing influence of clouds in the solar spectrum. After Davies et al. (1975) the parameterization of G_0 and R_s may be given as follows.

$$G_0 = a_R + \frac{b_R}{2}\left(\frac{r_0}{r}\right)^2 S \sin\gamma \left[\psi_{wa}(\psi_{ws}\psi_{rs}\psi_0 + \sqrt{\psi_0})\right] , \tag{97}$$

$$R_s = \left[1 - \left(1 - \frac{a}{G_0 m_a}\exp(-b m_a)\right) n\right] (1 - \alpha_c \alpha_g n) , \tag{98}$$

with the following explanations and definitions of parameters in the G_0-relation (97): $(r/r_0)^2$, γ, S are measures of astronomical excentricity, solar height at given location and time, and solar constant, respectively. ψ_{wa}, ψ_{ws}, ψ_{rs}, ψ_0 are transmission coefficients due to water vapour absorption, water vapour scattering, Rayleigh-scattering and scattering from dust. The regression coefficients a_R and b_R are introduced to fit this relation to the local conditions of Lindenberg.

The R_s-relation (98) depends on parameters describing different cloud properties, a and b are coefficients specifying the cloud type, a_c is the cloud albedo seen from below, n describes the cloud coverage ($0 \le n \le 1$), m_a defines the optical mass of the atmosphere and α_g is the albedo of the ground. The reliability of relation (96) together with the parameterizations of G_0 and R_s has been proved by use of NOAA-radiation fields. For the problem discussed here and in the following we confine the parameterization to G_0. The determination of the Reduction factor R_s follows from (96) by use of ground measurements of G (actually determined from ground measurements and METEOSAT/NOAA-satellite data as described above). Such an R_s-field is shown in Fig. 5.23a.

After having found R_s, it is possible now to separate D and/or I from the preliminary G. Therefore, we assume that the ratio D/G is a function of R_s:

$$\frac{D}{G} = \frac{D}{D+I} = f(R_s) \,. \tag{99}$$

For the cloudless case, with $R_s = 1$, we expect the ratio to have a minimum, $f(1) = D/G_0$. If the sky becomes overcast ($I \to 0$), R_s approaches to a minimum and the ratio to unity. Fortunately, the Diffuse Solar Radiation D is directly recorded at the BSRN-station at MOL and each 10 minutes available. Taking advantage of these data, the function $f(R_s)$ can be determined. In Fig. 5.19 the ratio D/G is plotted against R_s from measurements and by

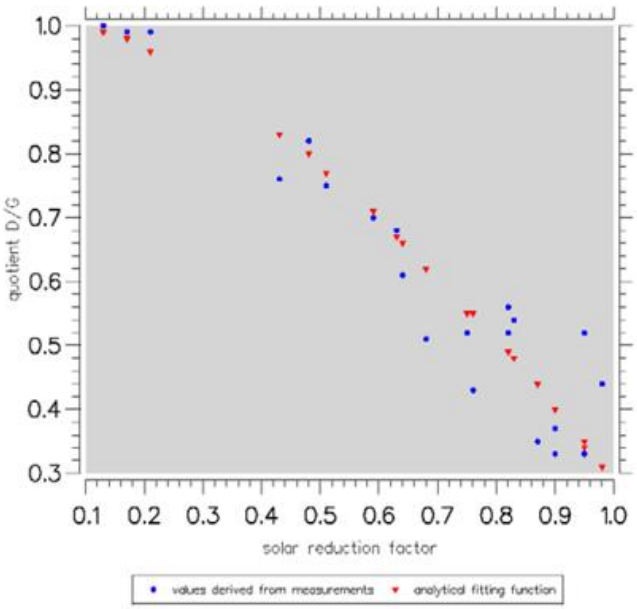

Figure 5.19: Quotient D/G as empirical function of solar Reduction factor (see text).

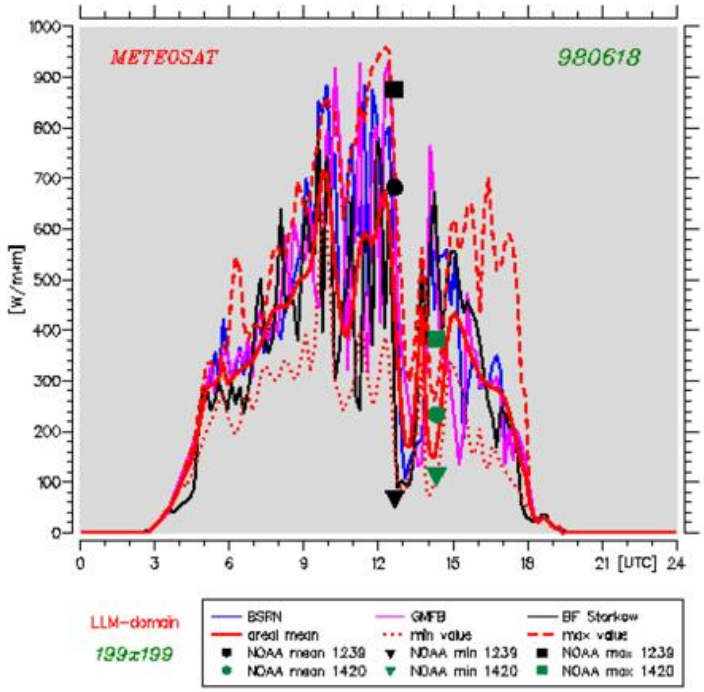

Figure 5.20: Diurnal variation of measured and derived Global Radiation over the LLM area (18 June 1998). Time variations of deduced area-average, -maximum and -minimum against selected NOAA- and surface measurements of Global Radiation at BSRN-station, forest station (BF Storkow) and Falkenberg site (GMFB).

using an analytical curve fitted to these data. The latter is assumed to be the appropriate tool to separate D and/or I from the given G which makes it immediately possible to modify I in the above sense and use that result together with the unchanged D to obtain the final composite of G.

Before we continue to derive further radiation balance components for the radiative forcing of the LLM the time-variation of G is shown in Fig. 5.20 for the same selected day (18 June 1998) from the LITFASS-98 period as in previous figures. This day was a particular occasion for LLM-simulations because of a helicopter flight with a sonde. By chance, this day was characterized by prevailing convective weather. The time-variations of G show in general rapidly passing small-scale cloud patterns accompanied by sharp peaks and gaps in the morning. At noon, a compact cloud field covers the entire LLM-area, from which a maximum of about 900 Wm^2 has been reduced down to 100 Wm^2. As seen in the figure, the various plots of G refer to three different recording stations and show in parallel the time-variations of the area-average, -maximum and -minimum which demonstrates the considerable spread of G-variations over the LLM-domain and so the radiative inhomogeneity at the surface.

In order to complete the Solar Radiation balance SB, we have to determine the Reflected Solar Radiation G_r, too, and to subtract it from the Global Radiation G:

$$SB = G - G_r\,. \tag{100}$$

Since D and I have already been derived in connection with the determination of G, we are now immediately able to carry out the necessary separation of G_r into the diffuse and the direct-beam component:

$$G_r = \alpha_d D + \alpha_{par} I\,. \tag{101}$$

Therefore, in accordance with (101), the determination of G_r can be reduced to the determination of the diffuse albedo α_d and the albedo of a parallel radiation beam α_{par}. Concerning the diffusive albedo α_d, we refer to comments at the end of Section 5.1 about the availability of external parameters like dry, diffuse albedo and emissivity, which are already prepared to be used separately for bare soil and vegetation. In case of precipitation both albedo components are modified provided the actual amount of rainfall exceeds 0.5mm over a 10minutes-interval. Then the surface is assumed to be wet. In this case the albedo of vegetation is reduced by 10 percent and the albedo of wet bare soil is treated in accordance to the VDI Guideline (1994). The diffuse albedo follows then by use of a weighted average of both components with the

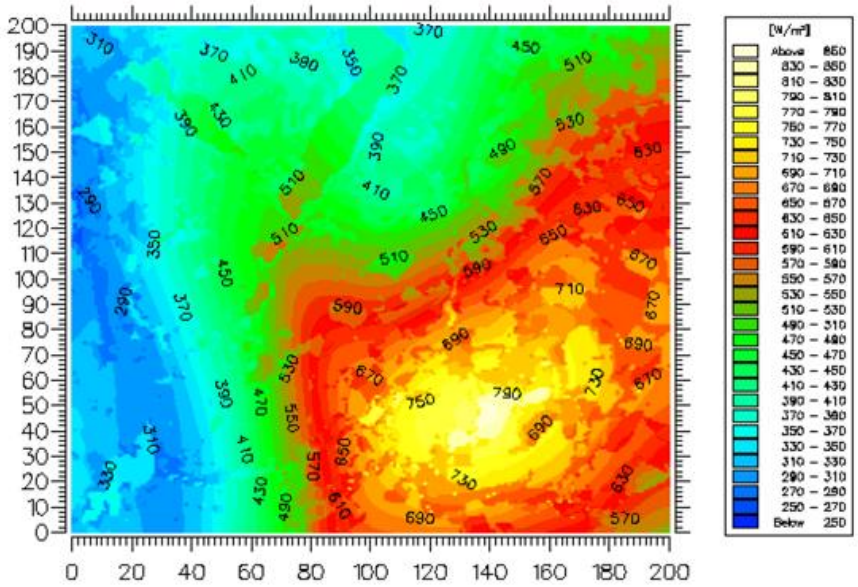

Figure 5.21: Example of Solar Radiation balance field over the LLM area (18 June 1998, 12:30 UTC).

fractional plant cover. This is similar to the treatment of the roughness length in (93). In the following step, the albedo of a parallel radiation beam is calculated as a function of α_d and solar height γ (Ritter, cf. Doms and Schättler 1999):

$$\alpha_{par} = \frac{1 + \frac{\gamma}{2(\alpha_d - 1)}}{\left(1 + \frac{\gamma}{\alpha_d - 1}\right)^2} . \tag{102}$$

Using α_d and α_{par}, the reflected component G_r can be found from (101), which leads to the Solar Radiation balance (100). An example of an SB-field is shown in Fig. 5.21.

In a final step we still have to determine the Thermal Radiation of the atmosphere A and the Thermal Radiation E emitted from the ground. In case of A we need a method which also operates on the basis of available Global Radiation data G. In a similar way an Amplification Factor M_{IR} is introduced in order to determine A by use of a reference value

$$A_0 = (\alpha_{IR} - \beta_{IR} \exp\{-\gamma_{IR} e_{2m}\})\ \sigma T_{2m}^4 , \tag{103}$$

valid for cloud-free conditions (Rietschel 1994), that is, by

$$A = M_{IR} A_0 . \tag{104}$$

Here, the general problem is shifted to the determination of M_{IR}, while A_0 can easily be approximated by use of temperature T_{2m} and water vapoure pressure e_{2m} at 2 meters above the ground as meteorological input-parameters taken from measurements. During simulation runs these data are directly provided from the LLM in order to determine the A_0-values in a consistent manner to the model. α_{IR}, β_{IR} and γ_{IR} are empirical constants with reference to Rietschel (1994), and σ is the Stefan-Boltzmann constant. The true problem is to estimate

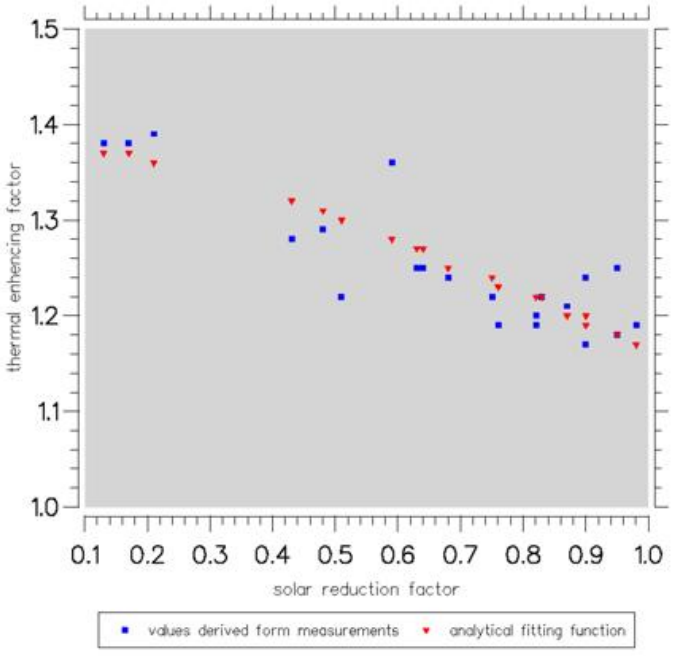

Figure 5.22: Empirical relationship between thermal Amplification factor and solar Reduction factor for a given time interval on 18 June 1998, 9 - 12 UTC (see text).

the factor $M_{IR} \geq 1$. In order to have an approach consistent with our treatment of the Solar Radiation component, it is reasonable to find out an empirical relation between R_s and M_{IR}, which is expected to have in a crude manner a reciprocal proportionality. This means, the enhancement of Thermal Radiation from the atmosphere compared to the cloud free case must directly be related to a reduced Global Radiation, which is expressed by a decreasing Reduction factor R_s. In our approach, this relation has been determined every 10 minutes and is shown for a selected time interval in Fig. 5.22. On the basis of this operation M_{IR} is given and the estimation of A follows using (104). Fig 5.23a,b demonstrates the consistent relation between R_s and M_{IR}.

In the following the Thermal Radiation emitted from the ground,

$$E = \varepsilon \sigma T_{sfc}^4 \tag{105}$$

must be estimated, Here, the problem confines to the use of the infrared emissivity ε, which has already been provided as an external parameter field. Similar to the diffuse albedo, these values have been provided separately for vegetation and bare soil and possibly modified owing to precipitation.

We close the Section with a marginal remark concerning the Photosynthetically active Radiation P, which is needed in the vegetation parameterization part after Dickinson of the soil model 'terra'. P is approximated by the very simple relation $P = 0.5G$. A view on Fig. 5.24 may finally serve us as a summary of the present section. This figure is self-explaining. To organize the important forcing due to radiation processes from below, four groups of input data are of interest. These are ground-based radiation measurements, preprocessed satellite data from NOAA- and METEOSAT-instruments, meteorological near-surface data and basic data as orography, land use and soil type maps to derive relevant external parameters from them. All these data are stored in order to make a synthesis having finally the ground-based fields relevant for the radiative forcing (Solar Radiation balance, infrared Amplification factor, precipitation (cf. Section 5.3), infrared emissivity, Photosynthetically active Radiation) and the external parameters (cf. Section 5.1) which are orography plus displacement height, roughness length, LAI, fractional plant cover, root depth and landpoint mask.

These data are always ready for LLM-access. In case of radiation data their input to the LLM takes place every 10 minutes of integration time. All computer runs are carried out at

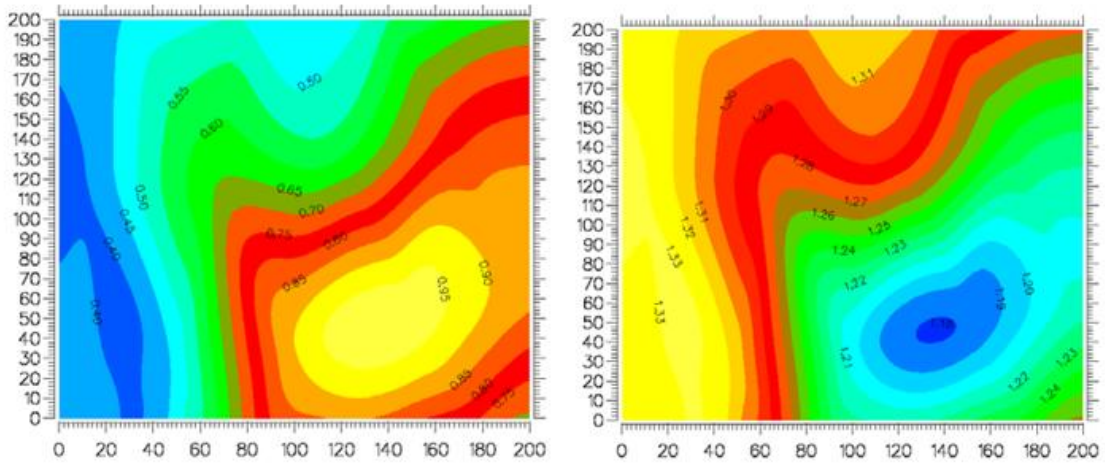

Figure 5.23: Consistent distributions of solar Reduction factor (left) and thermal Amplification factor (right) over the LLM area.

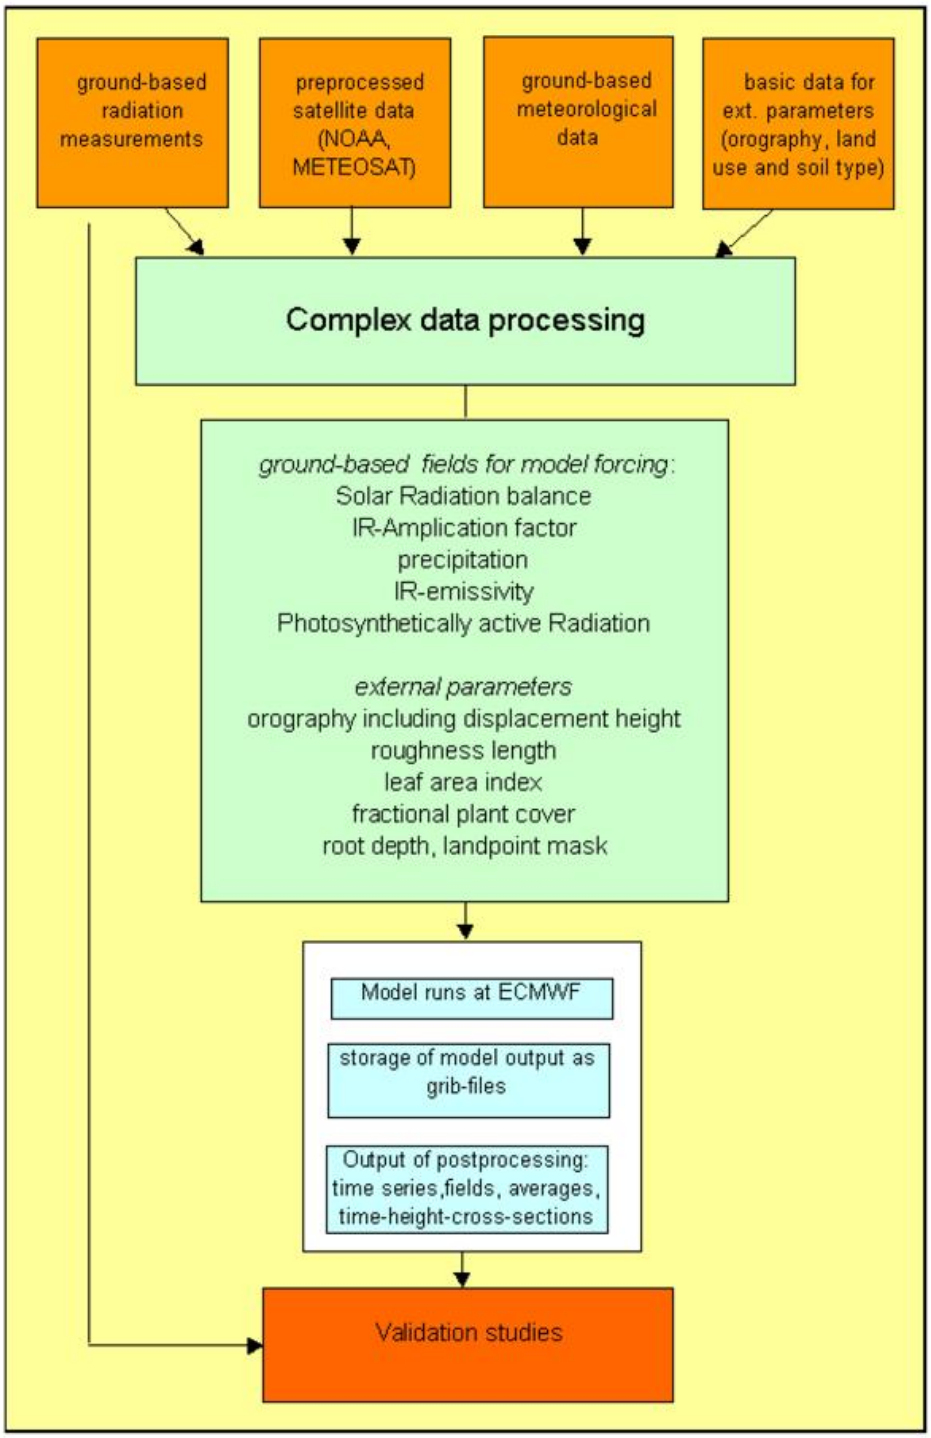

Figure 5.24: Summarizing scheme of data processing for physical forcing at lower boundary.

ECMWF on the VPP700 machine where all LLM output-arrays are also stored as Grib-files, and so the postprocessing is organized to be performed there, before results as time-series, selected fields, averages and specified sections of fields are transferred to Potsdam. There, the validation of the LLM products is executed by direct use of measurements, which are e.g. ground-based Radiation balance records. Ultimately, this kind of validation is part of a more general validation system as shown in Fig. 1.1.

5.3 Precipitation Forcing

We have already explained in Section 2.5 that in view of real-case simulations with the LLM its precipitation parameterization is ignored and the precipitation flux reaching the earth surface is inserted by a real-data field. This philosophy is similar to what has been carried out in the previous Section concerning the radiative forcing. In the following we describe the way how the horizontal distribution of precipitation at the surface is analyzed from given measurements. For that purpose a special network of Hellmann gauges commonly in use and automatically recording pluviometers has been established. RADAR data are not available.

In Fig. 5.25 the placement of 19 Hellmann gauges and 12 pluviometers is depicted. As can be seen, most of the pluviometers are placed within the extended LLM-area (199 × 199 gridpoints), while the gauges are distributed also far outside. At 7 places gauges and pluviometers have the same location. For these stations the pluviometer measurements are only used. Both instruments differ from each other by summing up the rainwater over quite different time intervals. In the gauges the rain water is gathered to obtain sums over 24 hours, normally observed at 5, 6 or 7 UTC in the morning, while the pluviometer records yield very high-resolved sums over every 10 minutes. By a simple operation the pluviometer values will be used as reference measurements to derive pseudo-values from the 24hour-Hellmann-data with the same high time-resolution. Then all measurements are put together for a following analysis.

The production of such pseudo-values may be demonstrated by Fig. 5.26. In Fig. 5.26a a pluviometer record is shown over 1 June 1998 at the village Limsdorf, placed in the LLM-area. Already in the morning a maximum of 5.6 mm/10min occurred during a heavy shower, and further showers with diminishing intensity took place during the second half of this day.

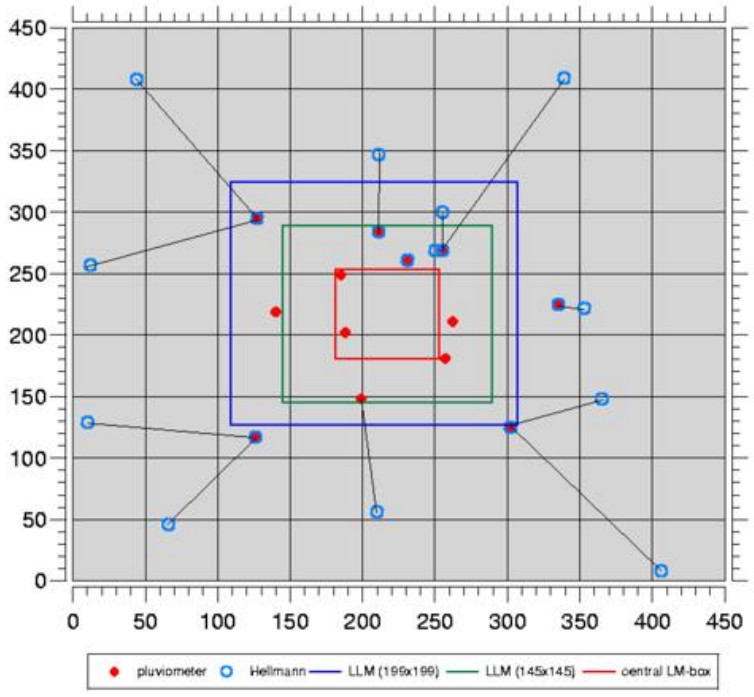

Figure 5.25: Placement of pluviometers and Hellmann gauges within and around the LITFASS area.

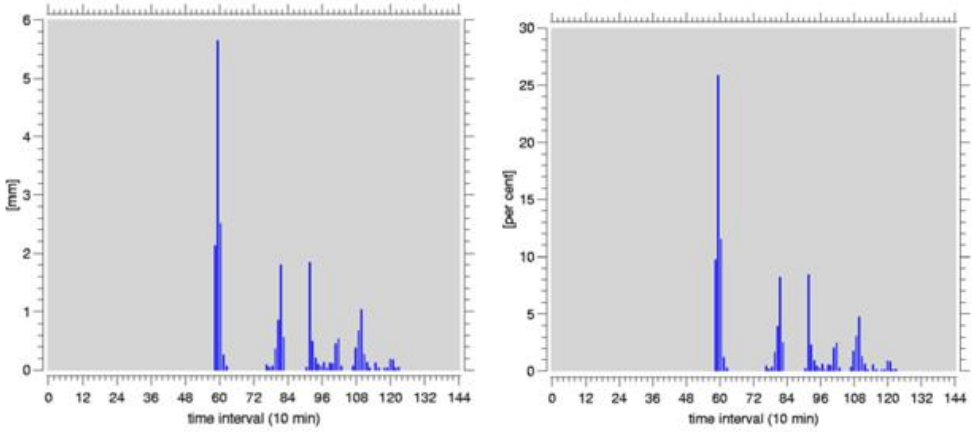

Figure 5.26: Time series of precipitation sums on 1 June 1998 at Limsdorf.
Left: Precipitation sums (mm/10min) in the diurnal course (144 time intervals of 10 minutes).
Right: Percentage distribution of 10-minute precipitation sums referred to daily sum (144 time intervals of 10 minutes).

The total sum amounts to 21.8 mm/day. With reference to this sum the time-series shown can easily be transformed into a corresponding time-variable percentage-distribution (Fig. 5.26b). Such a percentage-distribution found from each given pluviometer is then assumed to be valid for the nearest Hellmann-stations. (This is symbolized by connecting lines in Fig. 5.25). From this approximation the pseudo-values with a 10minute-resolution can be determined from the 24 hour-sum of the respective gauge. The irregular horizontal distribution of precipitation obtained every 10 minutes as explained above is the data basis for the following interpolation onto the LLM-gridpoints. This interpolation rests on a triangulation standard method.

The outcome of such treatment is shown in Fig. 5.27 for the same convection situation of the 1 June 1998 at 9:50 UTC, with a maximum near Limsdorf (cf. the peak at this time in

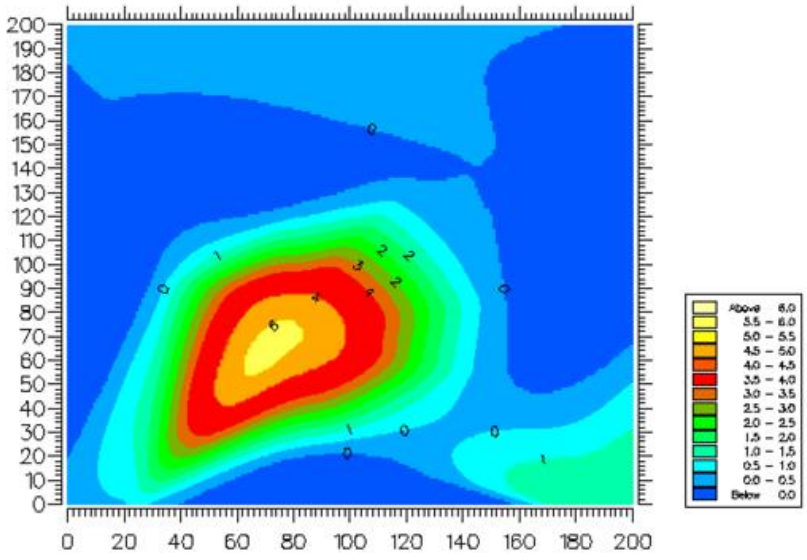

Figure 5.27: Deduced precipitation field over the LLM area on 1 June 1998, 9:50 UTC.

Fig. 5.26a). In this way precipitation forcing fields are made ready for the LLM-access every 10 minutes similar to that of radiation data. In case of large-scale precipitation our method presented seems to be sufficient. In case of convective rain events, however, further research supported from RADAR data is desirable in order to find out more adequate fine-scale field structures.

5.4 Soil-Moisture Modelling

Soil-moisture modelling is a specific problem of great importance for real-world simulations with the LLM. Obviously, that topic is seen to be closely related to the precipitation analysis we have treated in Section 5.3. The soil-moisture is a very complex factor caused by water influx due to precipitation. It interacts permanently with a diversity of processes like interception, surface runoff, infiltration, evapotranspiration, vertical water transport within the soil and runoff into the ground water. These processes again depend strongly on the soil properties, and they have very different characteristic time-scales. The longest of them make up the memory of the soil which is important to consider for the soil moisture initialization. This problem is of particular interest and must be solved in a pragmatic way.

While the LLM integration mode is generally characterized by a time-dependent external forcing founded on measurements – these are composite profiles (Chapter 4), external parameters (Section 5.1), surface radiation (Section 5.2) and precipitation (Section 5.3) – soil moisture measurements are only available at one measurement point at the Falkenberg site. As will be pointed out, this single measurement is absolutely insufficient to support an initialization approach needed and seems also to be unsuitable for the validation of simulation. It follows that LLM-simulations themselves are thought to be used as a possible soil moisture initialization procedure. These LLM-integrations are pre-runs started sufficiently long before the beginning of the actual run in order to produce a soil moisture spin-up towards a realistic initial field. The initial soil-moisture state of such a spin-up LLM-run is assumed to be a reasonable approximation, and this run will be controlled from the real time-dependent radiative and precipitation forcing as discussed above. We have to be aware, however, that

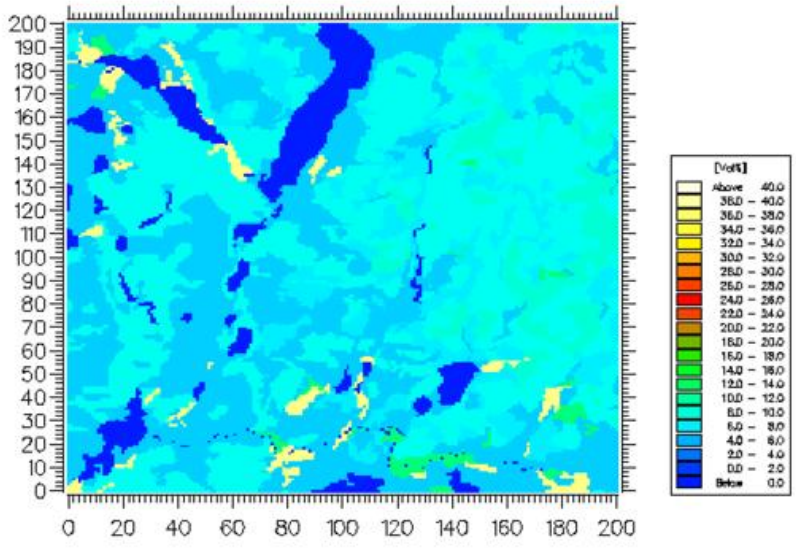

Figure 5.28: Initial field of soil moisture referred to the upper soil-model layer (1 June 1998, 00 UTC).

the approach is dependent on the potential of the coupled soil-model (Jacobsen and Heise 1982, Doms and Schättler 1999).

Because all LLM-simulations we have made were strictly connected with the measurement equipment installed for the project LITFASS-98 and further on for LINEX 2000, corresponding pre-runs were dictated from these facts and from the availability of real data before these campaigns. In case of LITFASS-98 it would have been desirable to have the basic data for the radiative forcing and of precipitation already since April 1998, in order to start the spin-up simulations in time with respect to a very dry May. Unfortunately, satellite data have not been available in that time, and the rain gauge network was still in preparation. While in case of LINEX 2000 the spin-up runs were possible already since 10 August 2000, our LITFASS-98 simulation had to be performed without such a desirable soil-moisture spin-up before.

For LINEX 2000 the spin-up start at 10 August was accepted due to heavy rain during August which makes the soil-memory from the months before possibly lost. In case of LITFASS-98 with its simulation time from 1 June to 20 June 1998 we are going to point out the soil moisture course from LLM-integrations over that time at a selected gridpoint which coincide with the only measurement point, and the model had to start with an approximate soil-moisture field without a necessary pre-run. That approximation is as follows. By use of the only measured value the percentage of the field capacity at the measurement point is known as an additional useful information. Since the horizontally inhomogeneous distribution of the field capacity over the LLM-domain is also known from the associated soil-type map, the assumption of the same percentage at each gridpoint leads immediately to an inhomogeneous soil-moisture field. This is assumed to be valid for both active model layers. In Fig. 5.28 the result is shown for the 1 June 1998. It is valid for the upper layer of the soil-model 'terra' having a thickness of 0.1m. (The present soil-model version has two active layers. The second layer, below, reaches from 0.1 m to 1 m depth.)

In the Fig. 5.29 the time variation of the soil-moisture at the gridpoint Falkenberg is shown as the result of an extensive LLM-simulation over all 20 days of the LITFASS-98 simulation period against the measurements there. For that experiment the LLM has externally

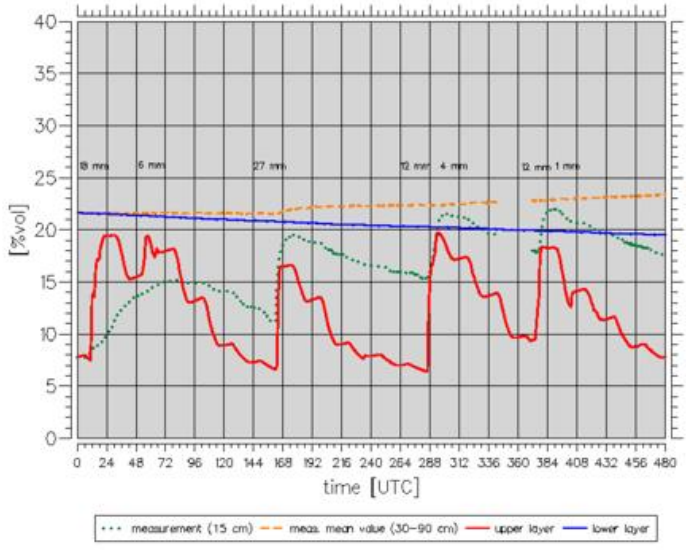

Figure 5.29: Time series of measured and LLM-simulated soil moisture over the LITFASS-98 simulation period from 1 June - 20 June 1998.

been driven at the lateral and upper boundaries only by radiosonde information, because composite profiles have been available only at 9 days of the whole simulation period (9-14, 18-20 June 1998). In parallel to the measured and simulated soil-moisture curves the 24 hour-rain-sums at 7 days with precipitation can also be seen in Fig. 5.29.

Prior to an interpretation of the LLM-results against measurements some comments about the measurements must be given. It is important to note that the uppermost measurement point is in a depth of 0.15 m, while further three points are placed at depths of 0.3, 0.6 and 0.9 m. In order to have initial values from these points for the given soil-model, the value at 0.15 m depth is used to be valid in the uppermost active model layer with its thickness of 0.1 m, while a vertical mean taken from the three lowest points is assumed to be valid in the second active soil-model layer.

Fig. 5.29 demonstrated that these values seem to be unsuitable for the model validation. At least, it can be seen that for the uppermost layer the curve derived from measurements differs significantly from the LLM-simulation. The reason is that the upper measurement point with its depth of 0.15 m is not appropriate to be used in the upper soil-model layer having a depth of 0.1 m. But it is unavoidable to do so. As one can see this kind of initialization error seems incidentally diminished due to considerable precipitation on 1 June 1998. The model simulation shows a more believable result in the upper layer compared to the measured values (which are provided every 10 minutes). Already in the afternoon of that first day a strong shower led to a considerable increase of the soil moisture in the upper layer from 8 %vol. to about 20 %vol. As a consequence, the second integration day started from a much higher soil moisture value while the measured one remained much smaller from a rather slow growth rate. On the second day no precipitation occurred. This led to a decrease of soil-moisture. Measurements, however, indicated a further slow increase. The moisture was obviously transported downwards with some delay. After a further moisture increase from precipitation on 3 June the upper model layer dried out over the next days down to 7 % vol. The degree of drying out seems to be caused by a small plant cover of 0.27 due to assumed grassland. That decrease is, however, not continuous and shows a diurnal course.

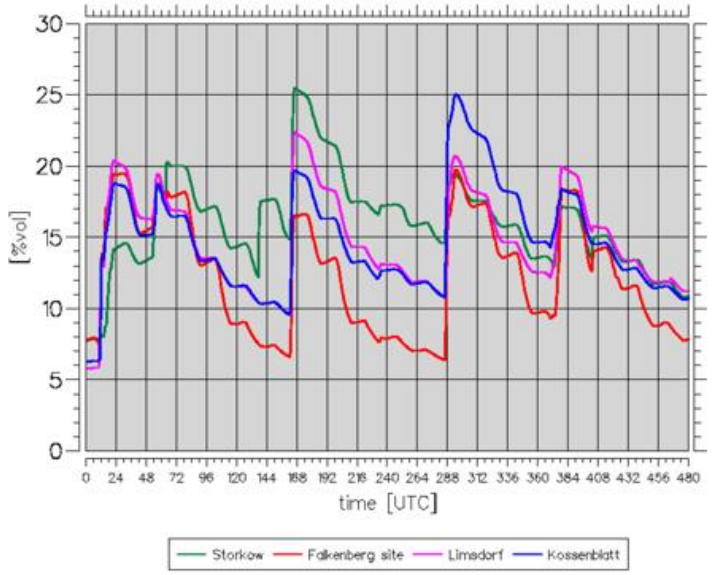

Figure 5.30: Time series of LLM-simulated soil moisture at different locations within the LLM area from 1 June - 20 June 1998.

Here, we drop a further quantitative discussion in this way.

In general, it should be noticed that the soil moisture of the uppermost layer in the model indicates a very sensitive response to precipitation, and it tends to be either significantly higher or smaller than the measured values. From that point of view we have made the decision to initialize each 24-hour run with a simulated moisture value, while the virtue of the measurement is not obvious as long as it is recorded actually 5 cm deeper than the 10-cm thickness of the uppermost soil-model layer. In case of the second active layer a comparison between measured and simulated values cannot be qualified although they show a slightly contrary trend.

Coming to an end, in Fig. 5.30 we show to what extent the soil-moisture can vary over the LLM-integration area as the result of simulations over the above mentioned 20-day LITFASS-98 period as in the previous Fig 5.29. In Fig. 5.30 the same time-variation of the soil-moisture from the uppermost layer at the Falkenberg measurement site is shown and further curves from three selected locations (Fig. 5.31) are added to demonstrate the possible inhomogeneity following from LLM-integrations. The added places are the stations Storkow, Limsdorf and Kossenblatt, where on average over the LITFASS-98 simulation period relative maxima of precipitation occurred.

The corresponding curves in Fig. 5.30 are a sample from the inhomogeneous soil-moisture distribution demonstrating one aspect of a great manifold of results from the rather extensive simulations with the LLM. The simulated soil-moisture variations in time and location indicate the result of a complex interplay between the processes in the soil, in the near-surface atmospheric region and at the interface between both subsystems. Here, these special results were shown first of all to complete the description and documentation of the present state of the LLM implying a great variety of aspects, theories and pragmatic concepts in strict relation to the observational potential and the richness of an elaborated data-pool due to the LITFASS project.

An Epilogue to Part I

Although in the Introduction announced that the entire LLM-report will contain nine Chapters, the presented Part I with its first five Chapters may be already reason enough to us for some comments and acknowledgements. First of all, the authors dedicate their paper to Dr. E. Müller. He gave the decisive impetus to the LITFASS-project, and it was particularly his basic idea to determine near-surface turbulent fluxes over a realistic inhomogeneous area like Lindenberg by use of a high-resolving nonhydrostatic simulation model. It was a great challenge for us to start working in this field and to bring that task till to the present state. We will not deny our feeling to have worked not only hard over a longer time but to have also always been conscious of taking part in a DWD-pilot project of sustainable meaning, where all the investment over that project time is now available to connect observatory capacity immediately with the urgent needs of NWP - and to have contributed so far with our efforts in this line. We appreciate very much E. Müller's productive impatience, criticism and his permanent interest over most of the project time until his retirement.

Furthermore, all the countless working meetings and discussions in various circles of colleagues from the NWP modelling groups of the Research/Development field and the Observatory Lindenberg have been indispensible. In that way a close cooperation with Dr. E. Heise, the leader of the NWP-parameterization group, must be emphasized, who himself was involved in the LITFASS-project from the very beginning. In the first years of the project Prof. Th. Foken has been the leader and coordinator. After that, Dr. F. Beyrich's intensive conduction of LITFASS brought us great benefit due to his indivisible sense of responsibility both for the measurement - and the simulation component. Concerning important details, we are thankful to Prof's H. Fortak, G. Groß and to Dr. A. Dörnbrack for several hints, advices and their general interest to our topic. Almost all extensive LLM-integrations has been carried out at the ECMWF. The care for the great many of series of LLM-runs was excellent. We are very grateful to the people in the Computing Centre there, who were involved with our jobs. In particular, N. Kreitz from the User Support has actually supported us very intensively.

Concerning ourselves, the first author was told to be responsible for the whole LLM-subproject of LITFASS, while he is also responsible for the subjects of Chapters 1-4 and 7 in Part II. Dr. G. Vogel is responsible for the content of Chapter 5 and in Part II for Chapters 6 and 8. Mrs. Dr. U. Schubert's contributions are overlapping. She has solved all problems of programming and program organization concerning the specific LLM-problem of external real-data updating at low, lateral and upper boundaries, and moreover, she has organized and managed all computing runs at ECMWF, the postprocessing there included. She wrote Chapter 9 about the LLM-computing problems. Mrs. A. Fiedler is responsible for all programs in parallel code contained in Chapters 2-4 (lateral boundary technique, inclusion of 3D-turbulent flux termes, TKE-SGS model) and for preparing all Figures in these Chapters. Mrs. R. Kirchner's contributions and untiring efforts concern the widespread delivery and preparation of model- and measurement data necessary for the LLM and for different purposes of validation. Finally, the authors are very grateful to Mrs. E. Sulz for her reliable assistance in the wide field of postprocessing and to Mrs. Ch. Baudach, who wrote the text in that final form.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *Consortium for Small-Scale Modelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (UGM, ARPA-SMR) and Switzerland (MeteoSwiss). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the Lokal-Modell (LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completition of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction

It is well known that in numerical atmospheric simulation models for vertical discretisation a so-called Lorenz (L-)-grid or a Charney-Phillips (CP-)-grid is normally applied in order to define the staggered placement of model variables at grid points along the vertical. In case of an L-grid the variables of temperature, pressure and horizontal momentum are placed at 'main-levels', each of them centred within a finite model layer, while the vertical velocity is assumed to be positioned at 'half-levels', which are the interface levels between adjacent model layers. The difference of the CP-grid to the L-grid consists in having placed temperature together with vertical velocity at half-levels. For instance, the Lokal-Modell of the DWD uses an L-grid, while the Unified Model of the United Kingdom Met Office is based on a CP-grid. A representative discussion of pros and cons concerning both types of vertical grid staggering can be found in a thorough paper by Arakawa (2000). There, Arakawa gives statements and draws conclusions from his own work and so from many other authors that the CP-grid seems preferable compared to the L-grid also widespread in use. In order to characterise an obvious shortcoming of the L-grid we quote from Arakawa's article (2000, p.721-780) the following statement: 'The problem with the L-grid is due to the existence of an extra degree of freedom in the vertical distribution of θ that cannot be controlled by any baroclinic (or internal) modes... This extra degree of freedom introduces a vertical "computational mode" in the solution, characterised by a zigzag vertical structure of θ, which has no counterpart in the solutions of the continuous equation... It is important to note, that this problem with the L Grid is a property of the grid rather than of a particular scheme. An increase in order of accuracy does not reduce the error due to this mode because a computational mode cannot become "accurate" since there is no corresponding true solution with which to compare it.'
This statement is a more general motivation, but due to the fact that the Lokal-Modell (=LM) as a model of particular interest uses an L-grid, our concern and starting point comes immediately from a paper by Arakawa and Konor (1996). In this article the main point we are interested in is the author's comparing numerical simulations with the L-grid and the CP-grid. For this, they use two linearised versions of a primitive equation model for meridionally uniform perturbations, one for the grid type L and the other for the CP-grid. In order to show the existence of a computational mode produced by the L-grid and to demonstrate that this artificial effect is avoided in case of a CP-grid, a local initial potential temperature perturbation as one specific set of integration is imposed on a resting isothermal ($T_0 = 250K$) basic state on a zonally cyclic f-plane. The model uses simple centered vertical differences on a p-coordinate and 40 equally spaced layers below 100 Pa. For a detailed description of the model equations and the experimental set-up we refer to Arakawa and Konor (1996). The unbalanced initial perturbation in θ' is set equal to 0.5 K at levels with vertical index k=39/39.5 (k-index is counted downward), and with opposite sign at the adjacent level designed by k=38/38.5 for the L-grid/CP-grid, and $\theta' = 0$ everywhere else.
As an introduction for our own numerical experimentation we deliberately describe and show the experimental set-up and important results from Arakawa and Konor, concerning the isolated effect of a computational mode due to the L-grid. In Figure 1 an important result from the author's original paper is therefore shown again (original Figure 3 from Monthly Weather Review 124, at page 521): The original legend is sufficiently self-explaining. It shows in a time-height plot the evolution over 48 hours integration time of an initially specified spectral perturbation amplitude for two horizontal wave components with a wavelength of 100 km and 250 km, respectively. From another quotation in the relevant paper that simulation result may be characterised as follows. In case of the L-grid simulation '... The flow is dominated by stationary components... The vertically propagating oscillatory component is weak, having significant amplitudes only during early hours.' A pure artificial vertical zigzag structure is obvious. For the CP-grid, however, '... The simulation shows vertical propagation and almost complete dispersion of initial perturbations...' and a stationary computational mode does not occur.

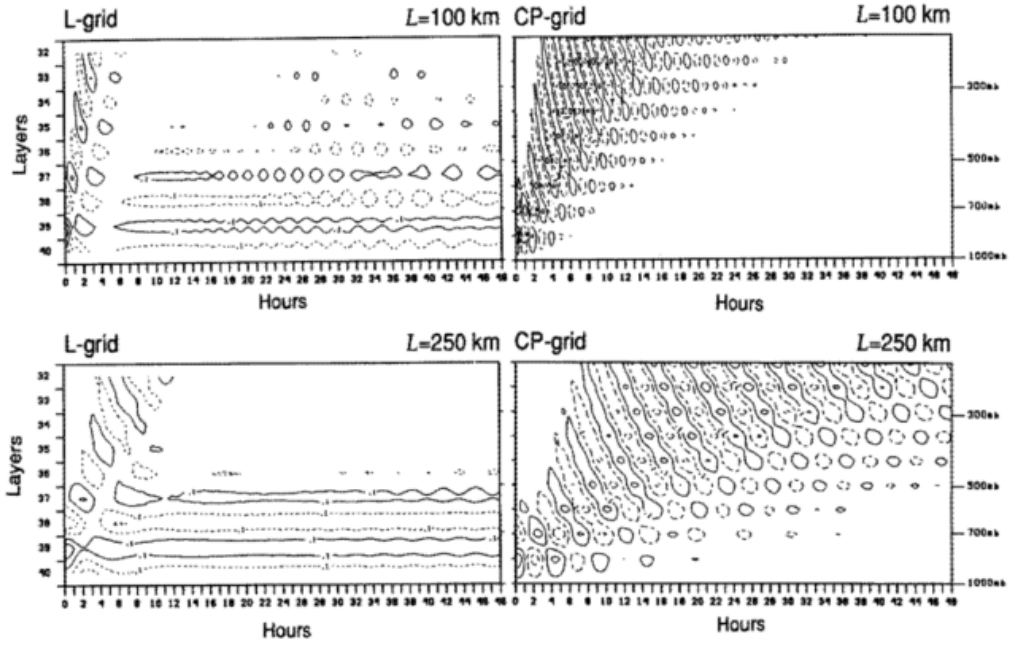

FIG. 3. Time evolution of the potential temperature perturbation θ' (K) in the lower portion of the vertical domain obtained from the models based on the Lorenz (left panels) and Charney–Phillips (right panels) grids for horizontal wavelengths L = 100 km (upper panels) and L = 250 km (lower panels). Simulations are started from unbalanced θ' at two adjacent levels with opposite signs. Solid and dashed lines correspond to positive and negative values, respectively. The contour interval is 0.2 K starting from ±0.1 K.

Figure 1: Original figure taken from Arakawa, A., and C.S. Konor, 1996 (see References)

In a first step of our following numerical simulations we are going to copy as exact as possible both the hydrostatic simulation model and the numerical set-up from Arakawa and Konor's paper, who provide the reader with a fairly good description of their approach. On this ground we were then easily able to copy the results from and could have obtained in such a way a comfortable method, and also an appropriate calibration tool, for our concern with a nonhydrostatic model having important characteristics of the fast-mode part of the LM. With the adopted thickness and number of model layers we were able to demonstrate for the LM-like compressible nonhydrostatic model with L-grid versus CP-grid simulation results similar to Arakawa and Konor's in case of hydrostatic gravity waves, where a computational mode is revealed in case of the L-grid type model, while it is avoided by using a CP-type model. To obtain this sort of simulations in a fairly neat form, we felt it necessary to introduce, in addition, a non-reflective upper boundary condition. Instead of a Rayleigh relaxation-type we have applied an radiative upper boundary condition (=RUBC) as suggested from Klemp and Durran (1983) and Bougeault (1983). Within the scope of this LM-toy model with essential components of the fast mode part of the real LM the possible occurrence of a computational mode due to the L-grid and the application of a CP-grid instead in order to avoid this numerical nuisance will be demonstrated. At this stage of work it seems however too early for a generalisation of that simulation results to draw already the conclusion that the vertical grid staggering in the LM should be changed from the L- to the CP-grid immediately. Neverthless, the results demonstrated in this contribution give serious hints that the LM is suspected to have possible unwanted numerical shortcomings related to the applied L-grid which are worth studying further in a more specific and systematic manner. The importance of this should be underlined by still another quotation from the key paper of Arakawa and Konor: 'The problem of the existence of the computational mode can be serious, especially in the models that include moist processes, since the computational mode can spuriously interact with the physical mode through inherently nonlinear condensation and associated processes. An example of the latter is the effect of cloud layers generated by the zigzag vertical structure of the potential temperature on the radiation field.'

2 A duplicate of Arakawa and Konor's simulation

As explained above we are interested in an almost exact repetition of numerical simulations from Arakawa and Konor (1996). Their results have been depicted in our Figure 1 (taken from the original paper). With strict quotation from that paper all the background may be assumed to be known, that is, how this simulation experiment has been conducted and the model and the numerics were

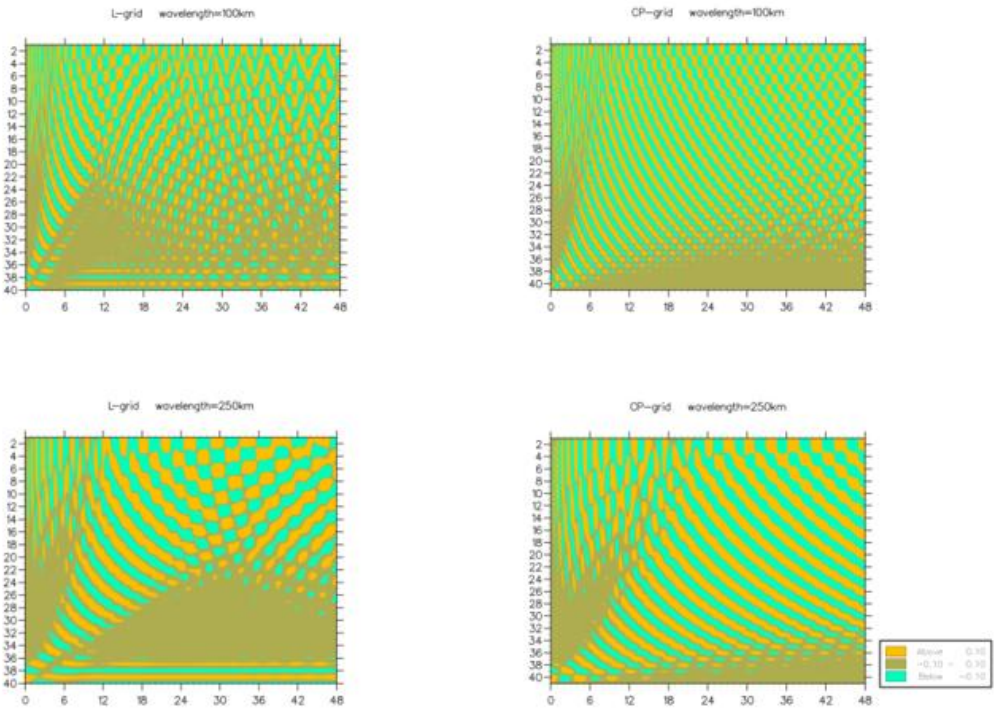

Figure 2: Almost the same result as in Figure 1, but over the entire integration domain, for L-grid (left panels) and CP-grid (right panels) and for horizontal wavelengths 100km (upper panels) and 250km (lower panels). For more details see text.

designed. Moreover, the comments describing the special experiment were already noted in the Introduction and need not be repeated here. In order to almost copy the result of interest shown in Figure 1, we decided to apply the leap-frog scheme as an sufficient numerical time-integration method, and for sake of caution, an Asselin time filter is added at every time step. In case of the model version with L=250km, the time step is chosen $\Delta t = 90s$, for L=100km we used $\Delta t = 30s$. In this way we are now in a position to be able to show the almost identical outcome, but here over the entire integration area, from the lower boundary (at 100000 Pa) up to the upper boundary (at 100 Pa) over 40 equally spaced layers, where the time evolution of the potential temperature perturbation in the lowest 9 layers of Figure 1 is recovered fairly good in Figure 2. In addition to a qualitative discussion of Figure 1 , and so of Figure 2, we make out that the gravity wave perturbations, here expressed in terms of potential temperature and caused by the defined initial state, propagate upward over a wider range of signal velocities different in dependence of an L-grid or a CP-grid, and that in any case these propagating perturbations are reflected at the upper boundary due to an lid condition imposed there. The reflected wave component as an obvious artificial phenomenon can then 'contaminate' in case of the L-grid even the computational mode of our concern. For the smaller spectral component with L=100km the degree of reflection seems more obvious than for L=250km, and for the experimental set with an CP-grid the strength of reflection seems apparently reduced compared to the model version with L-grid.

In the following we are interested in eliminating the reflected wave mode, which may be done by use of a radiative upper boundary condition (RUBC) instead of the lid condition. For the Arakawa-Konor model (AKM), which is linear and a hydrostatic one, the Klemp-Durran-Bougeault typ of an RUBC (=KDB-RUBC) is expected to be sufficient as an appropriate tool. Since the model variables in the AKM are spectral amplitudes of a horizontal wave component depending on pressure and time, the application of the KDB-RUBC is ideal. As known, this BC is local in time but global over the upper boundary level. In general, this needs the Fourier transforms of vertical motion and a mass variable at the upper boundary. Here, the RUBC is easily formulated in terms of the defined model variables without an additional transform. The reader may be convinced about this from a necessary reference to the original paper of Arakawa and Konor (1996). After a thorough and classical analysis we can derive the appropriate RUBC for the given AKM. It reads

$$\hat{\omega}_{top} = -\frac{k\ p_{top}}{c_0}\hat{\phi}_{top} \tag{1}$$

instead of the lid condition $\hat{\omega}_{top} = 0$. For the perturbation geopotential and vertical velocity variables of the given model we have

$$\phi^{'}(x,p,t) = \hat{\phi}(p,t)\ sin\, kx \quad , \quad \omega^{'}(x,p,t) = \hat{\omega}(p,t)\ sin\, kx \tag{2}$$

with horizontal wavenumber $k = 2\pi/L$, $p_{top} = 100\,Pa$, and the parameter $c_0 = +\sqrt{\kappa R T_0}, \kappa = c_p/c_v$. Here we make use of the normal meteorological notation also valid for the AKM . This form of a KDB-RUBC has been applied in the AKM for both its L-grid and its CP-grid version. It is important to note that in accordance with (1) the geopotential needed at the upper boundary (the uppermost half-level) must be extrapolated by use of an uncentered difference form of the hydrostatic equation different for L-grid and CP-grid due to different positions of the potential temperature on these grids. In that way we have repeated the AKM simulations, and the corresponding results are shown in Figure 3 [1] for the case with L =100km.

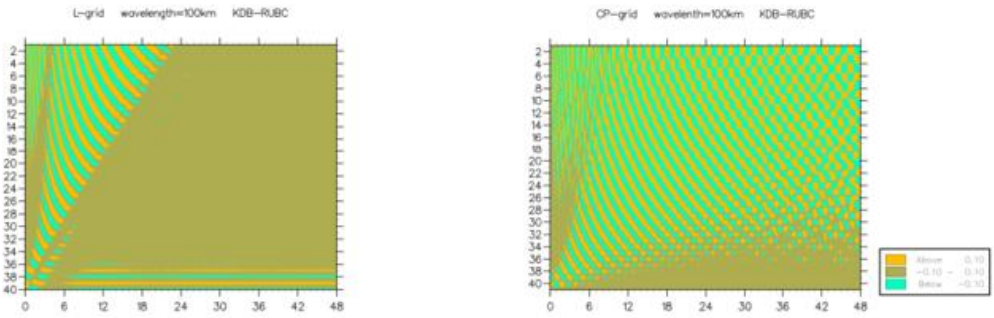

Figure 3: Repetition of Arakawa and Konor's (1996) simulation for L-grid and CP- grid with L =100km, but a radiative upper boundary condition taken into account (compare with upper panel of Figure 2).

A comparison with Figure 2 demonstrates that the reflection from the upper boundary could be removed as desired. Similar results not shown here were found for the wavelength L= 250km. In contrast to the CP-grid, we observe for the L-grid simulation a significant limitation of the gravity wave dispersion process accompanied by the stationary zigzag phenomenon of a computational mode.

[1] It needs a technical remark concerning Figures 2 and 3 and so on all Figures of this type. The contour colours are meant as follows: *brown* covers an interval from $\pm\,0.1\ K$, *yellow* covers values $>\ 0.1\ K$, and *green* is valid for $<\ -0.1\ K$

3 An LM fast-wave toy-model

With the information from Arakawa and Konor's simulation example, we turn now to the compressible nonhydrostatic equations in a linearised form, having in mind the relation to the fast-mode part of the LM. For this we refer to a thorough description of the LM dynamics and numerics documented by Doms and Schättler (2002). On this ground we are going to derive an appropriate simulation model with properties as much as possible of Arakawa and Konor's model set-up.

3.1 Model equation set

Starting point is the following equation set

$$\frac{\partial u'}{\partial t} = -\frac{1}{\bar{\rho}}\left(\frac{\partial p'}{\partial x} - \frac{1}{\sqrt{\gamma}}\frac{\partial \bar{p}}{\partial x}\frac{\partial p'}{\partial \zeta}\right) + f_0 v' \tag{3}$$

$$\frac{\partial v'}{\partial t} = \quad -f_0 v' \tag{4}$$

$$\frac{\partial w'}{\partial t} = \frac{g}{\sqrt{\gamma}}\frac{\partial p'}{\partial \zeta} - g\left(\frac{p'}{\bar{p}} - \frac{T'}{\bar{T}}\right) \tag{5}$$

$$\frac{\partial p'}{\partial t} = g\bar{\rho}w' - \kappa\bar{p}\left(\frac{\partial u'}{\partial x} - \frac{1}{\sqrt{\gamma}}\frac{\partial \bar{p}}{\partial x}\frac{\partial u'}{\partial \zeta} - \frac{g\bar{\rho}}{\sqrt{\gamma}}\frac{\partial w'}{\partial \zeta}\right) \tag{6}$$

$$\frac{\partial T'}{\partial t} = \frac{g\bar{\rho}}{\sqrt{\gamma}}\frac{d\bar{T}}{d\zeta}w' - \frac{\kappa}{c_p}\frac{\bar{p}}{\bar{\rho}}\left(\frac{\partial u'}{\partial x} - \frac{1}{\sqrt{\gamma}}\frac{\partial \bar{p}}{\partial x}\frac{\partial u'}{\partial \zeta} - \frac{g\bar{\rho}}{\sqrt{\gamma}}\frac{\partial w'}{\partial \zeta}\right) \tag{7}$$

These equations follow approximately from the fast-mode equation part of the LM by consequent linearisation. The perturbation variables (primed entities) are assumed to be meridionally uniform. Spherical metric terms have been dropped for the sake of simplicity. The variables $\bar{p}$, $\bar{\rho}$, $\bar{T}$ constitute a hydrostatic basic state. The vertical coordinate ζ is meant just as in the LM. In relation to the usual z-coordinate the following operator is valid

$$\frac{\partial}{\partial z} = -\frac{g\bar{\rho}}{\sqrt{\gamma}}\frac{\partial}{\partial \zeta} \tag{8}$$

Here, the reciprocal pre-factor $\left(\sqrt{\gamma}\right) / \left(g\bar{\rho}\right)$ is defined as the Jacobian of the transformation from the z- to the ζ - coordinate. The equation set (3) - (7) deviates slightly from the present formulation in the fast-wave part of the LM. In order to take into account inertia-gravity waves, that is without separation of the rotational effect, the Coriolis terms are included here. Further, we emphasize the presence of the first term on the right-hand side of equation (7), which is significant in case of a non-isothermal basic state as it is for the LM. There, a polytropic state is stipulated. Neglecting the term in that case leads however to an inconsistency concerning the gravity wave energetics and an overestimation of the gravity wave frequencies. To evade this problem a-priori, a prognostic equation for θ' should be used rather than for T'. We do so , although from the discussed point of view unnecessary, because we prefer an isothermal basic state which makes that term vanishing.

With this choice we are deliberately in accordance with the basic state of the AKM. Without any loss of physical background the vertical z- coordinate is simply taken, and a horizontally plane terrain may be sufficient for our considerations to be assumed. Thus, we change with these assumptions from (3) - (7) to a physically identical set

$$\frac{\partial u^{'}}{\partial t} = -\frac{1}{\bar{\rho}}\frac{\partial p^{'}}{\partial x} + f_0 v \tag{9}$$

$$\frac{\partial v^{'}}{\partial t} = -f_0 u^{'} \tag{10}$$

$$\frac{\partial w^{'}}{\partial t} = -\frac{1}{\bar{\rho}}\frac{\partial p^{'}}{\partial z} - \frac{g}{\bar{\rho}\, c_s^2}\, p^{'} + \frac{g}{\bar{\theta}}\theta^{'} \tag{11}$$

$$\frac{\partial p^{'}}{\partial t} = g\bar{\rho} w^{'} - c_s^2 \bar{\rho}\left(\frac{\partial u^{'}}{\partial x} + \frac{\partial w^{'}}{\partial z}\right) \tag{12}$$

$$\frac{\partial \theta^{'}}{\partial t} = -\frac{N^2}{g}\bar{\theta}\; w^{'} \tag{13}$$

For the isothermal basic state we have

$$N^2 = \frac{g}{\bar{\theta}}\frac{d\bar{\theta}}{d\, z} = \frac{g^2}{c_p\, T_0}\;\;,\;\; \bar{\theta} = T_0\; exp\left(\frac{N^2}{g} z\right)\;\;,\;\; \bar{\rho} = \frac{p_s}{R\, T_0}\; exp\left(-\frac{g}{c_p T_0} z\right) \tag{14}$$

with the familiar constants $c_s^2 = \kappa \bar{p}/\bar{\rho} = \kappa\; RT_0\;\;,\;\; \kappa = c_p/c_v\;\;,\;\; T_0 = 250K$, and $p_s = 100000\, Pa$ at the lower boundary. In order to perform similar numerical experiments as Arakawa and Konor (1996) demonstrated, we assume also that the perturbations are horizontally standing waves in the forms:

$$\begin{gathered} u^{'}(x,z,t) = \hat{u}(z,t)\, cos\, kx\;\;,\;\; v^{'}(x,z,t) = \hat{v}(z,t)\, cos\, kx \\ w^{'}(x,z,t) = \hat{w}(z,t)\, sin\, kx\;\;,\;\; p^{'}(x,z,t) = \hat{p}(z,t)\, sin\, kx\;\;,\;\; \theta^{'}(x,z,t) = \hat{\theta}(z,t)\, sin\, kx \end{gathered} \tag{15}$$

$k = 2\pi/L$ is the zonal wavenumber with the wavelength L. Inserting the wave-components (15) into the above equation set, we obtain a simple prognostic equation system for the perturbation amplitudes of their horizontal wave-components with wavelength L:

$$\frac{\partial \hat{u}}{\partial t} = -\frac{k}{\bar{\rho}}\hat{p} + f_0 \hat{v} \tag{16}$$

$$\frac{\partial \hat{v}}{\partial t} = -f_0 \hat{u} \tag{17}$$

$$\frac{\partial \hat{w}}{\partial t} = -\frac{1}{\bar{\rho}}\frac{\partial \hat{p}}{\partial z} - \frac{g}{\hat{\rho} c_s^2}\hat{p} + \frac{g}{\bar{\theta}}\hat{\theta} \tag{18}$$

$$\frac{\partial \hat{p}}{\partial t} = g\bar{\rho}\hat{w} - c_s^2\bar{\rho}\left(\frac{\partial \hat{w}}{\partial z} - k\,\hat{u}\right) \tag{19}$$

$$\frac{\partial \hat{\theta}}{\partial t} = -\frac{N^2\bar{\theta}}{g}\hat{w} \tag{20}$$

The associated local total energy budget equation reads

$$\frac{\partial}{\partial t}\left[\frac{1}{2}\bar{\rho}\left(\hat{u}^2+\hat{v}^2+\hat{w}^2\right) + \frac{1}{2c_s^2\bar{\rho}}\hat{\rho}^2 + \frac{g^2\bar{\rho}}{2N^2}\left(\frac{\hat{\theta}}{\bar{\theta}}\right)^2\right] = -\frac{\partial\left(\hat{p}\;\hat{w}\right)}{\partial z} \tag{21}$$

and, for some reasoning further below, we note here the normal mode frequencies for the internal gravity waves solution (ω_g) and the acoustic wave solution (ω_a) of the equation set (16) - (20) with the rotational effect ignored $(f_0 = 0)$, following an usual analysis:

$$\omega_a^2 \approx c_s^2\left(k^2+n^2+\frac{1}{4H^2}\right) \tag{22}$$

$$\omega_g^2 \approx \frac{k^2N^2}{k^2+n^2+\frac{1}{4H^2}} \tag{23}$$

n denotes a vertical wavenumber, and H , $\left(H^{-1} = g/c_s^2 + N^2/g\right)$, a constant vertical scale height.

3.2 Time differencing scheme

For our linear system (16) - (20) we are going to adopt the time integration scheme as close as possible from the fast mode part of the LM. To compare that with the LM we refer to the thorough LM-documentation by Doms and Schättler (2002) and there with further quotations of Skamarock and Klemp (1992), Ikawa (1988), and Dudhia (1993). With that application we have here

$$\frac{\hat{u}^{(\tau+1)} - \hat{u}^{(\tau)}}{\Delta t} = -\frac{k}{\bar{\rho}}\hat{p}^{(\tau)} + f_0\hat{v}^{(\tau+1)} \tag{24}$$

$$\frac{\hat{v}^{(\tau+1)} - \hat{v}^{(\tau)}}{\Delta t} = -f_0\hat{u}^{(\tau+1)} \tag{25}$$

$$\begin{aligned}\frac{\hat{w}^{(\tau+1)} - \hat{w}^{(\tau)}}{\Delta t} = &-\frac{1}{\bar{\rho}}\left(\beta^+\frac{\partial \hat{p}^{(\tau+1)}}{\partial z} + \beta^-\frac{\partial \hat{p}^{(\tau)}}{\partial z}\right)\\ &-\frac{g}{\bar{\rho}c_s^2}\left(\beta^+\hat{p}^{(\tau+1)} + \beta^-\hat{p}^{(\tau)}\right) + \frac{g}{\bar{\theta}}\hat{\theta}^{(\tau)}\end{aligned} \tag{26}$$

$$\begin{aligned}\frac{\hat{p}^{(\tau+1)} - \hat{p}^{(\tau)}}{\Delta t} = &\;g\bar{\rho}\left(\beta^+\hat{w}^{(\tau+1)} + \beta^-\hat{w}^{(\tau)}\right)\\ &-c_s^2\bar{\rho}\left(\beta_+\frac{\partial \hat{w}^{(\tau+1)}}{\partial z} + \beta^-\frac{\partial \hat{w}^{(\tau)}}{\partial z}\right) + c_s^2\bar{\rho}\,k\,\hat{u}^{(\tau+1)}\end{aligned} \tag{27}$$

$$\frac{\hat{\theta}^{(\tau+1)} - \hat{\theta}^{(\tau)}}{\Delta t} = -\frac{N^2\bar{\theta}}{g}\left(\beta^+\hat{w}^{(\tau+1)} + \beta^-\hat{w}^{(\tau)}\right) \tag{28}$$

As one can see, the terms for vertically propagating waves are treated implicitly. For the weights of averaging these terms we have

$$\beta^+ = \frac{1}{2}(1+\varepsilon) \quad , \quad \beta^- = \frac{1}{2}(1-\varepsilon) \tag{29}$$

with the LM default-value $\varepsilon = 0.4$, determining the strength of implicity of the scheme. Since the scheme in this form behaves neutral for acoustic waves, a so-called divergence damping is added in the horizontal momentum equations as a remedy, which in our case means that in equation (24) the pressure in the gradient term is replaced such

$$\hat{p}^{(\tau)} := \hat{p}^{(\tau)} + \alpha_d\,\Delta t\,\bar{\rho}c_s^2\left(k\,\hat{u}^{(\tau)} - \frac{\partial\hat{w}^{(\tau)}}{\partial z}\right) \tag{30}$$

$\alpha_d = 0.1$ is the default-value used in the LM. We drop here critical remarks concerning this measure. The inclusion of the rotation terms in the momentum equations deviates from the LM fast-mode part, but is a concession to the AKM with which we want to compare our solutions. For the sake of stability these terms are formulated implicitly.

3.3 Vertical discretisation with an L-grid

In addition to the semi-discrete equations (24)- (28) with an LM-specific time differencing scheme, we want to exactly apply the vertical layering from the AKM with either an L-grid or a CP-grid. We introduce the L-grid first. In this way the scheme is shown in Figure 4

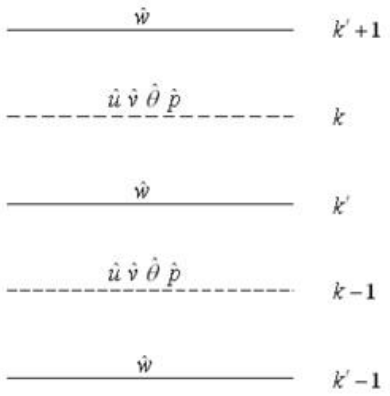

Figure 4: Vertical staggering of variables of LM fast-wave toy-model with equally spaced layers in accordance with AKM (see text)

As can be seen, the variables $\hat{u}, \hat{v}, \hat{\theta}, \hat{p}$ (and also $\bar{\rho}, \bar{\theta}$, not shown in Figure 4) are positioned at main-levels indicated with indices $k \in [1, ke]$, while the perturbation amplitude of vertical velocity, $\hat{w}$, is defined at so-called half-levels with index numbering $k' \in [1, ke1]$. Coinciding with the numerical set-up in the AKM, we assume 40 model layers, which means $ke = 40$ and $ke1 = ke + 1$. In accordance with a vertical z-coordinate the index k is counted upward here, which is in contrast to

the LM with its terrain-following coordinate. The thickness of model-layers is constant. It is given by

$$\Delta z = \frac{1}{40}\frac{RT_0}{g} ln(1000) \qquad . \tag{31}$$

With that scheme we introduce simple centred differences in the vertical in the equation system (24) - (28), which leads straightforward to the following difference equation system:

$$\hat{u}_k^{(\tau+1)} = \hat{u}_k^{(\tau)} - \Delta t \frac{k}{\bar{\rho}} \hat{p}_k^{(\tau)} + f_0 \, \Delta t \, \hat{v}_k^{(\tau+1)} \tag{32}$$

$$\hat{v}_k^{(\tau+1)} = \hat{v}_k^{(\tau)} - \Delta t \, f_0 \, \hat{u}_k^{(\tau+1)} \tag{33}$$

for $k \in [1, ke]$.

$$\begin{aligned} \hat{w}_{k'}^{(\tau+1)} = \hat{w}_{k'}^{(\tau)} &- \frac{2}{\bar{\rho}_{k-1} + \bar{\rho}_k} \left(\frac{\Delta t}{\Delta z}\right) \beta^+ \left(\hat{p}_k^{(\tau+1)} - \hat{p}_{k-1}^{(\tau+1)}\right) \\ &- \frac{2}{\bar{\rho}_{k-1} + \bar{\rho}_k} \left(\frac{g \Delta t}{2c_s^2}\right) \beta^+ \left(\hat{p}_k^{(\tau+1)} + \hat{p}_{k-1}^{(\tau+1)}\right) + C_{k'}^w \end{aligned} \tag{34}$$

with

$$\begin{aligned} C_{k'}^w = &- \frac{2}{\bar{\rho}_{k-1} + \bar{\rho}_k} \left(\frac{\Delta t}{\Delta z}\right) \beta^- \left(\hat{p}_k^{(\tau)} - \hat{p}_{k-1}^{(\tau)}\right) \\ &- \frac{2}{\bar{\rho}_{k-1} + \bar{\rho}_k} \left(\frac{g \Delta t}{2c_s^2}\right) \beta^- \left(\hat{p}_k^{(\tau)} + \hat{p}_{k-1}^{(\tau)}\right) + \frac{g \Delta t}{2} \left(\left(\frac{\hat{\theta}^\tau}{\bar{\theta}}\right)_k + \left(\frac{\hat{\theta}^\tau}{\bar{\theta}}\right)_{k-1}\right) \end{aligned} \tag{35}$$

$$\begin{aligned} \hat{p}_k^{(\tau+1)} = \hat{p}_k^{(\tau)} &- \left(\frac{c_s^2 \Delta t}{\Delta z}\right) \bar{\rho}_k \; \beta^+ \left(\hat{w}_{k'+1}^{(\tau+1)} - \hat{w}_{k'}^{(\tau+1)}\right) \\ &+ \left(\frac{g \Delta t}{2}\right) \bar{\rho}_k \; \beta^+ \left(\hat{w}_{k'+1}^{(\tau+1)} + \hat{w}_{k'}^{(\tau+1)}\right) + C_k^p \end{aligned} \tag{36}$$

with

$$\begin{aligned} C_k^p = &- \left(\frac{c_s^2 \Delta t}{\Delta z}\right) \bar{\rho}_k \; \beta^- \left(\hat{w}_{k'+1}^{(\tau)} - \hat{w}_{k'}^{(\tau)}\right) \\ &+ \left(\frac{g \Delta t}{2}\right) \bar{\rho}_k \; \beta^- \left(\hat{w}_{k'+1}^{(\tau)} + \hat{w}_{k'}^{(\tau)}\right) + \Delta t \, c_s^2 \, k \, \bar{\rho}_k \, \hat{u}_k^{(\tau+1)} \end{aligned} \tag{37}$$

for $k \in [1, ke]$.

$$\hat{\theta}_k^{(\tau+1)} = \hat{\theta}_k^{(\tau)} - \left(\frac{N^2 \bar{\theta}}{g}\right)_k \Delta t \left[\beta^+ \left(\frac{\hat{w}_{k'}^{(\tau+1)} + \hat{w}_{k'+1}^{(\tau+1)}}{2}\right) + \beta^- \left(\frac{\hat{w}_{k'}^{(\tau)} + \hat{w}_{k'+1}}{2}\right)\right] \tag{38}$$

for $k \in [1, ke]$.

For the application of these difference equations boundary conditions for $\hat{w}$ have to be taken into account

$$\begin{aligned} &\text{at the lower boundary:} \quad \hat{w}_1 = 0 \quad \text{and} \\ &\text{at the upper boundary:} \quad \hat{w}_{ke1} = 0 \quad \text{(lid-condition).} \end{aligned} \tag{39}$$

(It should be mentioned, that our notation is not quite consistent, since the symbol k is used to indicate both the horizontal wavenumber and a vertical gridpoint index as subscript. The physical background may, however, prevent any confusion!)

3.4 Numerical integration algorithm with an L-grid

Here, we rewrite the difference equations (32)-(39) with its implicit formulation of time differences to come to an explicit time integration process. This will be done just as demonstrated in Doms and Schättler (2002) for the LM. For the *horizontal momentum equations* (32) and (33) it follows easily

$$\hat{u}_k^{(\tau+1)} = \left(1 + \Delta t^2 \, f_0^2\right)^{-1} \left(\hat{u}_k^{(\tau)} + \Delta t \, f_0 \, \hat{v}_k^{(\tau)} - \Delta t \, \frac{k}{\bar{\rho}_k} \, \hat{p}_k^{(\tau)} \right) \tag{40}$$

$$\hat{v}_k^{(\tau+1)} = \hat{v}_k^{(\tau)} - \Delta t \, f_0 \, \hat{u}_k^{(\tau+1)} \tag{41}$$

with an additional *divergence damping* approach, where the pressure perturbation in (40) is altered:

$$\hat{p}_k^{(\tau)} := \hat{p}_k^{(\tau)} + \alpha_d \, \Delta t \, \bar{\rho}_k \, c_s^2 \left(k \, \hat{u}_k^{(\tau)} - \frac{\hat{w}_{k'+1}^{(\tau)} - \hat{w}_{k'}^{(\tau)}}{\Delta z} \right) \quad . \tag{42}$$

Due to the implicit treatment of the Coriolis terms the prognostic time-step of $\hat{u}$ is carried out first before the $\hat{v}$ - prognosis can follow.

An explicit procedure for the *vertical velocity* component must be derived next. For that purpose the pressure perturbation amplitude at the prognostic time-level $\tau + 1$, $\hat{p}_k^{(\tau+1)}$, in equation (34) is eliminated using equation (36). In the well-known manner a tri-diagonal vertical structural equation for $\hat{w}_{k'}^{(\tau+1)}$ is explicitly obtained:

$$\begin{aligned} B_2 \; \hat{w}_2^{(\tau+1)} + C_2 \; \hat{w}_3^{(\tau+1)} &= D_2^{(\tau)} \\ A_{k'} \; \hat{w}_{k'-1}^{(\tau+1)} + B_{k'} \; \hat{w}_{k'}^{(\tau+1)} + C_{k'} \; \hat{w}_{k'+1}^{(\tau+1)} &= D_{k'}^{(\tau)} \quad ; \quad k' \in \left[3, ke' - 1\right] \\ A_{ke'} \; \hat{w}_{ke'-1}^{(\tau+1)} + B_{ke'} \; \hat{w}_{ke'}^{(\tau+1)} &= D_{ke'}^{(\tau)} \end{aligned} \tag{43}$$

The right-hand side terms $D_{k'}^{(\tau)}$, at time-level τ, are known, and the time-independent coefficients $A_{k'}$,$B_{k'}$,$C_{k'}$ either. Thus, the time-extrapolated values of $\hat{w}_{k'}^{(\tau+1)}$, for $k' \in \left[2, ke'\right]$, can be determined from a Gaussian elimination process with an adherence condition at the lower boundary, $\hat{w}_1 = 0$, and a lid-condition at the upper boundary, $\hat{w}_{ke1} = 0$. The coefficients $A_{k'}$,$B_{k'}$,$C_{k'}$ and the function $D_{k'}^{(\tau)}$ in (43) read

$$A_{k'} = \left(\beta^+\right)^2 \frac{\bar{\rho}_{k-1}}{\left(\bar{\rho}_{k-1} + \bar{\rho}_k\right)/2} \left[\left(\frac{c_s\,\Delta t}{\Delta z}\right)^2 - \left(\frac{g\,\Delta t}{2c_s}\right)^2\right] = \left(\frac{\bar{\rho}_{k-1}}{\bar{\rho}_k}\right) C_{k'} \qquad \text{for } k' \in \left[3, ke'\right] \tag{44}$$

$$C_{k'} = \left(\beta^+\right)^2 \frac{\bar{\rho}_k}{\left(\bar{\rho}_{k-1} + \bar{\rho}_k\right)/2} \left[\left(\frac{c_s\,\Delta t}{\Delta z}\right)^2 - \left(\frac{g\,\Delta t}{2c_s}\right)^2\right] = \left(\frac{\bar{\rho}_k}{\bar{\rho}_{k-1}}\right) A_{k'} \qquad \text{for } k' \in \left[2, ke' - 1\right] \tag{45}$$

$$B_{k'} = 1 + 2\left(\beta^+\right)^2 \left[\left(\frac{c_s\,\Delta t}{\Delta z}\right)^2 + \left(\frac{g\,\Delta t}{2c_s}\right)^2\right] + 2\left(\beta^+\right)^2 \left(\frac{\bar{\rho}_k - \bar{\rho}_{k-1}}{\bar{\rho}_k + \bar{\rho}_{k-1}}\right) \left(\frac{g\,(\Delta t)^2}{\Delta z}\right) \qquad \text{for } k' \in \left[2, ke'\right] \tag{46}$$

$$\begin{aligned} D_{k'} = \hat{w}_{k'}^{(\tau)} &- \frac{2\beta^+}{\left(\bar{\rho}_{k-1} + \bar{\rho}_k\right)} \left(\frac{\Delta t}{\Delta z}\right) \left[\left(\hat{p}_k^{(\tau)} - \hat{p}_{k-1}^{(\tau)}\right) + \left(C_k^p - C_{k-1}^p\right)\right] \\ &- \frac{2\beta^+}{\left(\bar{\rho}_{k-1} + \bar{\rho}_k\right)} \left(\frac{g\,\Delta t}{2c_s^2}\right) \left[\left(\hat{p}_k^{(\tau)} + \hat{p}_{k-1}^{(\tau)}\right) + \left(C_k^p + C_{k-1}^p\right)\right] + C_{k'}^w \end{aligned} \qquad \text{for } k' \in \left[2, ke'\right] \tag{47}$$

with the auxiliary variables:

$$C_k^p = -\beta^-\, c_s^2 \left(\frac{\Delta t}{\Delta z}\right) \bar{\rho}_k \left(\hat{w}_{k'+1}^{(\tau)} - \hat{w}_{k'}^{(\tau)}\right) + \beta^- \left(\frac{g\,\Delta t}{2}\right) \bar{\rho}_k \left(\hat{w}_{k'+1}^{(\tau)} + \hat{w}_{k'}^{(\tau)}\right) + \Delta t\, c_s^2\, k\, \bar{\rho}_k\, \hat{u}_k^{(\tau+1)} \qquad \text{for } k \in [1, ke] \tag{48}$$

$$\begin{aligned} C_{k'}^w = &- \frac{2\beta^-}{\left(\bar{\rho}_{k-1} + \bar{\rho}_k\right)} \left(\frac{\Delta t}{\Delta z}\right) \left(\hat{p}_k^{(\tau)} - \hat{p}_{k-1}^{(\tau)}\right) - \frac{2\beta^-}{\left(\bar{\rho}_{k-1} + \bar{\rho}_k\right)} \left(\frac{g\,\Delta t}{2c_s^2}\right) \left(\hat{p}_k^{(\tau)} + \hat{p}_{k-1}^{(\tau)}\right) \\ &+ \left(\frac{g\,\Delta t}{2}\right) \left[\left(\frac{\hat{\theta}_k^{(\tau)}}{\bar{\theta}_k^{(\tau)}}\right) + \left(\frac{\hat{\theta}_{k-1}}{\bar{\theta}_{k-1}}\right)\right] \end{aligned} \qquad \text{for } k' \in \left[2, ke'\right] \tag{49}$$

The Gaussian elimination procedure is then applied to (43)- (49) in a common way. By a 'top-down sweeping' the following auxiliary entities are determined first:

$$E_{ke'} := -\frac{A_{ke'}}{B_{ke'}} \qquad , \qquad F_{ke'} := \frac{D_{ke'}}{B_{ke'}} \tag{50}$$

and then for $k' \in \left[ke' - 1, 2\right]$:

$$\begin{aligned} E_{k'} &:= -\frac{A_{k'}}{B_{k'} + C_{k'} E_{k'+1}} \qquad , \qquad F_{k'} := \frac{D_{k'} - C_{k'} F_{k'+1}}{B_{k'} + C_{k'} E_{k'+1}} \\ E_1 &:= 0 \qquad , \qquad F_1 := \frac{D_2 - C_2 F_3}{B_2 + C_2 E_3} = \hat{w}_2^{(\tau+1)} \end{aligned} \tag{51}$$

From all following 'down-top sweeping' the vertical motion perturbation is easily calculated:

$$\hat{w}_{k'}^{(\tau+1)} = E_{k'} \hat{w}_{k'-1}^{(\tau+1)} + F_{k'} \qquad k' \in \left[3, ke'\right] \tag{52}$$

Once the prognostic *vertical motion perturbation* is calculated, the *pressure perturbation* and the *potential temperature perturbation* at that time-level can immediately be found from the equations ((36), (37)) and (38).

To complete the numerical integration algorithm, we list the constants how they are chosen in this model:

$f_0 = 10^{-4}\, s^{-1}$ - Coriolis parameter

$k \ = 2\pi / L$ - wavenumber associated with wavelength $L = 100, 250km$

$R \ = 287 m^2\, s^2\, K^{-1}$ - gas constant

$g \ = 9.80665 m\, s^{-2}$ - gravity constant

$c_p = 1005 J\, K^{-1}\, kg^{-1}$,

$c_v = 718 J\, K^{-1}\, kg^{-1}$ - specific heat at constant pressure and constant volume, respectively

$\varepsilon \ = 0.4$ - implicity parameter (see Subsection 3.2, (29))

$\alpha_d = 0.1, ...0.3$ - divergence damping parameter (see 3.2, (30))

$T_0 = 250K$ - assumption of an isothermal model atmosphere

$p_s = 100000Pa$ - pressure at lower boundary

$c_s^2 = \kappa\, RT_0\,, \ \ \kappa = c_p / c_v$ - constant sound wave speed squared

$\Delta t = 1s, ...10s$ - time-step

$\Delta z = (1/40)\, RT_0\, 1n\,(1000)\,/g$ - constant model layer thickness of the 40-layer model

together with formulae to calculate basic state parameters in the difference equations above

$$\bar{\rho}_k = \frac{p_s}{RT_0} \exp\left(-\frac{g}{RT_0}\, z_k\right) \;,\; \bar{\theta}_k = T_0 \exp\left(\frac{g}{c_p\, T_0}\, z_k\right)$$

$$\left(\frac{N^2\bar{\theta}}{g}\right)_k = \left(\frac{d\bar{\theta}}{d\, z}\right)_k = \frac{g}{c_p} \exp\left(\frac{g}{c_p\, T_0} z_k\right) \qquad \text{for } k \in [1, ke] \;.$$

3.5 Simulations with L-grid model version

Based on the model algorithm for a vertical L-grid, described in the previous Subsection 3.4, we carry out simulations similar to Arakawa and Konor's (1996) with their model (AKM). It serves us to calibrate our LM toy-model. Therefore, our concern is mainly to simulate hydrostatic gravity waves, which is guaranteed with the choice of relatively large horizontal wavelengths of $L = 100, 250km$ compared to the initially produced vertical wavelength. On a state of rest a local zig-zag initial perturbation in θ' is imposed to $\pm 0.5K$ at the vertical gridpoints indexed with $k = 2/3$, and $\theta' = 0$ everywhere else. From this manipulation sound- and gravity waves are generated, and their propagation can then be simulated in terms of a dispersion process. Besides linearisation, our approach differs from the leap-frog / split-explicit time-scheme of the LM in such a way, that we run the fast-mode model part in a stand-alone form not linked within a splitting scheme with the slow-mode model part. In a first set of simulations we assume a horizontal wavelength of $L = 250km$

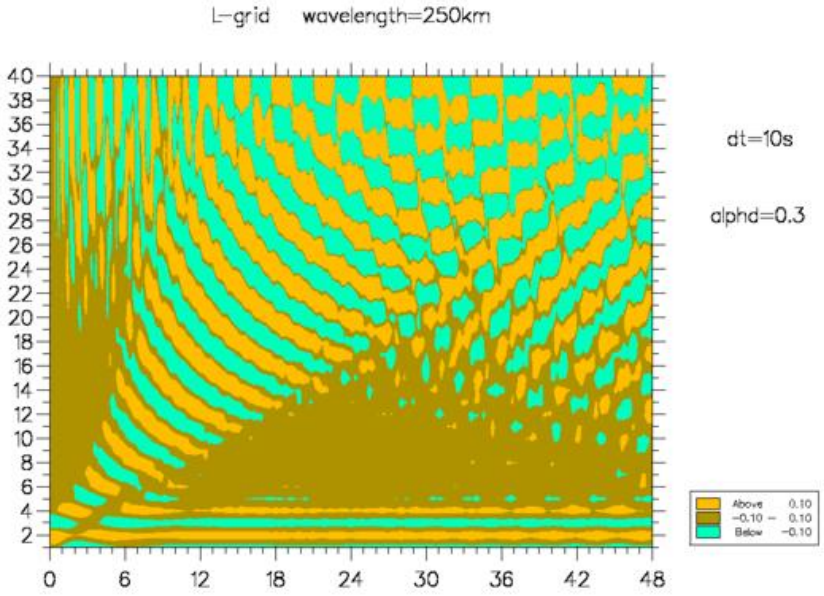

Figure 5: Linear LM fast-mode simulation with L-grid for a horizontal wave length of 250km. Time evolution of the potential temperature perturbation amplitude over 48 hours integration time with time-step $\Delta t = 10s$ and a divergence damping parameter of $\alpha_d = 0.3$ (Further explanation see text, contour interval similar to previous figures).

On an empirical ground the time-step is chosen $\Delta t = 10s$ and the divergence damping parameter has been set $\alpha_d = 0.3$ in order to damp out acoustic waves. Over 48 hours integration time the simulation shows, how a gravity wave dispersion process takes place from the assumed initial potential temperature perturbation in case of the L-grid staggering of variables and influenced by an upper lid-condition. Obviously, wave perturbations propagate only partially upward, where they are reflected at the upper boundary to reach lower parts of the integration domain again, while another wave mode remains to be stationary as a pure computational mode (Fig. 5).

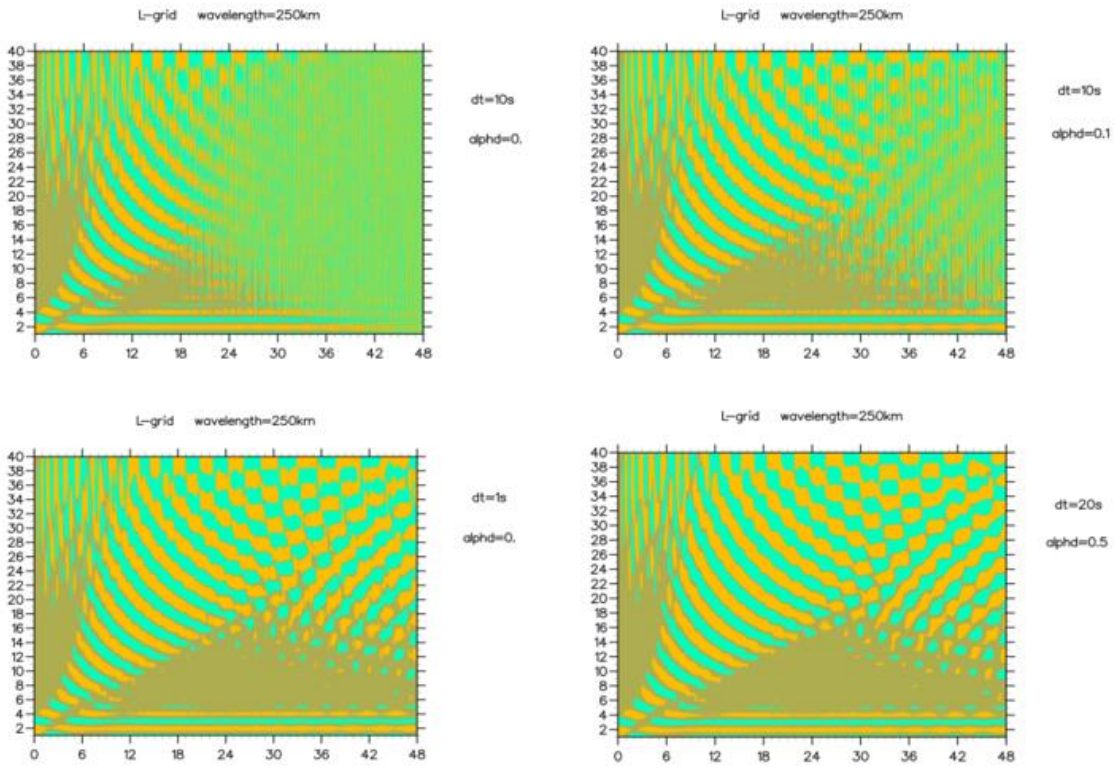

Figure 6: Further simulations with L-grid for a 250km horizontal wavelength over 48 hours integration time in dependence of varying time-step $\Delta t = 1, 10, 20s$ and divergence damping parameter of $\alpha_d = 0., 0.1, 0.5$, and compared to the simulation with $\Delta t = 10s$ and $\alpha_d = 0.3$ in Fig. 5.

From an empirical point of view the Figures 5 and 6 show that the simulation with $\Delta t = 10s$ brings about an optimal result, if the divergence damping term is switched on with $\alpha_d = 0.3$ while the choice of $\alpha_d = 0.1$ (LM-default value, see upper right panel of Figure 6) leads to an unsatisfactory solution, which tends to make the matter still worse, if $\alpha_d = 0$ (upper left panel of Figure 6) is taken. We interpret this outcome as an accuracy problem due to the choice of a time-step as large as $\Delta t = 10s$. Related truncation errors seem to become the cause of artificial, horizontally propagating acoustic waves, which however can be damped, if the divergence damping mechanism is taken into account. Due to this, the choice of $\alpha_d = 0.3$ is shown to be sufficient, while $\alpha_d = 0.1$ is still too small to be effective. In the lower right panel of Figure 6 it is shown that even with a time-step of $\Delta t = 20s$, which is connected with a still more reduced time-difference accuracy, the simulation becomes successful, provided the divergence damping effect is sufficiently increased (e.g. $\alpha_d = 0.5$). If in contrast to this the time-difference accuracy is improved by using a sufficiently small time-step of $\Delta t = 1s$ there seems to be no reason to apply any divergence damping, since no spurious acoustic waves occur (lower left panel in Figure 6). Here we speculate about the nature of this kind of time-difference accuracy. From a physical point of view, an inherent hydrostatic adjustment process seems to take place, where the horizontally propagating acoustic modes play the role of a catalyst. If the timestep is small enough, the simulation is accurate to model the adaptation well enough in analogy to the well-known geostrophic adjustment, which must be simulated properly to avoid noisy gravity waves. This means here that larger timesteps appear to produce spurious acoustic waves which are then necessery to be damped out using some remedy in terms of an stronger divergence damping parameter. The same qualitative result can also be shown from simulations with a horizontal wavelength of $L = 100km$ for the assumed initial potential temperature perturbation (Figure 7). With $\Delta t = 1s$ and $\alpha_d = 0.3$ one obtains an optimal result, while with the same time-step, but ignored

divergence damping, the solution tends to become noisy. If then the time-step is further increased up to $\Delta t = 5s$ the emergence of spurious horizontally propagating acoustic waves is obvious, and the gravity wave solution is almost destroyed. The choice of an increased divergence damping parameter, $\alpha_d = 0.5$, makes, however, this larger time-step applicable and leads to a solution comparable with that from $\Delta t = 1s$ and $\alpha_d = 0.3$. With the specific time-differencing scheme suitable, and applied here to the compressible nonhydrostatic equations, we were able to recover the hydrostatic gravity wave solutions for a 100km- and 250km horizontal wavelength as found from the hydrostatic AKM concerning the L-grid. This has been demonstrated by comparing the appropriate solutions of Figure 2 with those of Figures 5 , 6 and 7 . Of particular interest is here, too, that the L-grid causes an unwanted stationary zigzag-computational mode which we know to be avoided in the AKM when introducing the CP-grid staggering instead. This change to the CP-grid must be managed in the following for our toy-model.

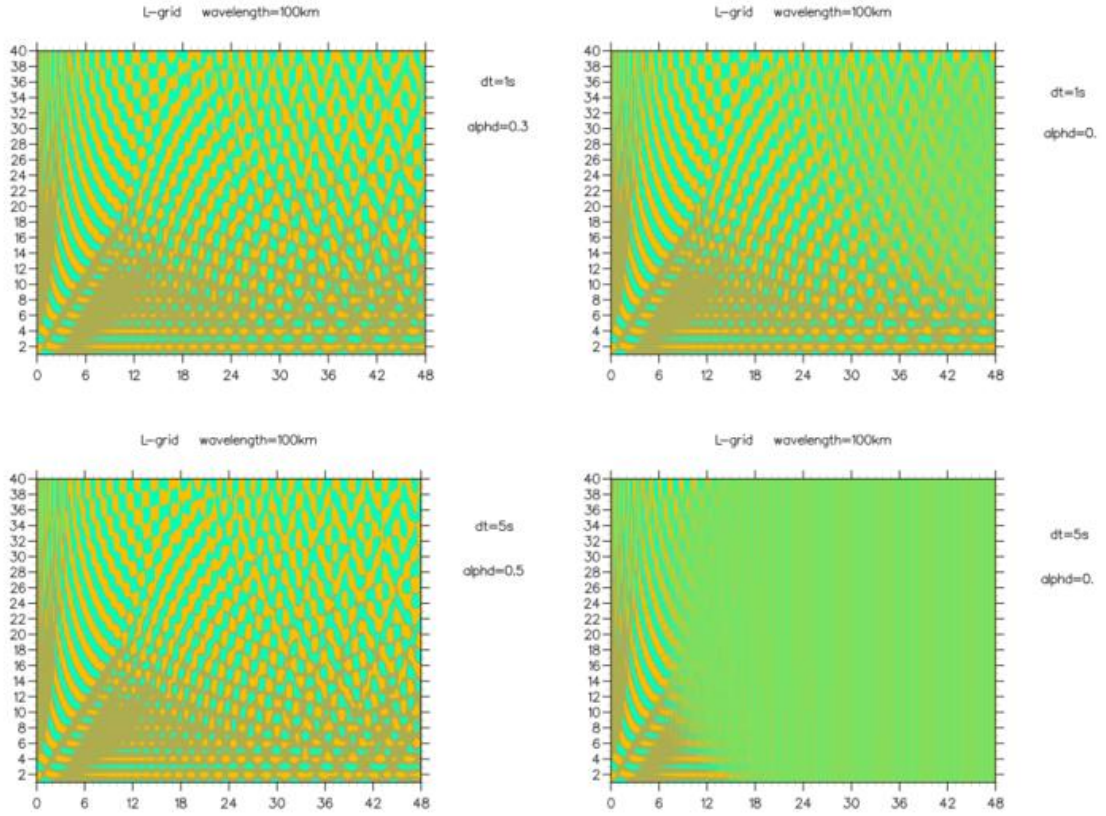

Figure 7: Simulations with L-grid for a 100km horizontal wavelength over 48 hours integration time for time steps $\Delta t = 1s$ and $5s$ in dependence of divergence damping parameter of $\alpha_d = 0., 0.3, 0.5$.

3.6 Vertical grid-staggering with a CP-grid

We refer strictly to our description of the L-grid algorithm in Subsections 3.3 and 3.4 . In order to define here the vertical differencing for a CP-grid option of the LM fast-wave toy-model, we need only list the differences to the L-grid formulation. In contrast to the L-grid scheme (see Figure 4) the CP-grid staggering scheme is shown in Figure 8.

In this case the variables $\hat{u}$, $\hat{v}$, $\hat{p}$ are placed at main-levels indicated with indices $k \in [1, k]$, while $\hat{w}$ and $\hat{\theta}$ are defined at half-levels indexed with $k' \in [1, ke1]$. For the basic state we assume again $\bar{\rho}$ to be positioned at main-levels, but $\bar{\theta}$ now at half-levels together with its perturbation value $\hat{\theta}$. To make the

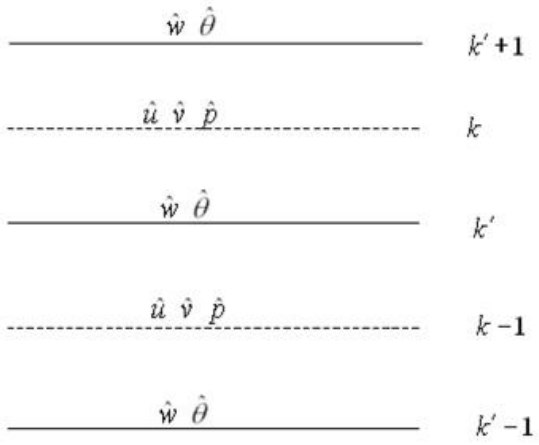

Figure 8: Scheme of vertical staggering according to CP-grid

matter simple enough, we comment here only the changes from the numerical integration algorithm written down in the Subsection 3.4 for the L-grid. The horizontal momentum equations (40), (41) with the divergence damping (42) included remain as they stand there. The Gaussian elimination procedure to compute the vertical velocity from a tri-diagonal vertical structural equation system (43) remains also formally untouched . Only the term $C^w_{k'}$ involved, obtains a more simple form compared to (49). Due to a more natural formulation of the buoyancy term with a CP-grid, its vertical averaging is avoided. Instead of (35) we have

$$C^w_{k'} = \ldots \quad g\Delta t \left(\frac{\hat{\theta}^{(\tau)}}{\bar{\theta}} \right)_{k'} \qquad \text{for} \quad k' \in \left[2, ke' \right] \tag{53}$$

The first two terms on the right-hand side of equation (35)/(49) are identically introduced in (53) written in symbolic form by dots. The pressure perturbation equation ((36), (37)) is used without any change, while a minimal modification is made for the potential temperature perturbation equation (38):

$$\hat{\theta}^{(\tau+1)}_{k'} = \hat{\theta}^{(\tau)}_{k'} - \left(\frac{N^2 \bar{\theta}}{g} \right)_{k'} \Delta t \left(\beta^+ \hat{w}^{(\tau+1)}_{k'} + \beta^- \hat{w}^{(\tau)}_{k'} \right) \qquad \text{for} \quad k' \in [1, ke1] \tag{54}$$

The boundary conditions (39) are assumed here, too, and the list of constants used in the L-grid version is also valid. With this specifications we are going to carry out similar simulations with the CP-grid model version to show the impact of the CP-grid against the L-grid as already demonstrated with the hydrostatic AKM in Section 2.

3.7 Simulation with the CP-grid model version

Here we carry out simulations on the basis of the CP-grid model version described in Subsection 3.6 . With reference to 3.5, the numerical set-up is chosen to compare the results with the previous L-grid simulations. For horizontal wavelengths $L = 100, 250km$ with time-step $\Delta t = 1s$ and $10s$, respectively, and $\alpha_d = 0.3$ in each case, the CP-grid results are shown in Figure 9, compared with the corresponding L-grid simulations over 48 hours integration time. This result can be compared with that in Figure 2, where analogous runs have been shown with the hydrostatic AKM. The similarity of results between Figure 2 and Figure 9 was expected to be found in this way, because in both situations

hydrostatic gravity waves were simulated due to the same, relatively long horizontal wavelengths of the assumed initial perturbation. Therefore, the discussion of the results depicted in Figure 9 is qualitatively the same as that about Arakawa and Konor's simulation shown in Figure 2, and need not be repeated here. So we can refer to our discussion in Section 2. On the whole, we can state that a computational mode in the L-grid nonhydrostatic model version is possible to occur - here deliberately provoked by a special initial perturbation - and due to the introduction of a CP-grid instead this unphysical nuisance is removed, and, moreover, we observe that the CP-grid seems to support the gravity wave dispersion process much better.

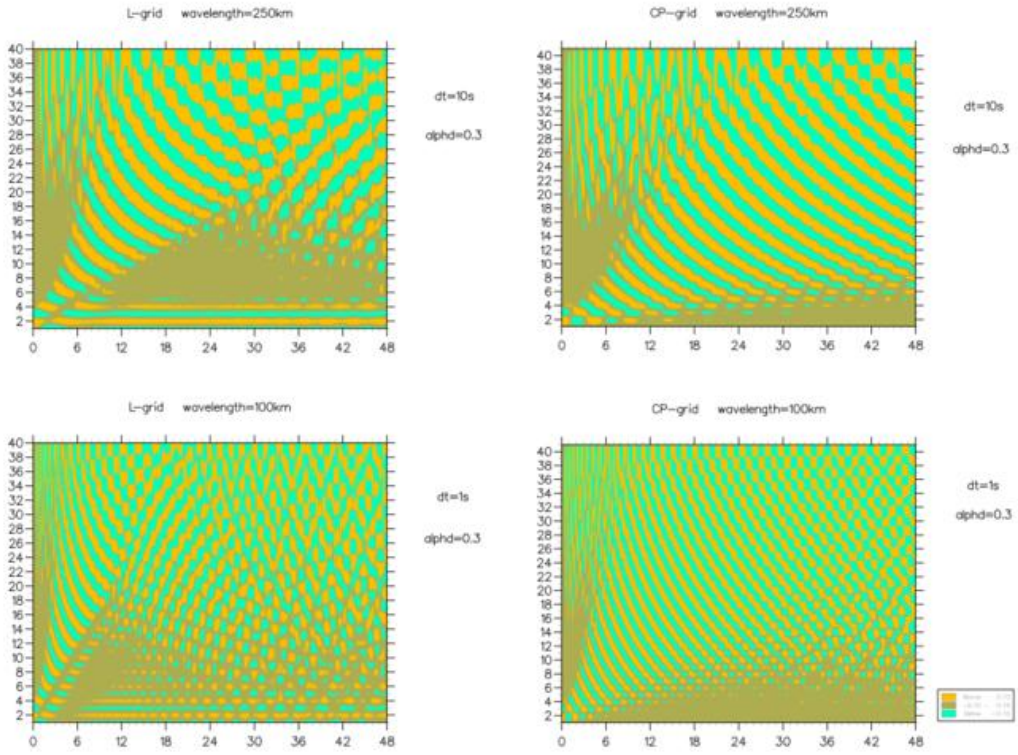

Figure 9: Comparison of L-grid simulations with corresponding CP-grid runs for horizontal wave components with $L = 100, 250km$ wave length over 48hours integration time.

In order to demonstrate further aspects of the possible occurrence of a computational mode in the L-grid, Arakawa and Konor (1996) carried out still a second set of simulations with their AKM not mentioned up to now in this paper. We will add this in brief from the point of view of the LM toy-model. In this set, the initial conditions are modified in a way that $\theta^{'} = 0$ is assumed everywhere without any local perturbation imposed. Instead, a Newtonian-type diabatic heating term is added in the prognostic equation for $\hat{\theta}$, (20), on its right-hand side, using a time-independent equilibrium value amplitude $\hat{\theta}^*$. The modified potential temperature equation reads then

$$\frac{\partial \hat{\theta}}{\partial t} = -\frac{N^2 \bar{\theta}}{g}\,\hat{w} - \lambda\left(\hat{\theta} - \hat{\theta}^*\right) \tag{55}$$

with $\hat{\theta}^* = 10K$ for the equilibrium value, and $\lambda = 1/86400\,s^{-1}$ for the relaxation constant. This term is applied at only one single model level, at $k = 4$ and $k^{'} = 4$, respectively. These parameters are identical with those in Arakawa and Konor's paper. In Figure 10 we show the corresponding results from this set of simulations.

The simulation with the horizontal wavelength of 250 km is not shown here. It brings qualitatively

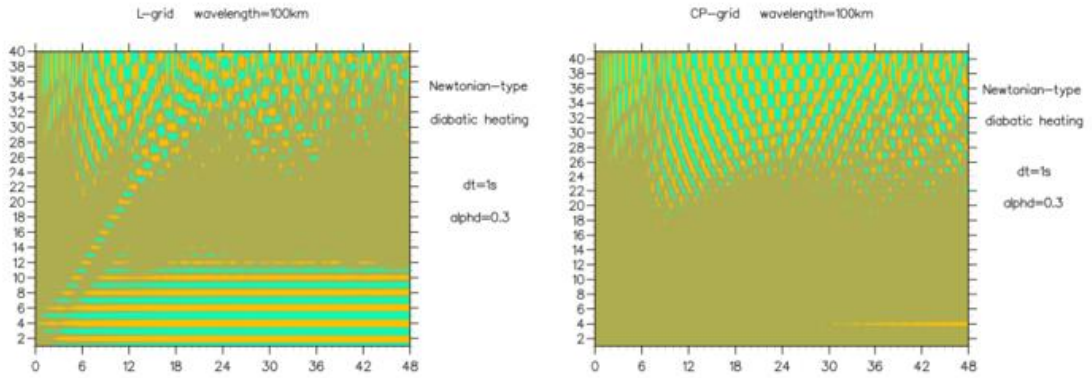

Figure 10: Simulation with Newtonian-type heat forcing at a single model level for horizontal wavelength of 100km and L-grid against CP-grid.

an analogous result as shown for the 100km-wave component. Since for both these large wavelengths the nonhydrostatic model simulates wave solutions comparable with the hydrostatic approximation, the results can be compared directly with the corresponding AKM-simulations (see Figure 4 in Arakawa and Konor 1996). Thus, the same qualitative discussion of the result in Figure 10 is valid and, with reference to Arakawa and Konor (1996), needs not be repeated here. In particular, we see the generation of a spurious zigzag distribution of the potential temperature perturbation due to the L-grid, which does not occur when using the CP-grid instead. We add still another experiment, where the effect of a subgrid-scale convective forcing is simulated with the given toy-model. For that purpose the continuity equation is thought to be extended to take into account an additional term describing the divergence of a subgrid mass flux. In terms of equation (19), which is the continuity equation for the given system, we add an expression of the vertical divergence of a vertical mass flux like this:

$$\frac{\partial \hat{p}}{\partial t} = g\bar{\rho}\,\hat{w} - c_s^2\,\bar{\rho}\left(\frac{\partial \hat{w}}{\partial z} - k\hat{u}\right) - c_s^2\,\frac{\partial \hat{F}_z}{\partial z} \tag{56}$$

With background values $w' \sim 5m\,s^-1$, $\rho' \sim 10^{-3}kg\,m^{-3}$, $\Delta z \sim 10^3 m$ we make use of an estimate

$$\left|c_s^2\,\partial\,\hat{F}_z/\partial z\right| \sim 0.5kg\,m^{-1}\,s^3 \qquad .$$

The positive value is imposed at an altitude corresponding to level $k = 3$, while its negative value holds at $k = 8$. Otherwise this term is set equal zero. Thus, a step-like vertical distribution of an constant mass flux directed upward in between an interval $3 \leq k \leq 8$ is imposed, while it is zero below and above. In the simulation with this kind of forcing the term of concern is assumed to be constant in time. In this experimental set-up no initial local perturbation is otherwise imposed.

Due to this specification of a vertical massflux distribution the following result is expected: massflux divergence (convergence) is accompanied with flow convergence (divergence) at $k = 3$ ($k = 8$). Thus, we observe at $k = 8$ downward motion of air with higher θ from above, which leads to local heating there, while upward motion right next at $k = 9$ carries air with lower θ from below bringing local cooling. The same takes place at $k = 3$, and $k = 4$, respectively, but in reverse order and somewhat weaker. As demonstrated in Figure 11, the typical difference of simulation results between L-grid and CP-grid is observed. The L-grid produces a stationary computational zig-zag structure, while the physical solution expected cannot be reproduced. The CP-grid, however, avoids this non-physical phenomenon and seems even necessary to properly simulate the adopted process.

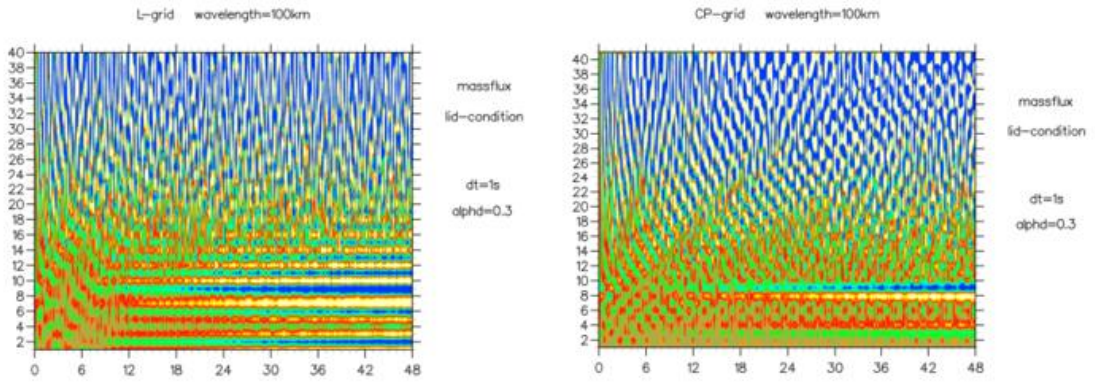

Figure 11: Time evolution of the potential temperature perturbation with imposed subgrid-scale massflux (see text) for horizontal wavelength of 100km with L-grid versus CP-grid. (contour colour interval here 0.01K in between (-0.1; + 0.1).

In all Figures above the simulation results have been shown over the entire integration domain. There we have always tacitly accepted that the internal gravity wave pattern propagating upward arrive eventually at the upper model boundary, where they are reflected owing to the assumed lid-condition $\hat{w}_{top} = 0$ with a following contamination of the physical solution. These results suggest urgently the implementation of an absorbing upper boundary condition instead of the reflective lid-condition here still applied. This will be our concern in the next section.

4 Application of a radiative upper boundary condition

In all our results shown by now it can be observed that reflecting wave components occur which propagate downward as an unnatural phenomenon to contaminate then internal solutions, and, moreover, veil and distort even unphysical modes like zigzag patterns owing to an L-grid which might then not always be detected easily from. With this motivation, but also from much more general reasons, it is strongly indicated to improve any model of concern in order to get rid of an upper lid-condition and introduce an absorbing or non-reflecting upper condition instead. Here, we are interested in applying a radiative boundary condition for our compressible nonhydrostatic toy-model as a desirable improvement in the above sense. Moreover, we have in mind to start finding out in principle a way to extend this application to the real LM. In the following Section, however, we deal with that problem in the narrow sense. It needs no explanation, why we are here particularly interested in applying a radiative boundary condition, since our toy-model is a simple horizontally spectral model. Thus, we operate always in the Fourier space with a monochromatic wave component which allows the direct application of a radiative boundary condition, while normally a Fourier transform is necessary to apply.

4.1 Derivation of the Klemp-Durran-Bougeault type of a radiative upper boundary condition

The following analysis starts from the toy-model equations (16) - (20) with all their explanations given in Section 3. The only modification is thought to be done in the prognostic $\hat{w}$ - equation, where a hydrostatic switch μ is added to be multiplied with the vertical acceleration term in (18). Setting $\mu = 1$ gives the full nonhydrostatic system while $\mu = 0$ reduces the system to the hydrostatic model equations. With this notation we carry out the elimination of the horizontal momentum components and the potential temperature perturbation amplitude to obtain two relationships for pressure and vertical momentum:

$$\left[\frac{1}{c_s^2}\left(\frac{\partial^2}{\partial t^2}+f_0^2\right)+k^2\right]\frac{\partial \hat{p}}{\partial t}=-\left(\frac{\partial^2}{\partial t^2}+f_0^2\right)\left(\frac{\partial}{\partial z}+\frac{N^2}{g}\right)(\bar{\rho}\hat{w}) \tag{57}$$

$$\left(\frac{\partial}{\partial z}+\frac{g}{c_s^2}\right)\frac{\partial \hat{p}}{\partial t}=-\left(\mu\frac{\partial^2}{\partial t^2}+N^2\right)(\bar{\rho}\hat{w}) \tag{58}$$

The z- and t- dependencies may now be separated

$$\begin{pmatrix}\hat{p}\\ \bar{\rho}\hat{w}\end{pmatrix}=\mathrm{Re}\begin{pmatrix}P(z)\\ W(z)\end{pmatrix}\exp(-i\omega t) \tag{59}$$

allowing the following to be written:

$$\left[\frac{\partial^2}{\partial z^2}+\left(\frac{g}{c_s^2}+\frac{N^2}{g}\right)\frac{\partial}{\partial z}+\frac{N^2}{c_s^2}\right]\begin{pmatrix}P\\ W\end{pmatrix}+\left(\frac{N^2-\mu^2\omega}{\omega^2-f_0^2}\right)\left(k^2-\frac{\omega^2-f_0^2}{c_s^2}\right)\begin{pmatrix}P\\ W\end{pmatrix}=0 \tag{60}$$

Normalising equation (60), the change of variables is made

$$\begin{pmatrix}P(z)\\ W(z)\end{pmatrix}=\begin{pmatrix}\tilde{P}(z)\\ \tilde{W}(z)\end{pmatrix}\exp\left(-\frac{z}{2H}\right) \tag{61}$$

using the definition of a reciprocal vertical scale height

$$\frac{1}{H} = -\frac{1}{\bar{\rho}}\frac{d\bar{\rho}}{dz} = \frac{N^2}{g} + \frac{g}{c_s^2} \qquad , \tag{62}$$

finally leaves the well-known wave equation

$$\frac{d^2}{dz^2}\begin{pmatrix}\tilde{P}\\ \tilde{W}\end{pmatrix} + n^2\begin{pmatrix}\tilde{P}\\ \tilde{W}\end{pmatrix} = 0 \tag{63}$$

with the vertical wavenumber squared

$$n^2 = \frac{\left(N^2 - \mu^2\omega^2\right)k^2}{\omega^2 - f_0^2} + \frac{\mu^2\omega^2}{c_s^2} - \frac{1}{4H^2} \tag{64}$$

The general solution of (63) reads

$$\tilde{W}(z) = a\,\exp(i\,n\,z) + b\,\exp(-i\,n\,z) \tag{65}$$

and similar for $\tilde{P}(z)$. The relationship (64) constitutes a rather general dispersion equation to determine the frequency ω for acoustic and inertia-gravity modes. A fairly detailed discussion for $\mu = 1$ can be found in Gossard and Hooke (1975, p. 112). In a next step we are interested in considering the vertical energy flux averaged over a periodic time length $2\pi/\omega$. For the present we find

$$\begin{aligned}\overline{\hat{p}\hat{w}} = \overline{\mathrm{Re}\left(P\exp(-i\omega t)\right)\mathrm{Re}\left(\frac{W}{\bar{\rho}}\exp(-i\omega t)\right)} &= \frac{1}{4\bar{\rho}}\left(P\overset{*}{W} + \overset{*}{P}W\right)\\ &= \frac{1}{2\bar{\rho}(0)}\mathrm{Re}\left(\overset{*}{\tilde{W}}\tilde{P}\right)\end{aligned} \tag{66}$$

The upper stars in (66) denote complex-conjugate entities. This general expression needs to be more specified in view of introducing now the Klemp-Durran-Bougeault radiative boundary condition (= KDB-RUBC) with its rather restricting assumptions. We are motivated to do so, since it is common that a radiative boundary condition following from the general case is impracticable to be applied due to its global properties in space and time. In contrast, the KDB-RUBC seems here particularly attractive, because it is local in time, and the global character in space is not an obstacle at all due to the specific definition of model variables. The list of assumptions to arrive at the KDB-RUBC is:

- hydrostatic approximation $(\mu = 0)$
- anelastic condition $\left(c_s^2 \to \infty\right)$
- isothermal basic state
- no rotation $(f_0 = 0)$ (67)
- Boussinesq - approximation $\left(\frac{\partial}{\partial z} \gg \frac{1}{H}, n^2 \gg \frac{1}{H^2}\right)$

With this limitations the dispersion equation reduces to

$$\omega n = \pm N\, k \tag{68}$$

and from (57) follows with (59) and (61) the relation

$$\tilde{P} = i\frac{\omega}{k^2}\frac{d\tilde{W}}{dz} \qquad . \tag{69}$$

Inserting (69) in (66) leads, together with (65), to

$$\overline{\hat{p}\hat{w}} = -\frac{\omega n}{2\bar{\rho}_0 k^2}\left(|a|^2 - |b|^2\right) \tag{70}$$

At this point we have to specify the energy flux (70) at the upper boundary. In accordance with a condition of outgoing wave energy there, it is inferred from the energy budget equation (21) by integration from the bottom to the upper boundary that

$$\overline{(\hat{p}\hat{w})}_{top} > 0 \tag{71}$$

must hold. With always $n > 0$ (cf. with (65)) we start assuming $\omega n = Nk > 0$. In accordance with the desirable condition (71) it follows from (70) at the upper boundary $a = 0$. In this case we infer from (65) $d\tilde{W}/dz = -in\tilde{W}$, and via (69) we arrive at

$$\tilde{P}_{top} = \frac{N_{top}}{k}\tilde{W}_{top} \qquad . \tag{72}$$

If, however, $\omega n = -N\,k < 0$, we find with $b = 0$ from (65), (69), (70) the same result as (72). Provided that $z_{top} < \infty$, we finally obtain by use of (61) and then ((57), (58)) the KDB-RUBC in the form

$$\hat{p}_{top} = \frac{(\bar{\rho}N)_{top}}{k}\hat{w}_{top} \qquad . \tag{73}$$

In our case $k > 0$ is always valid. A direct application of (73) would be possible in our toy-model, provided the limiting assumptions behind this RUBC can be neglected compared to its desirable advantages. Apart from the original references (Klemp and Durran 1983, Bougeault 1983) we refer particularly to Durran (1999) who gave in his monography an excellent overview about this subject. Moreover, Durran has suggested an interesting computational method, how to incorporate the KDB-RUBC in a nonhydrostatic linear model algorithm. In the following we want to take up with his idea in order to apply it for the present model scheme.

4.2 Implementation of the KDB - RUBC

Before we put forward the matter, it seems worth thinking about, if there is really a good reason to deal with the KDB-RUBC in connection with a compressible nonhydrostatic model because of rather limited assumptions implied in this boundary condition. We are motivated to do so because of a reasoning as follows. The time differencing scheme used and described in Section 3.2, which

is essentially the time scheme in the fast-wave part of the LM, treats those terms responsible for vertically propagating acoustic waves implicitly in order to damp them significantly. Moreover, the divergence damping modifying the horizontal pressure gradient term serves to damp acoustic waves, so that, on the whole, acoustic modes seem to be significantly removed, while gravity modes, as the essential physical content of this equation part, remain untouched due to these numerical techniques. Having almost only gravity modes involved in this scheme we want to make, in addition, sure the applicability of the KDB-RUBC by treating approximately hydrostatic gravity waves (which makes then the solution comparable with the simulations from Arakawa and Konor who used a hydrostatic system). In this line we carry out a special simulation with our toy-model stipulating now $k = 0$ for an infinite horizontal wavelength and the case of no rotation, $f_0 = 0$. The model is initialised again with the above defined zigzag-perturbation for $\hat{\theta}$ with $\pm 0.5K$ at vertical gridpoints indexed with k=2 and k=3, respectively. In contrast to the complete equation system (16) - (20) the reduced one leads instead of the dispersion relations (22) and (23) here to a stationary gravity solution $\omega_g^2 = 0$ and to acoustic wave modes propagating vertically only, $\omega_a^2 \approx c_s^2\, n^2$. This simulation is shown in Figure 12. It supports the possible application of the KDB-RUBC.

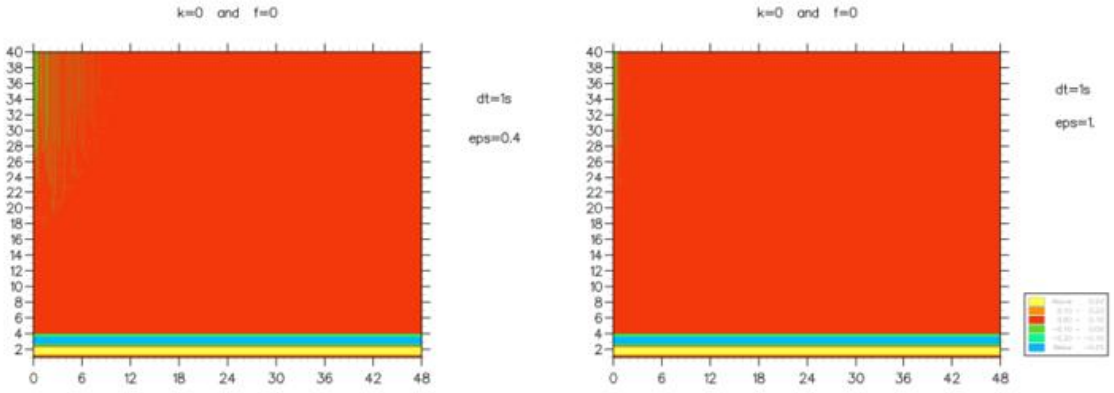

Figure 12: No rotation case simulation over 48 hours integration time with zero horizontal wavenumber. Lower stripe demonstrates a stationary gravity mode with no dispersion at all in both panels. Vertically propagating acoustic waves are treated implicitly, in the left panel with $\varepsilon = 0.4$, and in the right panel fully implicit with $\varepsilon = 1$. (plot valid both for L- and CP-grid).

Figure 12 demonstrates that the propagation of gravity modes have been suppressed. The local initial potential temperature perturbation can therefore not trigger a dispersion process compared to the more general toy-model simulations discussed above. Instead, the initial zig-zag perturbation remains so during the integration owing to a stationary mode, $\omega_g^2 = 0$. Due to the existence of a vertically propagating acoustic mode we can, however, test how the implicit time-scheme does work to damp off this mode in dependence of the implicity parameter ε. In an isolated manner we can observe that with the LM default-value $\varepsilon = 0.4$, that is with the implicity weights $\beta^+ = 0.7$ and $\beta^- = 0.3$, the acoustic mode, also caused by the special initial perturbation, is significantly reduced and eventually totally removed. In case of a fully implicit treatment ($\varepsilon = 1$, that corresponds to $\beta^+ = 1$ and $\beta^- = 0$) the effect of filtering out the acoustic mode is still more obvious. Since the implicit technique seems sufficient to remove vertically propagating acoustic waves, we conclude that the introduction of the KDB-RUBC, exclusively effective for (hydrostatic) gravity modes, may be possible to be used also in a nonhydrostatic compressible model frame provided that acoustic modes are sufficiently removed by appropriate numerical methods. From this thinking we are motivated to apply the KDB-RUBC in the given model. We start from the model equations with the given time- and vertical differencing scheme, described above in Subsection 3.2, 3.3 and 3.4 (equations (24) - (30), (31) - (39), and more directly, equations (40) - (51)). To demonstrate the method, we use the

vertical L-grid version first. The adaptation to the CP-grid is then easy to be done. Fortunately, a *first method* how to accomplish our approach, has been proposed by Durran (1999, p.429-430), which seems encouraging to be adopted for our purpose.

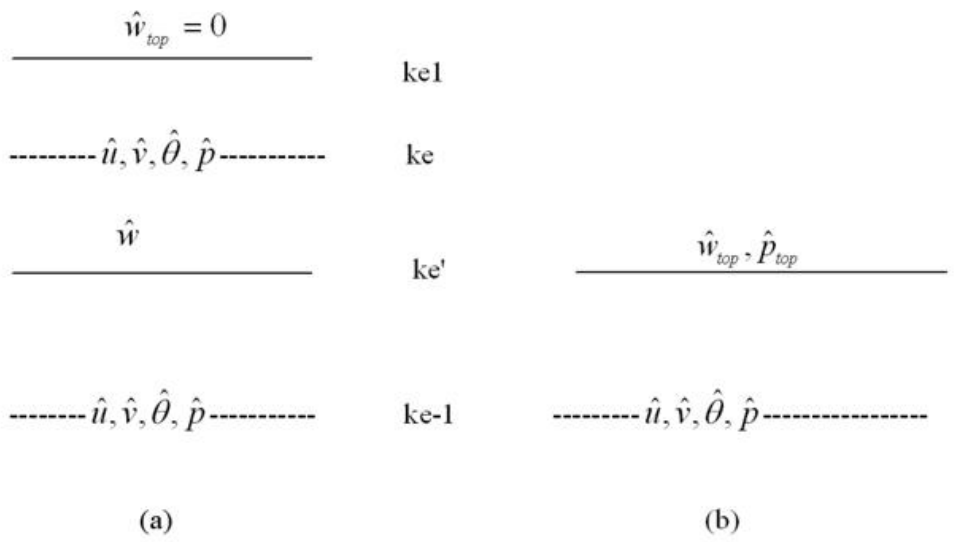

Figure 13: Change of uppermost gridpoint placement from case with (a) upper lid-condition to case (b) for introducing an RUBC according to Durran's (1999) approach.

According to Durran (1999), we change the numerical integration algorithm shown in Subsections 3.3 and 3.4 as follows. As indicated in Figure 13, we reduce the number of vertical computational gridpoints from ke to $ke-1$. Thus, the horizontal momentum equations ((40), (41)), with (42) involved, the pressure perturbation equation (27) and the potential temperature equation (28) are applied at vertical gridpoints $k \in [1, ke-1]$. With these difference equations for $k = ke-1$ there is, in particular, an access to $\hat{w}_{ke'}^{(\tau,\tau+1)} = \hat{w}_{top}^{(\tau,\tau+1)}$ which appears to be now the non-zero upper boundary value. Durran's approach consists then in changing in the tri-diagonal structural equation set for $\hat{w}_{k'}^{(\tau+1)}$, (43), the latter equation for $k = ke'$. This will be elaborated next. We start from the prognostic $\hat{w}_{k'}^{(\tau+1)}$ - equation (34) which must be reformulated for $k = ke'$ in such a way that an access to $\hat{p}_{ke}^{(\tau,\tau+1)}$ is avoided. This is made by using forward differences for the corresponding terms in (34) together with (35), where we define a new pressure value at the half-indexed gridpoint $k' = ke'$, $\hat{p}_{ke'}^{(\tau,\tau+1)} = \hat{p}_{top}^{(\tau)}$. This becomes necessary due to the proportionality of spectral perturbation pressure and vertical motion in the KDB-RUBC (73). So we have

$$\begin{aligned}\hat{w}_{top}^{(\tau+1)} = \hat{w}_{top}^{(\tau)} &- \frac{4}{\bar{\rho}_{ke-1} + \bar{\rho}_{ke}} \left(\frac{\Delta t}{\Delta z}\right) \beta^{+} \left(\hat{p}_{top}^{(\tau+1)} - \hat{p}_{ke-1}^{(\tau+1)}\right) \\ &- \frac{2}{\bar{\rho}_{ke-1} + \bar{\rho}_{ke}} \left(\frac{g\Delta t}{c_s^2}\right) \beta^{+} \hat{p}_{top}^{(\tau+1)} + C_{top}^{w}\end{aligned} \tag{74}$$

with a similar change in C_{top}^{w}:

$$\begin{aligned}C_{top}^{w} = -\frac{4\beta^{-}}{\bar{\rho}_{ke-1} + \bar{\rho}_{ke}} \left(\frac{\Delta t}{\Delta z}\right) \left(\hat{p}_{top}^{(\tau)} - \hat{p}_{ke-1}^{(\tau)}\right) - \frac{2\beta^{-}}{\bar{\rho}_{ke-1} + \bar{\rho}_{ke}} \left(\frac{g\Delta t}{c_s^2}\right) \hat{p}_{top}^{(\tau)} \\ + \frac{g\Delta t}{2} \left(\frac{\hat{\theta}_{ke-1}}{\bar{\theta}_{ke}} + \frac{\hat{\theta}_{ke-1}}{\bar{\theta}_{ke-1}}\right)\end{aligned} \tag{75}$$

and some reasonable approximation for the latter term in (75). In the next step, equation (36) for $k = ke - 1$ is used to eliminate $\hat{p}_{ke-1}^{(\tau+1)}$ from equation (74) which leads in contrast to the general procedure of Subsection 3.4 to a more specific relationship

$$A_{top}\hat{w}_{ke'-1}^{(\tau+1)} + B_{top}\hat{w}_{top}^{(\tau+1)} = D_{top}^{(\tau)} - \tilde{\alpha}_{top}\hat{p}_{top}^{(\tau+1)} \tag{76}$$

with coefficients A_{top}, B_{top}, differing from the former $A_{ke'}$, $B_{ke'}$ in (43), and with an additional coefficient $\tilde{\alpha}_{top}$:

$$A_{top} = -\left(\beta^{+}\right)^{2} \frac{\bar{\rho}_{ke-1}}{\left(\bar{\rho}_{ke-1} + \bar{\rho}_{ke}\right)/2} \left[2\left(\frac{c_s \Delta t}{\Delta z}\right)^{2} + g\frac{(\Delta t)^{2}}{\Delta z}\right] \tag{77}$$

$$B_{top} = 1 + \left(\beta^{+}\right)^{2} \frac{\bar{\rho}_{ke-1}}{\left(\bar{\rho}_{ke-1} + \bar{\rho}_{ke}/2\right)} \left[2\left(\frac{c_s \Delta t}{\Delta z}\right)^{2} - g\frac{(\Delta t)^{2}}{\Delta z}\right] \tag{78}$$

$$\tilde{\alpha}_{top} = \frac{4\beta^{+}}{\left(\bar{\rho}_{ke-1} + \bar{\rho}_{ke}\right)} \left[\left(\frac{\Delta t}{\Delta z}\right) + \left(\frac{g\Delta t}{2c_s^{2}}\right)\right] \tag{79}$$

The right hand side term $D_{top}^{(\tau)}$ reads

$$D_{top}^{(\tau)} = \hat{w}_{top}^{(\tau)} + 4\beta^{+}\frac{(\Delta t/\Delta z)}{\left(\bar{\rho}_{ke-1} + \bar{\rho}_{ke}\right)} \left(\hat{p}_{ke-1}^{(\tau)} + C_{ke-1}^{p}\right) + C_{top}^{w} \tag{80}$$

Here we arrive at a point, where the KDB-RUBC (73) needs to be introduced explicitly. We use it in the form

$$\hat{p}_{top}^{(\tau+1,\tau)} = \left(\frac{N\bar{\rho}}{k}\right)_{top} \hat{w}_{top}^{(\tau+1,\tau)} \qquad \Rightarrow \qquad b_{top}\ \hat{w}_{top}^{(\tau+1,\tau)} \tag{81}$$

with the definition

$$b_{top} := \left(\frac{N\bar{\rho}}{k}\right)_{top} = \frac{g\sqrt{\kappa - 1}}{2c_s k}\left(\bar{\rho}_{ke-1} + \bar{\rho}_{ke}\right) \quad , \quad \kappa = c_p/c_v \tag{82}$$

for the assumed isothermal basic state. The KDB-RUBC ((81) , (82)) is then inserted in (76) to eliminate $\hat{p}_{top}^{(\tau+1)}$. In contrast to the Gaussian elimination procedure in Subsection 3.4, the 'top down sweeping' for the auxiliary entities $E_{k'}$, $F_{k'}$ begins here instead of (50) with

$$E := -\frac{A_{top}}{B_{top} + \tilde{\alpha}_{top}b_{top}} \qquad and \qquad F_{ke'} := -\frac{D_{top}}{B_{top} + \tilde{\alpha}_{top}b_{top}} \tag{83}$$

while the other entities for $k' \in \left[ke' - 1, 2\right]$ remain unchanged as in (51). It should be noticed that $\hat{p}_{top}^{(\tau)}$ in C_{top}^{w} is eliminated by using ((81) , (82)) either. The following 'down-top sweeping' to calculate the vertical motion $\hat{w}_{k'}^{(\tau+1)}$ for $k' \in \left[3, ke'\right]$ is then accomplished according to (52). The prognostic step for the pressure perturbation and also for the potential temperature follows as usual to complete one time-step cycle.

Apart from this Durran-method we suggest still a *second method*. This approach attempts to avoid the introduction of the KDB-RUBC into the vertically implicit time-scheme, but it applies this boundary condition in an explicit way rather. We demonstrate this as follows. For that purpose we need not modify the uppermost gridpoint placement as necessary in the previous method and shown in Figure 13a, b. The gridpoint arrangement demonstrated in Figure 13a is maintained, and the only modification is to assume $\hat{w} \neq 0$ at the upper boundary (at $k^{'} = ke1$) owing to the RUBC:

$$\hat{w}_{top}^{(\tau+1,\tau)} = \frac{kc_s}{g\bar{\rho}_{top}\sqrt{\kappa-1}}\hat{p}_{top}^{(\tau+1,\tau)} \tag{84}$$

which is a rearranged form of the KDB-RUBC ((81) , (82)). Provided this vertical motion value is prescribed at the upper boundary, the prognostic step for pressure with (36) and for potential temperature (38) is possible for $k = ke$ with easy access to this boundary value. In order to execute the prognostic step for the vertical motion before by solving its tri-diagonal vertical structural equation set, the corresponding equation for $k^{'} = ke^{'}$ is slightly modified compared to the form in (43). Taking into account the significant boundary value, its contribution is added to the $ke^{'}$ - equation as follows

$$A_{ke'}\hat{w}_{ke'-1}^{(\tau+1)} + B_{ke'}\hat{w}_{ke'}^{(\tau+1)} = D_{ke'}^{(\tau)} - C_{ke'}\hat{w}_{top}^{(\tau)} \tag{85}$$

Here, the closure approximation is made to put the boundary value term on the right-hand side, where it is applied at the discrete time level τ instead of $\tau + 1$. From a practical point of view this small retardation is found to be irrelevant. In order to determine $\hat{w}_{top}$ from the KDB-RUBC (84), we need, however, the perturbation pressure $\hat{p}_{top}$ which is not directly available from the general time-stepping procedure. Thus, an extrapolation technique is invoked. The practical experimentation has shown that the application of some formal mathematical extrapolation is unsuitable. A successful method consists in using an adequate hydrostatic extrapolation. For that purpose it has shown to be necessary to use the consistent hydrostatic part of the prognostic $\hat{w}$ - equation with the given time-scheme included. In the present case we have to use the hydrostatic part of (26) which is here applied with L-grid and forward vertical differences:

$$\beta^{+}\frac{\hat{p}_{top}^{(\tau+1)} - \hat{p}_{ke}^{(\tau+1)}}{\Delta z/2} + \beta^{-}\frac{\hat{p}_{top}^{(\tau)} - \hat{p}_{ke}^{(\tau)}}{\Delta z/2} = -\frac{g}{c_s^2}\left(\beta^{+}\hat{p}_{ke}^{(\tau+1)} + \beta^{-}\hat{p}_{ke}^{(\tau)}\right) + \frac{g\bar{\rho}_{ke}}{\bar{\theta}_{ke}}\hat{\theta}_{ke}^{(\tau)} \tag{86}$$

This relation makes it possible to determine $\hat{p}_{top}^{(\tau)}$ as the input value in the KDB-RUBC (84) to determine $\hat{w}_{top}^{(\tau)}$, provided the prognostic step for the perturbation pressure with equation ((36), (37)) is made before.

This is our *second method* which is an explicit approach compared to the *first method* suggested from Durran (1999). The following application of both methods to our nonhydrostatic toy-model will be shown to be practically equivalent, though the Durran-approach demonstrates a perfect incorporation and adaptation to the given vertically implicit time-scheme, while our *second method* brings about some slight inaccuracies concerning the precise time-level assignment for $\hat{w}_{top}$ within the given time-scheme. Nevertheless, the latter approach promises to be a more simple method without troublesome preparatory changes in a given model and with more convenient properties for using different time-schemes. For numerical experimentation it becomes much more easy in the programming code to switch on/off the RUBC.

4.3 Results with KDB-RUBC

Here, we carry out toy-model simulations with KDB-RUBC instead of an upper lid-condition. We are going to apply both methods as explained in the previous Subsection, but the results shown in the following do not differ from each other at all. All the results up to now demonstrated with upper lid-condition have been repeated with KDB-RUBC involved and will be shown in the next Figures against the corresponding model version with upper lid. Figure 14 gives a comparison of lid-condition against RUBC for L- and CP-grid and in each panel for a horizontal wave component with 250km-wavelength.

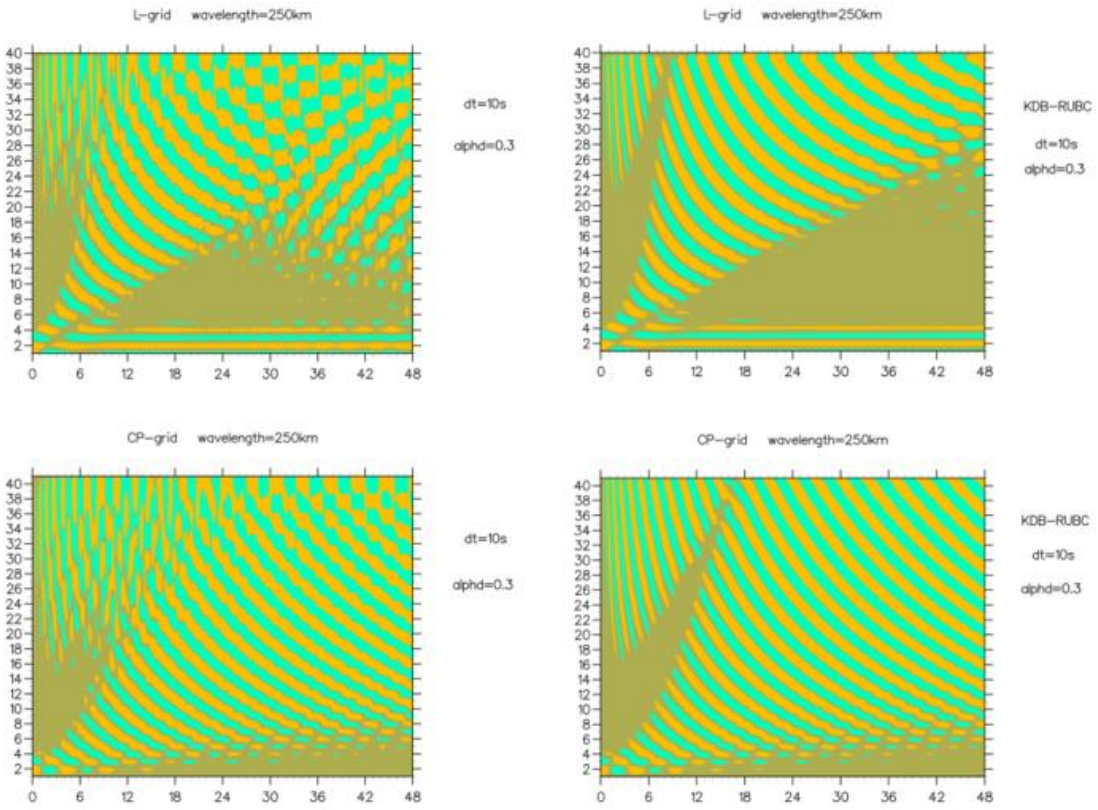

Figure 14: Simulations over 48 hours with 250km horizontal wavelength and both L- and CP-grid. Panels on the left row show the integrations with upper lid-condition, and the panels on the right row demonstrate the solution with KDB-RUBC involved.

The same type of simulation results follow immediately in Figure 15 for the potential temperature perturbation amplitude of a 100km horizontal wavelength.

In both figures (Figures 14, 15) the effect of the KDB-RUBC is clearly demonstrated. The reflective mode is essentially removed against the case with upper-lid condition. Thus, the advantages of the CP-grid on the one side and the disadvantages of the L-grid on the other side are much better revealed if a radiative upper boundary is assumed. In this case it is demonstrated best, how a dispersion process, here initiated by some special local imbalance of the hydrostatic basic state can be properly simulated. In spite of very specific and isolated simulations, deliberately adopted from Arakawa and Konor (1996) for methodical reasons, we still draw a more general conclusion that the L-grid can produce obvious shortcomings concerning the simulation of a possible dispersion process on the background of a given spectrum of internal gravity modes. Only in case of a CP-grid this dispersion process can be supported by a wide range of internal modes and is therefore simulated quite well, while using an L-grid, significant distortions of that process occur. In the latter case the associ-

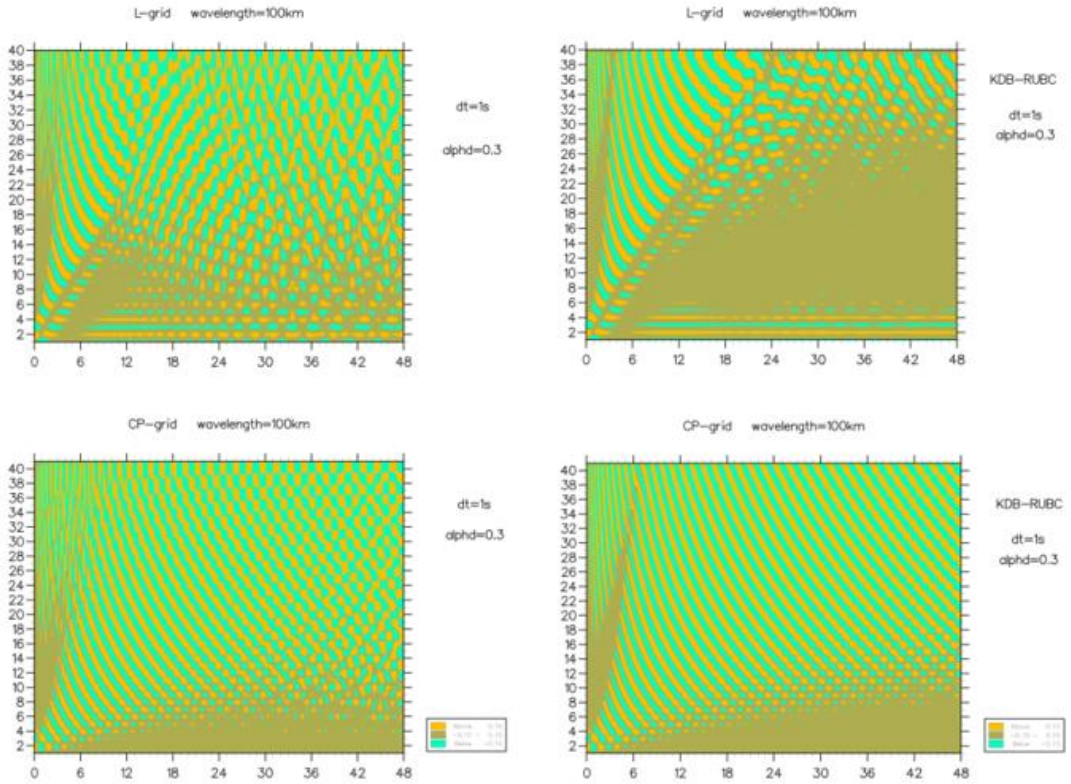

Figure 15: The same as in Figure 14 , but for 100km horizontal wavelength instead of 250km. Further explanation see text.

ated spectrum of internal modes is distorted, becomes shrunk, and brings about even an unphysical stationary mode.

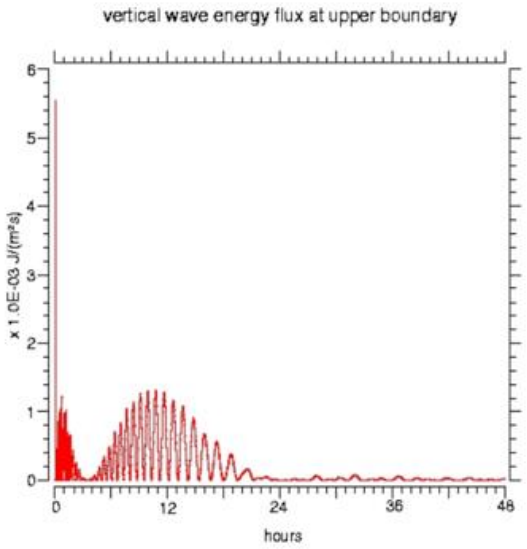

Figure 16: Vertical flux of wave energy over 48hour simulation with L-grid and 100km horizontal wavelength indicating how effective the KDB-RUBC operates

In Figure 16 we show the effectiveness of the KDB-RUBC for the L-grid simulation associated to the upper right panel of Figure 15. There can be seen the quantitative evaluation of the vertical flux of mechanical wave energy at the upper boundary in terms of $(\hat{p}\hat{w})_{top}$. This expression has to have a

positive sign in case of outgoing radiation, and Figure 16 demonstrates this positiveness over the 48 hour simulation time. The fastest vertically propagating signals associated to highest frequencies of the energy flux arrive at the upper boundary first, while after some gap the bulk of energy impinges on the model top at around 12 hour integration time having then the broadest amount of outgoing energy with slower frequencies. After that time increasingly less wave energy propagates upward, because most of it remains trapped as a stationary computational mode due to the L-grid properties, and, thus, the amount of outgoing energy dyes off over the following time.

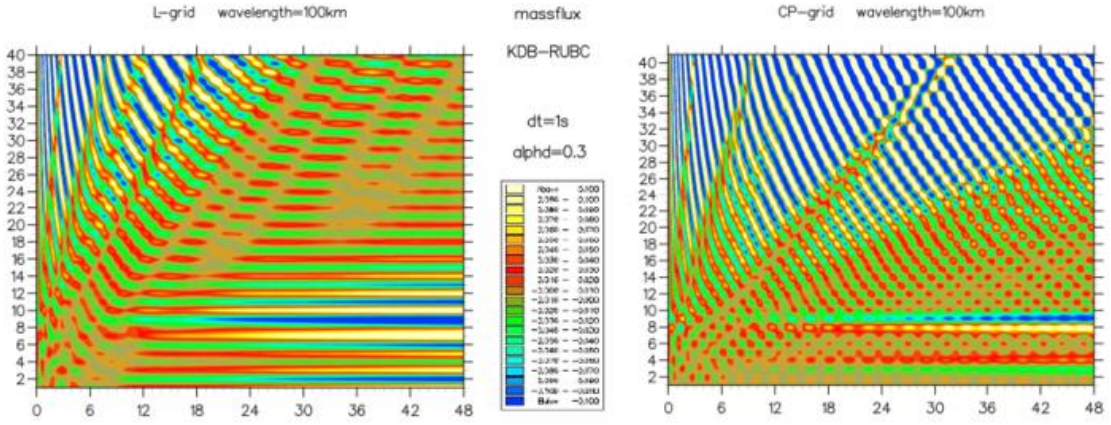

Figure 17: Time evolution of the potential temperature perturbation with imposed subgrid-scale massflux with L-grid versus CP-grid and with KDB-RUBC (compare with Fig.11).

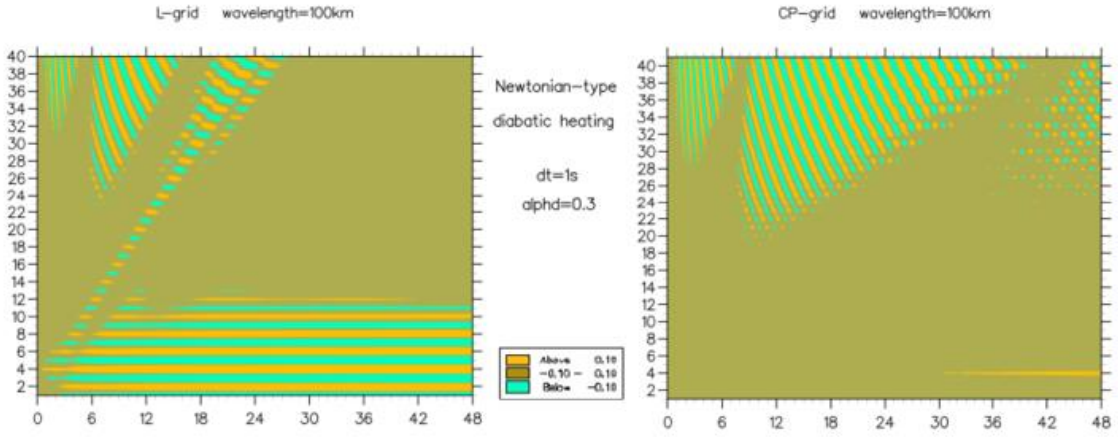

Figure 18: Simulation with Newtonian-type heat forcing at a single model level for horizontal wavelength of 100km and L-grid versus CP-grid, here with KDB-RUBC taken into account (compare with Fig.10).

Finally, we demonstrate the KDB-RUBC influence also from simulations already discussed in Subsection 3.7 for L-grid versus CP-grid, but executed there with upper lid-condition, where a simplified convective massflux and an Newtonian-heating case has been shown. A direct comparison without and with KDB-RUBC can be seen from Figure 10 versus Figure 18 in case of the Newtonian-heating simulation, and Figure 11 versus Figure 17 concerns the vertical massflux situation. The finding is also here that due to the impact of the KDB-RUBC the advantages of the CP-grid choice is much more distinct against the more distinct shortcomings of comparable L-grid simulations.

5 Simulations with LM - layering

All our previous simulations have used a vertical layering as proposed from Arakawa and Konor (1996). Instead of their choice of 40 geometrically equidistant vertical layers, we want to adopt now the vertically non-equidistant distribution of layers as valid in the LM. According to this a new experimental set-up with 35 layers is chosen from the COSMO LM-documentation by Doms and Schättler (2002, A description of the Nonhydrostatic Regional Model LM, Part I: Dynamics and Numerics, LM_F90 2.18, Nov.2002, at pages 57, 58 in Tables 4.1 and 4.2). In accordance with this the new vertically dicretised structure is formed by 35 main-levels and 36 half-levels, respectively. Since we remain here with a vertical z_k - coordinate as in the constant-layer model version above, the vertical z_k - distribution is adopted from the tables referred. For the present the basic state is assumed to be isothermal and not yet polytropic as normally used in the LM. On this basis the given LM fast-mode toy-model has been reformulated and extended to have then the LM - vertical layering. This has been made both for the vertical L-grid and the CP-grid staggering and in each case with KDB-RUBC omitted or involved. The documentation of all these modifications is rather lengthy and will therefore be dropped here.

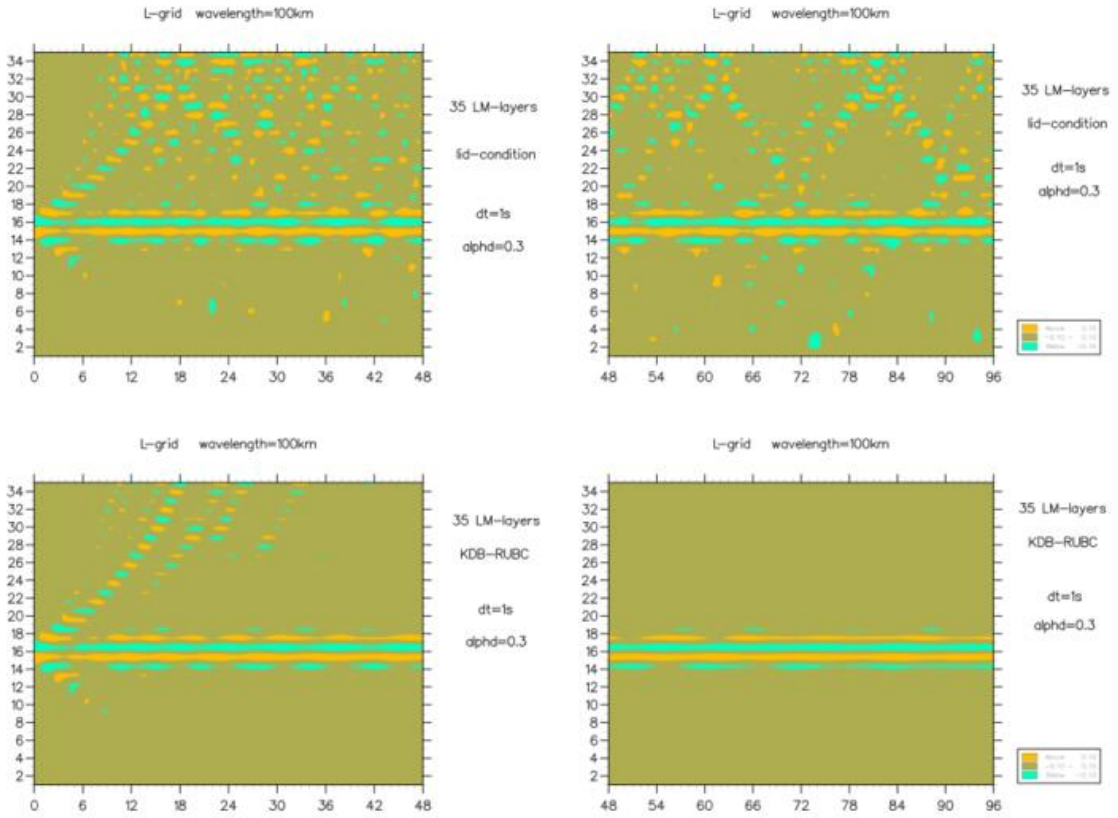

Figure 19: Time-height plot of potential temperature perturbation over 96-hour simulation time for L-grid with non-equidistant LM-layering , starting from an initial zig-zag perturbation. Upper row of panels: upper lid-condition. Lower row of panels: use of KDB-RUB. Each right panel is the continuation in time of the corresponding left one.

A simulation up to 96 hour integration time is shown in this context in Figure 19, where the typical L-grid deficiency can also be demonstrated and is more obvious with KDB-RUBC involved. The latter measure avoids a reflective mode downward from the upper boundary, so that almost all wave energy from the initial zig-zag perturbation with $\pm 0.5K$ prescribed only at vertical gridpoints $k = 15/16$ remains concentrated in an unphysical computational mode all over the integration time. It is interesting to note that the dispersion process triggered by the initial perturbation assumed here brings

about quite a different behaviour compared to all previous simulations with an equidistant layering adopted from Arakawa and Konor (1996). We postpone a deeper discussion of this numerical aspect beyond this report. Nevertheless, an anyhow triggered dispersion process with internal gravity modes involved depends for a given source strength on the thickness of layers and the way how the thickness of layers is varied through the depth of the model atmosphere (Gassmann 2003). In contrast to the L-grid simulation we show the comparable CP-grid case in the following Figure 20.

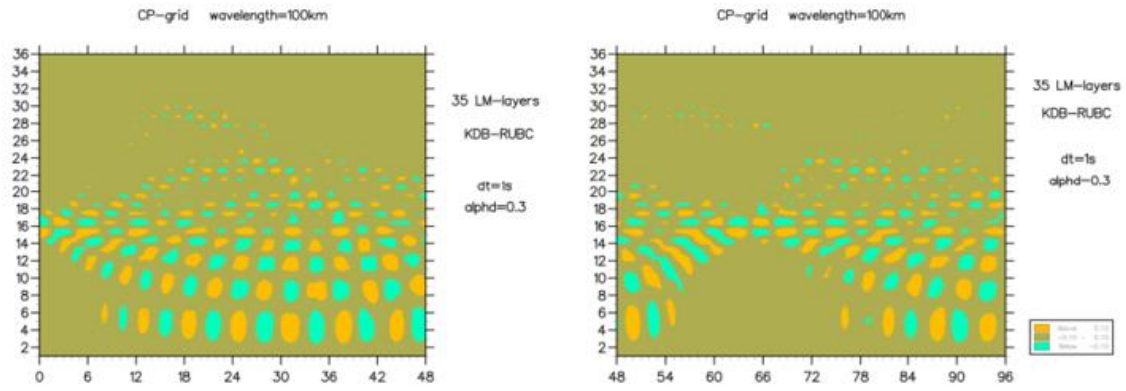

Figure 20: Comparable to Fig 19 the simulation with CP-grid property and KDB-RUBC involved.

We show here the simulation with KDB-RUBC only, since the related case with upper lid-condition has found to be not significantly different when using the CP-grid and having an initial zig-zag triggering at levels as assumed here. Compared to the result in Figure 19 it is demonstrated that the stationary computational mode is removed as expected, but the propagation of gravity modes behaves clearly different. Almost all wave energy seems trapped in the lower part of the model atmosphere where even reflections at the lower boundary can be observed. Although worth discussing these aspects we skip that here and restrict ourselves to the demonstration of L-grid shortcomings versus CP-grid advantages also in case of a vertical distribution of layer thickness used in the LM.

6 Conclusion

Starting point of our contribution was a paper by Arakawa and Konor (1996), in which these authors have carried out numerical simulations demonstrating important differences between the vertical grid type L and CP. They have shown that the L-grid version of their linear primitive model produces a computational mode without any physical meaning, while a model version with the CP-grid instead avoids this shortcoming. A thorough discussion including also quotations from many other authors are found in Arakawa (2000). We were particularly interested in the approach of Arakawa and Konor, because they have used a linearised hydrostatic model version as a simple and serious research tool, which is easy to copy for own investigations. After methodical studies with this model and with the identical experimental set-up we have then changed the model type to a compressible nonhydrostatic equation set in view of the linear fast-mode part of the LM. In order to be able to compare the solutions from this system with Arakawa and Konor's (1996) as close as possible, the design of vertical differencing (40 equally spaced layers), the choice of a basic state (isothermal and at rest) and the specific initialisation exactly remains as suggested by Arakawa and Konor. The model equations are written in spectral form for a horizontal wave component with vertically dependent perturbation amplitudes. The time-evolution of them can thus be investigated so as they are affected by the presence of gravity and sound wave modes. The given model design separates the combined effect of vertical differencing (layering, staggering) and LM - fast wave time-scheme with divergence damping involved in an isolated manner. First of all we apply this model tool in order to study computational influences on the dispersion process triggered by initially defined perturbations when using either the L-grid or the CP-grid. Within the scope of this investigation with a compressible nonhydrostatic model type very similar to the linearised LM fast mode equation part, we were also able to show that the CP-grid model version is clearly superior to an application of the L-grid in that model. Thus, there is a strong suspicion that the disadvantages of the L-grid demonstrated are expected to be possible also with the LM.

An important by-product of our simulations with L-grid versus CP-grid is that we have succeeded in incorporating the KDB-RUBC in the given scheme. The results without it suffer from strong reflections of gravity wave energy as a nuisance at and from the upper model-lid downward. Our investigation has shown that the application of the KDB-RUBC is possible and also successful in case of the nonhydrostatic compressible LM-like fast-mode model. Two methods how to incorporate the KDB-RUBC in this model has been tested. The first one is adopted from Durran (1999), and a second one is an explicit method. Both methods are equally successful showing almost identical results. In view of the present studies the impact of simulations with the KDB-RUBC included show that the advantage of a CP-grid is found to be much more distinct against the more distinct disadvantages with the L-grid.

Finally, we emphasise the meaning of our simple simulation model, that it is closely related to the linearised LM – fast mode equation part. In the sense of *res severa verum gaudium* it is a nice toy-model to study with it different options of time difference approximations in order to come then to an optimal time scheme for the LM as a whole. Furthermore, it is also possible to make studies concerning the proper way of layering through the vertical which seems also far from optimal.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *Consortium for Small-Scale Modelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (UGM, ARPA-SMR) and Switzerland (MeteoSwiss). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the Lokal-Modell (LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completition of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hardcopies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

Abstract

An online trajectory module is implemented in COSMO 5.1 and higher versions. The module is a diagnostic tool that enables to compute trajectories (i.e., to follow air parcels) and to trace any prognostic variable as well as diagnostic variables along the trajectories. The trajectory position is updated at each model time step based on the model wind fields, which allows to calculate trajectories very accurately for high spatial resolutions.

1 Introduction

The Lagrangian description of atmospheric motion is a valuable approach to study numerous phenomena ranging from large spatial scales, as extratropical cyclones (e.g., Wernli and Davies, 1997), to small scales, as the entrainment in stratocumulus clouds (e.g., Stevens et al., 1996). It is also very common to investigate the dispersion of atmospheric pollutants (e.g., Weil et al., 2012).

While many trajectory models for offline computation are currently available, they rely on the output of numerical weather prediction models. To capture the spatial and temporal variability of the wind field, that can be represented in the Eulerian model at high spatial resolution, model output would be required at a minute-scale temporal resolution (about 5 min for 2.2 km grid spacing) for the trajectory calculation. The temporal resolution of the wind field data has been shown to significantly influence the trajectory path (e.g., Rössler et al. 1992). It thus appears very attractive for a NWP model to incorporate a module for online trajectory computation, which allows to use the wind field at every model timestep and hence allows a very accurate calculation of trajectories also for high resolution applications.

This technical report describes shortly the implementation of the online trajectory module in the official COSMO code and presents the technical aspects that are relevant for the user of the module. It is based on the user guide published as supplement material of Miltenberger et al. (2013). Discrepancies that can be observed between both documents reflect the changes made to the code between the first version and the version that is currently implemented in the official COSMO version 5.1 and higher.

For a detailed documentation, the reader should refer to Miltenberger et al. (2013), where the scientific rational, the workflow and an example of scientific application are provided. The module has been tested on several platforms and applied in multiple research projects, demonstrating its versatility and scientific soundness.

2 Scientific rational

The scientific reasoning for implementing an online trajectory module into an atmospheric model is thoroughly described in Miltenberger et al. (2013). This paper is freely accessible at *http://www.geosci-model-dev.net/6/1989/2013/gmd-6-1989-2013.pdf*.

This comprehensive scientific documentation provides also insights in the workflow and the trajectory integration scheme. It discusses error sources for the trajectory calculation and

their relative importance and assesses the overall performance of the model. In addition a case study of an alpine foehn event is presented, demonstrating the scientific soundness of the method and the advantage of the online trajectory computation over offline trajectory computation using standard COSMO model output.

3 Implementation overview

The online trajectory module consists of two different source files, namely `data_traj.f90` and `src_traj.f90`. While the first file contains the definition of datatypes and the declaration of some variables used across the whole module (in particular some maximal values for the dimensioning of module arrays), the allocation of the module variables, the forward integration of the trajectories, the communication between the processors and the I/O subroutines are available in the second file. The interfaces to the rest of the COSMO code are slim: four calls to the organizing routine of the module in `lmorg.f90` and one call in `organize_data` as well as a global switch to activate/deactivate the module.

The module is controlled by a namelist and requires a text file containing the start positions of the trajectories (startfile).

In the following sections the technical details related to the use of the module and its implementation are described. Section 4 provides an overview of all relevant namelist swiches and section 5 explains how the start information of the trajectories should be specified. Reading these two sections should be enough to setup a trajectory computation. In section 6, more information about the output files produced by the trajectory module is provided while section 7 details the current implementation and should ease code comprehension and further extension.

4 Namelist settings

The online trajectory module can be switched on and off by an additional namelist parameter in the namelist group `RUNCTL` named `ltraj`, which is set to `FALSE` by default. The user-defined parameters for the trajectory calculation can be specified in a separate namelist named `INPUT_TRAJ` in a namelist group called `TRAJCTL`. These parameters are described below.

- `istart_mode_traj` : Specification mode of the trajectory start times:
  - `istart_mode_traj= 1` : A comma separated list of start times has to be given through the namelist parameter `hstart_traj` or `nstart_traj`. The list contains the start times in hours after model start (`hstart_traj`) or in model time steps (`nstart_traj`). Trajectories are always started at the same spatial locations for each specified start time. `nstart_traj` has priority over `hstart_traj` if both are specified.
  - `istart_mode_traj = 2` : Trajectories are started repeatedly at fixed time intervals from the same spatial locations. The first start time (in hours after the model start), the last start time (in hours after the model start) and the time interval (in hours) are specified through the namelist parameter `hcomb_start_traj` (a comma separated list of the three elements). The same triplet can be expressed in model time steps through the namelist parameter `ncomb_start_traj`. `ncomb_start_traj` has priority over `hcomb_start_traj` if both are specified.

  - `istart_mode_traj = 3` : Trajectories are started repeatedly at the times and locations provided in the startfile. The start times should be provided in hours and the entries in the startfile should be sorted according to starting time. Except for `nstop_traj` resp. `hstop_traj` all other namelist parameters pertaining to the start times (`hcomb_start_traj`, `ncomb_start_traj`, `hstart_traj`, `nstart_traj`) have no effect.
- `startfile_traj` : Path of the start file. The path can be a relative path and is limited to 100 characters. A description of the start file is provided in section 5.
- `hstop_traj` or `nstop_traj`: Time at which the trajectory calculation stops in hours after model start or in model time steps, respectively. It only has to be specified if the trajectory calculation should stop before the model integration. It has to be a multiple of the model time step. `nstop_traj` has priority over `hstop_traj` if both are specified.
- `ydir_traj` : Directory to which the trajectory output will be written. The directory specification is limited to 100 characters.
- `hinc_out_traj` or `ninc_out_traj`: Output frequency of the trajectory positions (and traced variables) in hours or in number of model time steps respectively. `hinc_out_traj` has to be a multiple of the model time step and `ninc_out_traj` has to be a whole number. If both parameters are specified, `ninc_out_traj` has priority over `hinc_out_traj`.
- `tracevar_traj` : Names of the variables which should be traced along the trajectories. The naming should be consistent with the table in the COSMO source file `src_setup_vartab.f90`, which is also used for the COSMO model output.

An example of the namelist `TRAJCTL` is given in Listing 1.

Listing 1: Namelist example

```
cat > INPUT_TRAJ << end_input_traj
 &TRAJCTL
  nstop_traj= 4320,
  hstop_traj = 24.0,
  istart_mode_traj = 1,
    hstart_traj = 3.0,6.0,12.0,
    nstart_traj = 540,1080,2160,
    !hcomb_start_traj=
    !ncomb_start_traj=
  startfile_traj = './startfile_case_n.txt',
  ydir_traj = './output_traj',
  !hinc_out_traj = 0.0333,
  ninc_out_traj = 6,
  tracevar_traj = 'T','P','QV','QC','QR','RELHUM',
/
end_input_traj
```

5 Start file

A start file containing the start positions (and times) of the trajectories has to be provided. It is specified by the user via the namelist parameter `startfile_traj` (see section 4). It contains the rotated longitudes, the rotated latitudes and the height and optionally the times at which the trajectories are started.

It is a textfile and it must comply with strict formatting rules.

The first 3 lines are header lines:

- First line: It contains the reference date, i.e., the date at which the COSMO simulation starts. This line is not considered by the program.
- Second line: Description of the file data columns. It should either be `"time lon lat z"` or `"lon lat z"` (without quotes). Only the first four non blank characters of this line will be analyzed by the program and in case the first four characters match the keyword `time`, the program will read the first data column as being the start times and expect the second column to be the rotated longitudes. If the first four characters do not match the keyword `time`, the first data column is assumed to contain the rotated longitudes.
- Third line: It is not relevant for the program. It traditionally contains only `"-------"` symbols.

The following lines in the file are content lines. In case the keyword `time` is present on the second line, the program reads the first column as the start times, the second as the rotated longitudes, the third as the rotated latitudes and the fourth as the height. If the keyword `time` is not present on the second line, the first column is read as the rotated longitudes, the second as the rotated latitudes and the third as the height. Column delimiters are blank spaces. The longitudes have to range between `-180.0` and `180.0` degrees and the latitudes can be comprised between `-90.0` and `90.0` degrees. They are expressed in the same referential than COSMO (i.e., same rotated pole coordinates). The height has to be given in meters AMSL. If time data is provided, it must be in hours after model start. The entries in the startfile should be sorted according to starting time.

The start file is read in an endless loop and all lines (except the 3 header lines) are considered as data.

Make sure that your start file fulfills the format requirements explained above!

A startfile should look similar to the example provided in Listing 2.

Listing 2: Start file example

```
Reference Date 19870725_0000
time lon lat z
----------------
 10.00    -8.000   -2.500 9000.000
 10.00    -8.000   -2.500 9100.000
 10.00    -8.000   -2.500 9200.000
```

6 Output

For all trajectories, their position as well as the value of the traced variables are written to file at the output frequency specified by the user via the namelist parameter `hinc_out_traj` or `ninc_out_traj` (see section 4) in the output directory specified by the user (`ydir_traj`, see section 4). Only NetCDF format is supported.
The output is split in the following way: The trajectories that start together at a given start time are considered as a group. If the group is too large to be contained in one single file,

the trajectories are further split over several files, according to their position in the start file. A limit of 2 GB is set as maximal file size in order to ease postprocessing. At all output time steps comprised between the start of the trajectory group and the end of the trajectory simulation (see namelist parameter `hstop_traj` or `nstop_traj` in section 4), the positions and traced variable values for the group of trajectories are written to one (or several) files. The files can thus have different lengths (for different start times).

One or several files `traj_tXXXXXX_pYYY.nc` are thus produced, where `XXXXXX` is the start time of the trajectory group expressed in minutes after the model start and `YYY` is the number of the file in the file set containing the trajectories starting at `XXXXXX` after the model start.

The output files follow the CF conventions. Some global attributes (reference date, duration of the simulation for the group of trajectories, coordinates of the rotated pole and output frequency) are written to each file. A variable `time` indicates the time elapsed since the model start in seconds. For each instance of `time` (first dimension) and for each trajectory identified by its ID (`id` as second dimension), the longitude, latitude and height (variables `longitude`, `latitude` and `z`) are written as well as the value of the traced variables. For each of these variables, the short name, the long name and the units are provided as attributes.

The header of an output file (here for 13507 trajectories starting after 120 minutes) thus looks like the example provided in Listing 3.

Listing 3: Output file example

```
netcdf traj_t000120_p001 {

                :output_timestep_in_sec = 20. ;
}
```

7 Implementation details

7.1 Workflow overview

An organizing routine `organize_traj` is called four times from `lmorg.f90`:

1. Once at the beginning of the initialization phase with the action `'input'`. The namelist `INPUT_TRAJ` is read as well as the start file. Necessary checks are performed in order to ensure that the specifications made by the user are meaningful. The user can proof the settings by inspecting the `YUSPECIF` file.

2. Once later on during the initialization phase with the action `'init'`. Arrays required for the whole trajectory simulation are allocated. A data structure is filled for all traced variables (see section 7.4). The rank of the eight surrounding processing elements for each processing element is defined in a parallel case. The position of the trajectories are initialized using the information read from the start file. Also, a status flag indicating if the trajectory has to be computed (`alive`), has left the domain (`dead`) or is not yet started (`embryonic`) is initialized using the start times read from or derived from the namelist settings (see section 4). In case the simulation is started from a restart file, the start positions are read directly from the restart file instead of the start file. The number of required output files is computed and the split of the trajectories among these files is determined. All NetCDF files are created and the global attributes are

written to the files. The variables are defined and their attributes written. In case the simulation is started from a restart file, this information is read from already existing output files. The NetCDF files will be kept open for the whole trajectory simulation.

3. Once at the end of each time step, where the other diagnostics are computed, with the action `'compute'`. For each compute time step of the trajectories (i.e., for each time step comprised between the start of the first trajectory and the end of the trajectory computation, both specified by the user via namelist parameters), it is checked for each trajectory, if it should be computed or not on each processor. In case it has to be computed, the forward integration is performed (see Miltenberger et al., 2013 for more details) and in case the trajectory leaves the processor domain after its integration, it is added to a buffer for communicating the new position to the relevant neighbor processor. After this has been done for all trajectories, the communication of all trajectories that have to be passed to a neighbor processor is performed. Finally output is performed, if the time step corresponds to an output time step.

4. Once at the end of the simulation with the action `'finalize'`. All NetCDF files are closed and the memory used for the trajectory simulation is freed.

In addition an organizing routine `organize_traj_restart('restart')` is called from `organize_data('results')` at the end of the time step in order to write out the trajectories to an extra restart file if needed.

7.2 Maximal values for array allocation

Some restrictions have to be set regarding the maximal size of arrays used in the module. All the maximal values are defined as parameters in the module `data_traj.f90`.
In case these maximal values have to be increased, one can simply change the values of the parameters listed below in `data_traj.f90` and test, if the model still works on the platform used.

The parameters are:

- `nmax_traj_starttime=100`: Maximal number of trajectory start times. It means that up to 100 values can be provided by the user through the namelist parameters `hstarts_traj` or `nstarts_traj` or that the namelist triplet `hcomb_start_traj` or `ncomb_start_traj` does not lead to more than 100 values. This parameter should be increased with caution!

- `nmax_traj_startpt=50000`: Maximal number of trajectories that can start at a given start time (from different locations). It thus means that a maximum of `100*50000=5 mio.` trajectories is imposed. Please note that so far, the module has been tested only with up to about 2 mio. of trajectories. If increasing this parameter or the previous one, intensive testing should be done.

- `nmax_traced_var=30`: Maximal number of variables that can be traced along the trajectories. This parameter could be increased, if more variables should be traced, but testing is recommended.

- `nmax_out_per_start_t=100`: Maximal number of output files per start time. It corresponds to the part `YYY` in the output filename `traj_tXXXXXX_pYYY.nc`. Please note that this could not be increased to more than 999 without modifying the naming scheme

of the output files. At the moment, we cannot produce more than `100*100=10'000` output files (`nmax_traj_starttime` times `nmax_out_per_start_t`).

- `nmax_nc_size=2*2^30`: Maximal size of an output file. The file size is currently limited to 2 GB in order to ease post-processing. If increasing this value, some post-processing facilities might fail.
- `header_nc_size=2*2^20`: Reserved space for the header in an output file (2 MB). If more information is added to the header in the future, it might be necessary to increase this number.

7.3 Restrictions of use

The periodic boundary conditions are not yet implemented for the trajectories. The trajectory module can be used in combination with periodic boundary conditions (`lperi_x` and `lperi_y`) and the trajectories will be computed using periodic winds but the trajectories themselves are not cycled.

Other configurations are supported.

7.4 Traced variables

A new data type `trajtrace_type` is defined in `data_traj.f90` to hold the needed information to handle properly the traced variables. Most of the information is inherited from the `var` structure available in `src_setup_vartab.f90`. It contains the following elements:

- `name`: name of the traced variable
- `levtyp`: level type (GRIB related)
- `ntri`: time range indicator (GRIB related)
- `rank`: rank
- `p4`: pointer to a 4-dimensional field
- `p3`: pointer to a 3-dimensional field
- `idef_stat`: status indicating if the variable has been computed already or if it should be derived from other model variables
- `istag`: staggering flag (`0`: no staggering; `1`: zonal staggering; `2`: meridional staggering; `3`: vertical staggering)
- `units`: units (NetCDF related)
- `sdname`: standard name (NetCDF related)
- `lgname`: long name (NetCDF related)

Only COSMO model variables can be traced. The name of the traced variables must match exactly the name of the corresponding variable in the `var` structure (in `src_setup_vartab.f90`). Only 4-dimensional and 3-dimensional variables in space can be traced. The traced variables

must be instantaneous values (i.e., have a time range indicator of 0), since it is not clear what should be traced in case of accumulated values or statistical quantities (mean, min, max). The variables can be on the half-levels or on the full-levels. They can be staggered in zonal direction (`U`) or in meridional direction (`V`). All variables that are valid at each time step in the model (`idef_stat=1` in `src_setup_vartab.f90`), i.e., all prognostic variables and several diagnostics, can be traced. The other model variables (`idef_stat=0` in `src_setup_vartab.f90`) must be derived before being written to the COSMO output. Only a subset of these variables has been implemented for tracing so far:

- `P`: total pressure
- `RELHUM`: relative humidity
- `POT_VORTIC`: potential vorticity

Other variables could easily be implemented by making use of the subroutines used in `src_output.f90` (e.g., `curl`).

At each output step the traced variables are interpolated to the trajectory position using a linear interpolation. The computed values for the traced variables as well as the trajectory ID and position (longitude, latitude and height) are gathered on processor 0, which writes the data to file.

7.5 Communication strategy

For each trajectory that leaves a processor, its ID as well as the three components of its position (longitude, latitude and height) are packed in a buffer dimensioned with the 8 neighbors and with the number of trajectories times the four needed pieces of information (ID, longitude, latitude and time). After having looped over all trajectories, actual communication is performed. For this, a "pairwise" non-blocking (`MPI_ISEND` and `MPI_IRECV`) communication strategy has been chosen. Two slices of the buffer for opposite neighbor processors (e.g., northern and southern neighbor) are communicated at a time. This is faster than communicating in each direction one after the other and requires less memory than a communication in all directions at a time. This solution is thus a compromise between performance in terms of communication speed and memory consumption. This could easily be changed if desired. The `MPI_IRECV` are pre-posted in order to improve performance.

7.6 Trajectory positions

The trajectory positions in the index space must be determined several times during a trajectory computation time step: To determine the winds at the trajectory position in order to update its position, to interpolate the orography at the trajectory position (in order to check if the trajectory has reached the ground), and finally to interpolate the traced variables to the trajectory location in case output must be performed. This computation is sensitive to the reference system and rounding errors thus occur when changing the domain decomposition. They are very small (typically differences of $O(10^{-9})$ for the longitudes and latitudes, $O(10^{-6})$ for height, $O(10^{-7})$ for traced temperature, $O(10^{-8})$ for traced wind or pressure, $O(10^{-10})$ for the traced humidity variables are observed) and do not affect the physical interpretation of the trajectories.

The required horizontal interpolation combined with the formulation of the lower boundary condition in the model (wind extrapolation) leads to trajectories that intersect the terrain, which is physically impossible. Any trajectory that reaches the ground is then lost for the rest of the simulation. In order to avoid unreasonable loss of trajectories, a trajectory that reaches the ground is reset to 10 meters above ground during the Euler forward integration (see Miltenberger et al., 2013 for more details). A hardcoded switch `ljump` controls this feature and could easily be set to `FALSE`, in order to let the trajectories leave the domain at the ground during the forward integration. Similarly, the value of the hardcoded parameter `hjump` that defines the height, at which the trajectories are reset (currently 10 meters above ground) can easily be modified.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW) and Romania (NMA). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction, configuration of the multi-layer soil model

During the last years a new multi-layer version of the GME/LM soil model was developed (Schrodin and Heise, 2002; Heise et al., 2003) to replace the former operational 2-layer version. It became operational in GME on September 27, 2004, and in LM with the new extended model area LME on September 28, 2005. The aim of this report is to describe the present state of experience gained with the new soil model during the first years of (pre)operational use.
The main reason for increasing the number of layers was the need to take into account for freezing/melting processes in the soil, which in the 2-layer model are neglected. Because of the comparably thick uppermost layer in that version, freezing/melting effects would cause near surface temperatures to stick close to 0^oC for much too long periods in situations where in reality temperatures change around the freezing point with considerable amplitudes. But the omission of freezing/melting results in too large amplitudes of the near surface temperature in these situations. Therefore, a new version of the soil model was developed. It's main characteristic is a very high resolution in the uppermost layers of the soil. In order to avoid problems with prescribing the lower boundary condition for the thermal part, it was decided to extend the soil model to a depth, in which the annual variation of temperature is negligible. The solution

$$\delta = \Delta T_s e^{z/D} e^{i(\omega t + z/D)} \tag{1}$$

of the heat conduction equation (where δ is the temperature difference to a constant deep soil temperature, ΔT_s is the amplitude of a periodic variation of the soil surface temperature with frequency ω, D is the e-folding depth for the temperature wave, and z is the vertical coordinate, negative downward), shows the amplitude reduction of the surface temperature wave with increasing depth in the soil. For typical values of the e-folding depth of an annual temperature wave in the soil ($D \approx 2m$) an amplitude reduction to roughly 3 % of the surface value is achieved in a depth of 7 m. This led to the layer structure as given in Figure 1. In correspondence with the solution of the heat conduction equation, the layer thickness increases exponentially with depth. An additional layer with a temperature being constant in time is added below 7.29 m. Here the annual mean atmospheric near-surface temperature is prescribed as a boundary condition.

In contrast to the former two-layer version, identical layer structures are used in the thermal and the hydrologic parts, respectively. However, in contrast to the thermal part no straightforward solution for the lower boundary condition is available for the hydrologic part. Therefore, we tentatively follow a suggestion expressed in the context of the EU-project ELDAS (http://www.knmi.nl/samenw/eldas/) and prescribe a flux-boundary-condition in a depth of 2.43 m. In this depth we only consider the gravitational drainage of water and neglect any water transport due to vertical soil water gradients. In ELDAS a detailed verification has been performed of multi-annual quasi two-dimensional simulations using the multi-layer soil model. Here data from the Rhône-AGGregation Experiment (Boone et al., 2001) have been used partly as forcing data and partly as verification data. The verification concentrated on the annual courses of the snow budget and of the runoff production. The results led to some reformulation of aspects of the soil model.
The soil model is still strictly one-dimensional, i. e., all horizontal transports of water and energy in the soil are neglected. The effect of freezing/melting of soil water/ice is taken into account. The formulation accounts for the capability of the soil to retain a certain amount of liquid water at temperatures well below the freezing point. A single layer snow module complements the soil model.
For details of the soil model formulation the reader should refer to the extended documentation of the soil model (Doms et al., 2005).

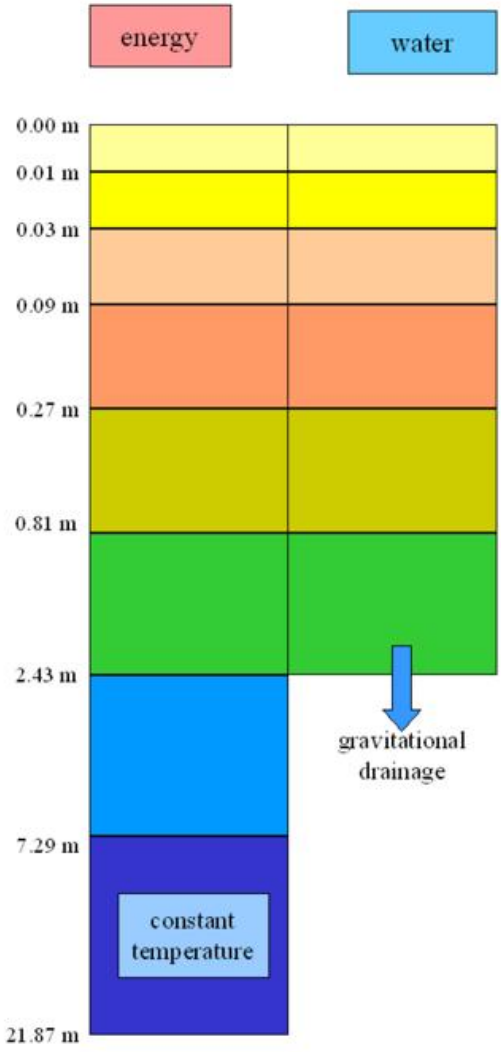

Figure 1:
Structure of the soil model

2 Operational use of the multi-layer soil model in the global model (GME) of DWD

Since September 2004 the multi-layer soil model is in operational use in the global model GME of the German Weather Service. A more than one year pre-operational run with GME preceded the operational introduction. During the operational use in GME some previously undetected problems were discovered, and a flux limiter was introduced.

2.1 Instability problems in connection with the interception store

In some cases an unfavourable interaction between the thin uppermost layer of the soil and the interception store was observed. As the interception store is not as important in the multi-layer model as in the former two layer model which used a thickness of the first layer of 0.1 m, the interception store was deactivated by setting it's maximum value to 10^{-6} m. The code related to the interception store was retained in order to allow for a later reuse of the interception store formulation.

2.2 Negative near surface temperature bias in the presence of snow, implementation of a prognostic treatment of snow density

In March 2005 excessive low temperatures were simulated over an old snow pack in southern Germany. The problem was traced back to the prescribed low density of the snow, which did not depend on external influences. The low value of snow density results in a) low heat conduction through the snow, and in b) a comparably thick snow layer for a given value of snow water equivalent. Both effects result in a very effective isolation between the soil surface and the top of the snow layer, leading to a de facto decoupling between soil and atmosphere. In order to overcome this problem, a time-dependent formulation of snow density was tested and implemented in GME. This formulation combines an ageing function, which simulates the various processes involved in the complex metamorphosis of an existing snow pack in a very crude way, with a reduction of the mean snow density in situations of fresh snow fall. The new value $\rho_{snow,new}$ of snow density at the end of time-step Δt is given by

$$\rho_{snow,new} = \left\{ \rho_{snow,age} W_{snow,old} + \rho_{snow,fresh} RR_{snow} \frac{\Delta t}{\rho_w} \right\} / W_{norm} \tag{2}$$

Here $W_{snow,old}$ is the snow water equivalent at the beginning of time-step Δt, ρ_w is the density of water. The ageing is accounted for by

$$\rho_{snow,age} = \rho_{snow,max} + (\rho_{snow,old} - \rho_{snow,max}) e^{-C_{age} \Delta t / \tau_\rho}, \tag{3}$$

where $\rho_{snow,old}$ is the snow density at the beginning of time-step Δt, and

$$C_{age} = 0.2 + (0.4 - 0.2) \cdot \frac{T_{snow} - T_{min}}{T_0 - T_{min}} \tag{4}$$

T_0 is the freezing point and we use $T_{min} = 258.15$ K. The time constant is set to $\tau_\rho = 1d$. The density of fresh falling snow is parameterized by

$$\rho_{snow,fresh} = \rho_{s,f,min} + (\rho_{s,f,max} - \rho_{s,f,min}) \cdot \frac{T_{low} - T_{min}}{T_0 - T_{min}}, \tag{5}$$

where $\rho_{s,f,min} = 50\ kg/m^3$, $\rho_{s,f,max} = 150\ kg/m^3$, and T_{low} is the temperature in the lowest atmospheric level. Finally, RR_{snow} is the rate of snowfall, and $W_{norm} = W_{snow,old} + RR_{snow}\frac{\Delta t}{\rho_w}$. The whole range of snow densities is restricted to $\rho_{snow,min} = 50\ kg/m^3$ and $\rho_{snow,max} = 400\ kg/m^3$.

In connection with the implementation of a time dependent snow density the determination of the snow heat conductivity was changed to

$$\lambda_{snow} = \lambda_{ice} \left\{ \frac{\rho_{snow}}{\rho_{ice}} \right\}^{1.88}, \tag{6}$$

where $\lambda_{ice} = 2.22\ W/(mK)$ is the heat conductivity of ice.

These changes became operational in GME on December 7, 2005.

2.3 High-frequency small-amplitude waves in the surface temperature

There is a tendency of the multi-layer soil model to produce $2\Delta t$-waves of small amplitude in the soil surface temperature. Normally these waves are not harmful to the rest of the (atmospheric) model. But in one case the effect became a problem because of an unfavourable coupling with atmospheric temperatures at grid-points with very large values of the roughness length. The small wave in the surface temperature combined with a more or less constant atmospheric temperature resulted in an alternation between stable and unstable stratification. Because of the large roughness length this led to a large-amplitude $2\Delta t$-wave in the transfer coefficient which resulted in a large-amplitude $2\Delta t$-wave in the diagnosed gusts. The runs with the LME seem not to be prone to this problem as LME uses a different formulation of the surface layer processes. In GME since August 24, 2005, the roughness length is restricted to 50 % of the height of the lowest atmospheric main level in order to overcome this problem.

2.4 Unfavourable interaction with the snow analysis

During the test-phase of the multi-layer soil model in combination with the assimilation cycle of GME it happened that snow cover was analysed in grid-elements with a soil surface temperature above the freezing point. As the analysed snow has the priority over the first guess of the model (zero snow cover in these grid-elements), an adjustment of soil temperatures is necessary. This was done by reducing the soil surface temperature to $0^o C$. In order to avoid too strong vertical gradients of the soil temperature across the first layer, a correction was applied to all soil layers with the temperature increment at the surface being linearly reduced to zero in the depth of the main level of the climate layer. In some parts of the Himalayas this led to soil temperatures of $0\,K$ during summer. The reason was a perpetual insertion of a few mm of snow in each analysis step. During the forecast this snow melted very fast, and soil surface temperatures increased considerably. But the next snow cover analysis again produced snow, and the correction had to be applied again. In the upper soil layers the energy gain due to solar radiation compensated the artificial temperature reduction in the analysis step and prevented temperatures from decreasing too much. But in the lower soil layers there was no effect counteracting the continual reduction of temperature. Therefore, the correction had to be modified. Now it is applied only in those uppermost layers, which exhibit temperatures above the freezing point. This version is applied since the start of the operational use of the multi-layer soil model in GME.

2.5 Limitation of transfer coefficients to alleviate stability problems in the multi-layer soil model

The continuous evolution of atmospheric and soil state variables which occur in the real world is not always guaranteed in the context of an NWP model. Abrupt changes may be caused in data assimilation steps but also within the actual forecast, where abrupt changes in the forcing terms (e.g. solar radiative surface flux) may be introduced as a consequence of a numerical method (e.g. rather infrequent calls of the radiative transfer scheme). If the inertia of model and soil layers is sufficiently large compared to the magnitude of the disturbances, a new balanced state can be achieved within a limited number of forecast time steps. If, in contrast, the disturbance is large compared to the model inertia, overshooting reactions may occur, which can subsequently lead to numerical instability.

The current multi-layer soil model, which features a top layer thickness of 1 cm, is prone to such over-reactions, following significant instantaneous changes in variables like snow water content or near surface wind in the analysis step or abrupt changes in the solar forcing caused by large variations in cloud cover between radiation time steps.

2.5.1 Turbulent transfer coefficient limitation at the surface

The overshooting reaction can be alleviated in many situations through the introduction of a situation-dependent upper limit for the turbulent fluxes exchanged between atmosphere and soil. For this purpose the flux will, if possible, be constrained such that the temporal tendency of the uppermost soil layer, i.e. the one with the smallest thermal inertia, does not exceed a prescribed limit in a single model time step.

The temperature tendency for each soil layer follows from:

$$\rho_{soil} c_{soil} \frac{\partial T_{soil}}{\partial t} = -\frac{\partial G}{\partial z} \tag{7}$$

with a typical value of the soil heat capacity of

$$\rho_{soil} c_{soil} = 1.4 \cdot 10^6 \frac{J}{m^3 K} \tag{8}$$

In (7) T_{soil} represents the soil temperature, z the soil depth and G the soil heat flux, which at the upper boundary is replaced by the surface fluxes of radiation, sensible and latent heat flux. For simplicity we will ignore the contributions by internal sources and sinks like melting and freezing of soil water.

Postulating an upper limit for the temporal temperature increment $\Delta T_{soil,max}$, we may derive a threshold for the heat flux at the earths surface. In discretized form we obtain:

$$\left| \frac{G(0) - G(1)}{z(0) - z(1)} \right| \leq \rho_{soil} c_{soil} \frac{\Delta T_{soil,max}}{\Delta t} \tag{9}$$

where the depths z refer to the half levels of the soil model grid and may be replaced by the thickness of the first soil layer, which we will denote byΔz_{soil}.

The presence of snow on the ground may be incorporated in (9) through the addition of a component representing a potential heating and melting of the snow layer. Based on (9) we then obtain:

$$\begin{aligned} &|G(0) - G(1)| \leq \\ &\left(\rho_{soil} c_{soil} \Delta T_{soil,max} \Delta z_{soil} + \rho_{H_2O} W_{snow} (c_{snow} \Delta T^0_{soil,max} + L_{melt})\right) / \Delta t \end{aligned} \tag{10}$$

The superscript "0" in the snow heating term reflects the fact that snow temperatures must not exceed the melting temperature. In this approach the latent heat of fusion should of course only be considered for events when the overall energy budget of the surface layer indicates a heating and the energy required for snow melting would therefore contribute to the thermal inertia of the uppermost soil layer and moderate the layer temperature tendency. A snow layer of 10 cm would typically have a heat capacity which is larger than the corresponding value of the uppermost soil layer and the energy required to melt such an amount of snow is even larger, provided the temperature increments are not excessively large. However, for simplicity, we will omit the snow contribution in the following. These effects may simply be added in the final form of the derived equations.

The flux at the upper boundary G(0) can be decomposed in the individual contributions from sensible heat flux J_s, latent heat flux J_q, net solar F_s and net thermal radiative flux F_t. Using this decomposition, we obtain:

$$\begin{aligned} &|J_s + J_q + F_s + F_t - G(1)| \leq \\ &\quad \left(\rho_{soil} c_{soil} \Delta T_{soil,max} \Delta z_{soil} + \rho_{H_2O} W_{snow} (c_{snow} \Delta T^0_{soil,max} + L_{melt})\right) / \Delta t \end{aligned} \tag{11}$$

This equation poses an upper limit on the total flux divergence for the uppermost soil layer. Since radiative fluxes are computed independently and the soil heat flux at the lower boundary of the layer is generally small compared to the other contributions, we will try to comply with the imposed limitation through an adjustment of the sensible (and latent) heat flux. As the sensible heat flux is computed from the relation:

$$J_s = C_D |\vec{u}| \rho_a c_a \Delta T_{as} \tag{12}$$

where ΔT_{as} represents the temperature difference between atmosphere and the earths surface, $|\vec{u}|$ the near surface wind speed and C_D the dimensionless transfer coefficient for heat. The atmospheric heat capacity has a typical value of $\rho_a c_a \approx 1000 J/(m^3 K)$.

A similar equation holds for the latent heat flux, i.e.

$$J_q = C_D |\vec{u}| \rho_a L_v \Delta q_{as} \tag{13}$$

with latent heat of condensation and moisture difference between surface and atmosphere as relevant properties.

Substitution of the turbulent flux equations (12) and (13) into (11), gives:

$$\begin{aligned} &|C_D |\vec{u}| \rho_a (c_a \Delta T_{as} + L_v \Delta q_{as}) + F_s + F_t - G(1)| \leq \\ &\quad \left(\rho_{soil} c_{soil} \Delta T_{soil,max} \Delta z_{soil} + \rho_{H_2O} W_{snow} (c_{snow} \Delta T^0_{soil,max} + L_{melt})\right) / \Delta t \end{aligned} \tag{14}$$

As all other properties are either fixed or can not be changed without major complications, we will attempt to comply with the soil temperature tendency limitation through a constraint to the surface-atmosphere transfer coefficient. In order to isolate the transfer coefficient in (14), we must now introduce a distinction between heating and cooling situations for the topmost soil layer.

Let us first consider a heating of the soil, i.e. the sum of all contributions on the left hand side of (14) is positive even before taking the absolute value. In this case, we may rewrite (14) as:

$$\begin{aligned} C_D |\vec{u}| \rho_a (c_a \Delta T_{as} + L_v \Delta q_{as}) \leq \\ \left(\rho_{soil} c_{soil} \Delta T_{soil,max} \Delta z_{soil} + \rho_{H_2O} W_{snow} (c_{snow} \Delta T^0_{soil,max} + L_{melt})\right) / \Delta t \\ - F_s - F_t + G(1) \end{aligned} \tag{15}$$

Despite the supposition of an overall heating, the energy transfer by turbulent fluxes may in certain situations be directed from the soil to the atmosphere. In such situations a reduction of the turbulent transfer coefficients would be counterproductive to our intention of limiting the heating of the first soil layer. In these cases we will therefore retain the original unlimited transfer coefficient. If turbulent fluxes would provide a positive contribution to the energy budget of the soil and thereby enhance the overall heating in situations when atmosphere and soil are not in balance (e.g. after the data assimilation step) a limitation of the transfer coefficient can alleviate the problem. In this situation, we may solve (15) for C_D to obtain the following constraint for the transfer coefficient:

$$\begin{aligned} C_D \leq \{ \left(\rho_{soil} c_{soil} \Delta T_{soil,max} \Delta z_{soil} + \rho_{H_2O} W_{snow} (c_{snow} \Delta T^0_{soil,max} + L_{melt}) \right) / \Delta t \\ - F_s - F_t + G(1) \} \; / \; \{ |\vec{u}| \rho_a (c_a \Delta T_{as} + L_v \Delta q_{as}) \} \end{aligned} \tag{16}$$

The physical meaning of (16) is obvious. Compared to the threshold soil temperature tendency the remaining possible contributions by turbulent fluxes to the heating of the first soil layer is diminished by the potential contributions of radiative fluxes at the surface and the internal heat flux between soil layer 1 and 2. In the presence of snow a (substantial) part of the energy gain may be used for the heating and/or melting of the snow layer, thereby allowing an overall larger total energy input.

Let us now consider a cooling of the soil, i.e. the sum of all contributions on the left hand side of (14) is negative before taking the absolute value. In this case, we may rewrite the equation:

$$\begin{aligned} C_D |\vec{u}| \rho_a (c_a \Delta T_{as} + L_v \Delta q_{as}) + F_s + F_t - G(1) \geq \\ -(\rho_{soil} c_{soil} \Delta T_{soil,max} \Delta z_{soil} + \rho_{H_2O} W_{snow} c_{snow} \Delta T^0_{soil,max}) / \Delta t \end{aligned} \tag{17}$$

leading to:

$$\begin{aligned} C_D |\vec{u}| \rho_a (c_a \Delta T_{as} + L_v \Delta q_{as}) \geq \\ -(\rho_{soil} c_{soil} \Delta T_{soil,max} \Delta z_{soil} + \rho_{H_2O} W_{snow} c_{snow} \Delta T^0_{soil,max}) / \Delta t - F_s - F_t + G(1) \end{aligned} \tag{18}$$

Note that the snow melting term has vanished since no melting will take place, if the overall forcing is negative. A limitation of the transfer coefficient in this situation can only alleviate the temperature tendency problem of the first soil layer, if the turbulent fluxes at the surface would contribute to an energy loss. Solving for the transfer coefficient, we obtain:

$$\begin{aligned} C_D \leq \{ (-\rho_{soil} c_{soil} \Delta T_{soil,max} \Delta z_{soil} + \rho_{H_2O} W_{snow} c_{snow} \Delta T^0_{soil,max}) / \Delta t \\ - F_s - F_t + G(1) \} \; / \; \{ |\vec{u}| \rho_a (c_a \Delta T_{as} + L_v \Delta q_{as}) \} \end{aligned} \tag{19}$$

Note the reversal from $\geq$ to $\leq$ when going from (18) to (19) due to the division by a negative quantity. In the absence of other contributions (e.g. from radiative fluxes) the energy loss through turbulent fluxes from the earths surface to the atmosphere is simply constrained to keep the cooling of the first soil layer below the specified threshold value. Positive contributions to the energy balance of the soil layer (e.g. by solar radiation or an upward heat flux within the soil) imply a larger potential for an energy loss through turbulence without violation of the imposed threshold.

2.5.2 Final remarks

The above derivation of a threshold equation for the transfer coefficient does not consider that the heat conduction equation is solved implicitly in the soil scheme. However, the upper limit for the temperature increment within one time step has to be chosen rather arbitrarily anyway. And the whole mechanism is only intended for a "soft" relaxation towards a more balanced atmospheric and soil structure in hopefully rare cases of "unphysical" changes of individual state variables or forcing components. In situations were a limitation of the transfer coefficient were counterproductive, the temporal tendency of the uppermost soil layer remains unchanged. If such a situation would lead to an unstable behaviour of the soil scheme, one would either have to reduce the model time step or extend the flux limitation approach to other forcing terms like the surface radiative fluxes.

3 Pre-operational and operational use in LME

In January 2005 the pre-operational test-suite of LME was initiated using the multi-layer soil model. Because at this time GME had been running pre-operationally and operationally for more than one year, temperatures and water content values in the LME-soil could be initialised by interpolation of the respective GME-fields. Therefore, the initial values could be regarded as being fairly adjusted to the model climate. No long spin-up period had to be anticipated. The soil moisture assimilation scheme was transferred from LM to LME with some adjustment because of the different layer structure. On September 28, 2005, LME replaced LM as the operational limited area model. Since the start in January no serious problem was noted in the LME soil model.
Most of the changes made during the first year of operational GME-runs with the new soil model were implemented step by step also in LME. The large negative bias of near surface temperatures observed for the GME in March 2005 was reduced in the LME by a provisional - and in fact not correct - method to convert snow heights to snow water equivalent in the LME-analysis. Purely by chance this method considerably reduced the problem. On January 05, 2006, the time-dependent treatment of snow density became operational in LME.
LME seems not to be prone to the problem with the small amplitude waves in surface temperatures as it uses a different formulation of the surface layer processes. Although no problems in the interaction with the snow analysis were noted, the respective method of GME was copied into LME.

4 Verification of soil temperature prediction over Germany

A soil model with a large active depth used operationally obviously needs to be validated in detail. However, observations of the prognostic soil variables at different depths are not available over the whole LME domain. Fortunately, all synoptic stations over Germany regularly report soil temperatures in different depths (2 cm, 5 cm, 10 cm, 20 cm, 50 cm, and 100 cm). This allows a direct comparison of observed/simulated temperatures in depths of 5/6 cm, 20/18 cm, and 50/54 cm. Figures 2 through 7 show observed and simulated temperatures in these three pairs of depths. As to be anticipated in early autumn, temperatures increase with increasing depth both in the observations and in the model.
Unfortunately it is difficult to obtain realistic area mean values. In the case of the observations they can only be estimated by taking the arithmetic average of the values reported. The respective values of the model simulations, computed by the plot-software, are biased by the

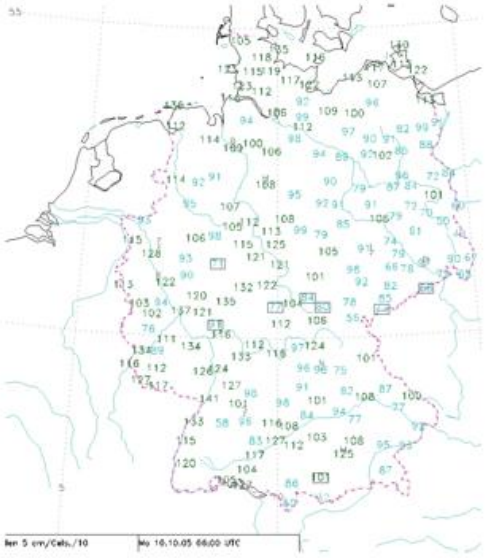

Figure 2:
Distribution of observed soil temperature $[0.1^0C]$ at 5 cm depth, 10 October 2005, 06 UTC.

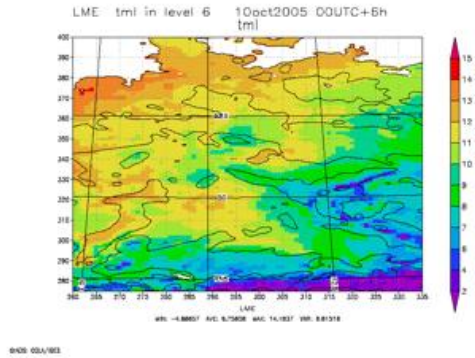

Figure 3:
Distribution of predicted soil temperature $[^0C]$ at 6 cm depth, 10 October 2005, 06 UTC.

inclusion of some part of the Alps with very low temperatures. Only very few observations are representative of higher regions, whereas the model simulations show comparably large areas with rather low temperatures because of comparably high values of the orography. Taking these effects into account, the area mean values seem to be in fairly good agreement between observation and simulation, but there seems to be some small warm bias in the model. The Upper Rhine Valley is correctly simulated as the warmest region in Germany. Although the eastern parts of northern Germany are simulated colder than the western parts, the difference is not as pronounced as in the observations. In contrast to this, some temperatures at the mountain peaks of the Thuringian Forest and of the Ore Mountains are colder in the simulations than in the observations.

5 Long-term diagnostics for LME and GME

The long-term behaviour of a soil model like the present has to be diagnosed carefully. Slow drifts might occur, especially for soil water content. A potential risk of a systematic drift in the soil temperatures is alleviated through the existence of the climate layer as a lower boundary condition. However, any systematic drift of temperatures or water content in the soil would have an impact on near surface temperatures. It is therefore mandatory to monitor the long term evolution of the soil variables in the model. For this purpose some statistical properties of the soil variables are checked on a regular basis. This monitoring is applied for layers below 0.09 m only. The rather thin three uppermost layers are excluded, as they immediately react to the atmospheric forcing. They are not characteristic of the long-term behaviour of the soil model.

5.1 Soil temperature

For the whole LME-area Table 1 shows the minimum (Min), the area averaged (Ave), and the maximum (Max) values of temperature for all soil model levels included in the diagnostic

evaluation since the start of the pre-operational LME runs in 2005. The respective values for the climatological boundary condition are: Min -11.74 ^0C, Ave 9.21 ^0C and Max 29.62 ^0C, being constant in time. The downward propagation of the annual temperature wave is clearly visible. The phase is in accord with the analytical solution of the heat conduction equation. Also, the decrease of temperature variations with increasing depth shows up in the results. In general the results appear to be realistic. There seems to be a slight discontinuity from April to May. The reason for this is a new start of LME on May 09. This was required by a new data-set of external parameters. After one year of simulation the temperatures are rather close to the initial values on 15 February, 2005. There is only a small decrease in average temperatures by less than 1 K, whereas the minimum values are slightly warmer. No uniform change is present in the maximum values. In general these results confirm the long-term stability of the soil model with respect to temperature.

5.2 Soil water content

Results for the behaviour of soil water content in LME are shown in Table 2. In the layer 0.09-0.27 m the maximum occurs in March after the snow melting in most of the model-area is finished. This high water content slowly penetrates to deeper layers. The maximum occurs in April in the layer 0.27-0.81 m and as late as August in the layer 0.81-2.43 m. Also the drying in summer is obvious, the minimum is simulated in October and November. For the whole LME-area the minimum value of soil water content is always zero because of the presence of grid-points with soil type ice or rock. For these soil types hydrological processes are not simulated and a water content of zero is prescribed. Therefore minimum values are not shown in this table. In the layers from 0.27 to 2.43 m a small decrease in average soil water content is observed. This could be a result of unsuitable initial conditions. But other data confirm a tendency of the soil model to decrease soil water content at least in part of the model area. The statistics are also available for some small regions, namely Iceland, Lapland, the Alps, and Asia Minor. Whereas for Iceland an increase in soil moisture is simulated, for the Alps a loss of 25% of the initial value is simulated for the layers from 0.27

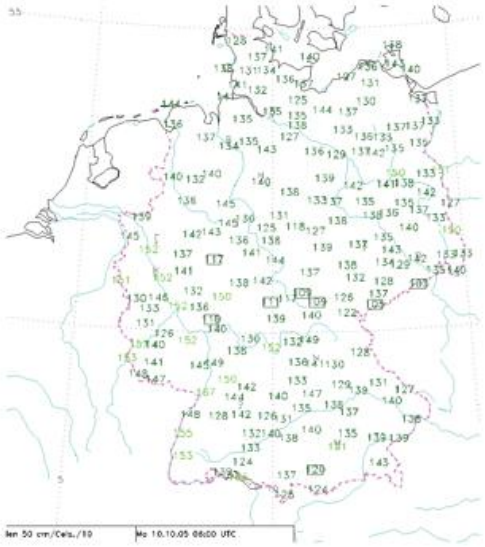

Figure 6:
Distribution of observed soil temperature $[0.1^0C]$ at 50 cm depth, 10 October 2005, 06 UTC.

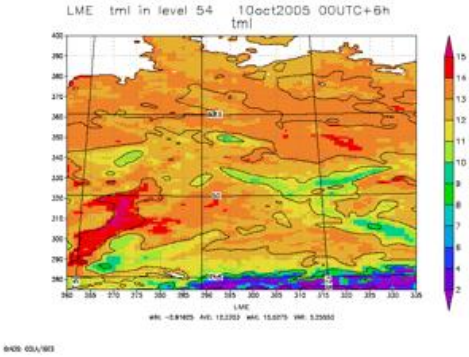

Figure 7:
Distribution of predicted soil temperature $[^0C]$ at 54 cm depth, 10 October 2005, 06 UTC.

to 2.43 m. A small decline in soil water content is also simulated for Lapland and for Asia Minor.

At the German Weather Service soil water content is measured on a regular basis in the area of the observatory Lindenberg (federal state of Brandenburg). For the year 2005 the results of the pre-operational and operational LME-runs are compared to direct measurements and to simulations performed with the model system AMBAV of the department for agricultural meteorology. AMBAV includes the very high resolution model AMBETI (Braden, 1995), which in AMBAV is driven by observations. The results of AMBAV-simulations can be used as surrogates for soil moisture measurements. Figure 8 shows a comparison of LME-forecast (6 to 30 hour forecasts for each day are combined to one quasi-annual result), direct measurements and AMBAV-results for the layer 9 to 27 cm. Taking into account for the limited comparability of direct soil water content measurements and model simulations for a rather large area (7 x 7 km^2), the results agree fairly well until the end of the second quarter of the year. But in July and August there is excessive drying in the LME-results. This effect is only partly compensated in September. In December the moisture values are much lower (roughly 50 %) than in January.

It must be noted that at DWD the operational LME is run including a soil moisture assimilation scheme (SMA). The SMA reacts on errors in the predicted 2m-temperatures, changing soil water content in order to minimize the error. The SMA partly counteracts changes of soil water content due to forcing by precipitation, evapotranspiration and runoff. During the pre-operational phase in 2005, the SMA-increments of soil water content in LME were compared with the respective changes in the operational LM (at the time with the old two-layer soil model). The average values for the LM-area turned out to be very similar in both models. This indicates that on average the multi-layer model and the old two layer model react in a nearly identical manner on the forcing of soil water content.

In Table 3 the soil water content values for GME are presented. Only the values determined for the LME-area are shown, in order to allow a comparison with the values for LME in Table 2. Obviously there is a much stronger decrease in soil water content in GME compared to LME in the upper layers during summer. This is consistent with the effect of the SMA, which in summer on average moistens the soil. But at the end of the one year period shown

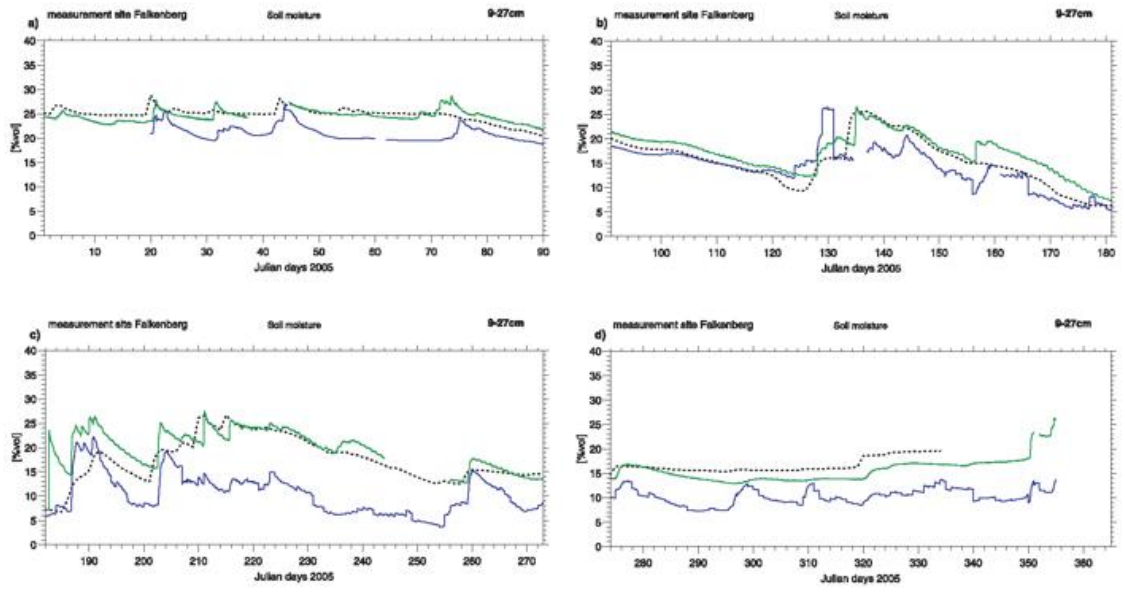

Figure 8:
Soil moisture (Vol %) in the layer 9 - 27 cm for the year 2005. Green: direct measurements, dotted: AMBAV-simulations, blue: LME-forecasts. a) January -March, b) April - June, c) July - September, d) October - December. See text for details.

in Table 3 the vaues are quite similar to the values in April 2005.

6 Changes after the operational implementation

The operational results of GME and LME with the multi-layer soil model revealed some problems. This resulted in changes of the soil model, which are described in this section.

6.1 Dependence of snow albedo on time and on forest cover

The first operational version of the multi-layer soil model used a constant snow albedo for solar radiation of 70%. Forest cover was not used to decrease the mean solar albedo in the case of existing snow decks. GME-results - especially in North America - revealed a strong negative temperature bias in spring. This could well be the effect of too high albedo values of old snow decks and snow cover in forested areas. This led to a reformulation of snow albedo. A snow-age indicator f_{snow} is introduced, being 1 for 'fresh' snow and 0 for 'old' snow. The albedo of snow is determined by

$$\alpha_{snow} = \alpha_{snow,max} \cdot f_{snow} + \alpha_{snow,min} \cdot (1 - f_{snow}), \tag{20}$$

where $\alpha_{snow,max} = 0.7$ and $\alpha_{snow,min} = 0.4$. The snow-age indicator is updated every time-step. One effect is a slow ageing term $\Delta t/\tau_\alpha$ with the time-step Δt of the model and a time constant $\tau_\alpha = 28d$. The second effect is a regeneration by falling snow: RR_{snow}/RR_{norm}, where RR_{snow} is the predicted rate of snowfall, and $RR_{norm} = 5mm/d$. Then the change of f_{snow} in one time-step Δt is given by

$$\Delta f_{snow} = f_{snow}\,[RR_{snow}/RR_{norm} - \Delta t/\tau_\alpha] \tag{21}$$

15 Apr	25.33	79.50	23.18	79.07	24.72	79.63

The snow-age indicator is initialised with 1.
Having determined the albedo of snow by (20), the value is reduced depending on forest cover. Although separate values are available for evergreen and for deciduous forests, respectively, at present we only use the total fractional forest cover σ_{forest} to compute the final snow albedo α_{sf} by

$$\alpha_{sf} = \alpha_{snow} \cdot (1 - \sigma_{forest}) + \alpha_{forest} \cdot \sigma_{forest}, \tag{22}$$

with $\alpha_{forest} = 0.2$.

6.2 Increase of infiltration at the expense of surface runoff

The indications given in the chapter on the long-term diagnostics for LME and GME on a possible drying of the soil led to some investigation of likely reasons for this behaviour. It turned out that the extremely low value of 10^{-6} m prescribed as the maximum value of the water content in the interception store had an unwanted effect on infiltration. As nearly no rain could be stored in the interception store, being available for later infiltration, nearly all rain was converted to runoff (see the paragraph on 'Interception store, Infiltration of Rain and Runoff from Interception Store' in the extended LM-documentation (Doms et al., 2005)). The parameter α tended to be 1, therefore in $I_{rain} = (1 - \alpha)P_r$ no rain is converted to infiltration. This situation was improved by artificially prescribing $\alpha = 0$. In GME a remarkable effect occurred, especially in the areas of high convective precipitation in the tropics. In LME only a very small effect could be noted, because the soil moisture assimilation masked most of the possible impact.

7 Suggested future work

There are especially three areas for future model improvement:

- The drying of the soil deserves further attention. A flux equal to zero at the lower

boundary of the hydrologically active layers should be tested. This could especially be advantageous in areas with long periods of snow cover. As long as the deeper soil layers are not completely frozen, the gravitational flux will reduce the water content. This might be the reason for extremely low soil moisture values in the Alps.

- A tile approach, which distinguishes between - at least - snow-covered and snow-free parts of a grid element will be helpful for temperature prediction in the case of melting snow. Presently the soil surface temperature sticks to 0^oC as long as some part of the grid element is snow-covered. This leads to much too cold 2m-temperatures in situations with melting snow. In reality the soil surface temperature in the snow-free areas of the grid element can be considerably warmer than 0^oC.

- With a much larger effort the implementation of a multi-layer snow module should be considered. Such a model can deal with the layered structure of old snow decks and with the downward transport of water (rain or melted snow) through the snow. Also, the problem of snow density can be dealt with in a much more consistent manner.

8 Summary

A multi-layer soil model was implemented and tested in GME and LME. As a main new feature the model includes the effect of freezing/melting of soil water/ ice. Thorough testing in the global model GME preceded the pre-operational (since January 2005) and operational (since September 28, 2005) use in LME. The soil moisture assimilation scheme of LM was adjusted to the new layer structure and used in the pre-operational LME-runs since May 2005. A lot of minor and also some major bugs in the model were detected and corrected through the (pre)operational runs. Additionally, some improvements have been introduced in the code in the years 2005 and 2006. The long-term behaviour of soil water content still deserves special attention.

9 Acknowledgement

A lot of technical problems in the interplay of analysis, interpolation from GME to LME and operational LME-runs had to be solved with the help of M. Buchhold, Th. Hanisch and U. Schättler. M. Arpagaus and his colleagues at Meteoswiss used the multi-layer soil model in parallel runs and provided a lot of input for the improvement of the model. P. Meyring performed the diagnostic evaluation of the model results and assisted in solving problems with different graphic formats.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *Consortium for Small-Scale Modelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (UGM, ARPA-SMR, ARPA Piemonte) and Switzerland (MeteoSwiss). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the Lokal-Modell (LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completition of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

Parameterization of Lakes in Numerical Weather Prediction. Description of a Lake Model

Dmitrii V. Mironov[†]

German Weather Service, Offenbach am Main, Germany

Abstract

A lake model intended for use as a lake parameterization module in numerical weather prediction (also in climate modelling and other environmental applications) is developed. The model is capable of predicting the vertical temperature structure and mixing conditions in lakes of various depth on the time scales from a few hours to many years. It is based on a two-layer parametric representation of the evolving temperature profile and on the integral budget of energy for the layers in question. The structure of the stratified layer between the upper mixed layer and the basin bottom, the lake thermocline, is described using the concept of self-similarity (assumed shape) of the temperature-depth curve. The same concept is used to describe the temperature structure of the thermally active upper layer of bottom sediments and of the ice and snow cover. An entrainment equation is used to compute the depth of a convectively-mixed layer. A relaxation-type equation is used to compute the wind-mixed layer depth in stable and neutral stratification, where a multi-limit formulation for the equilibrium mixed-layer depth accounts for the effects of the earth's rotation, of the surface buoyancy flux, and of the static stability in the thermocline. Both mixing regimes are treated with due regard for the volumetric character of solar radiation heating. Simple thermodynamic arguments are invoked to develop the evolution equations for the ice and snow depths. In this way, the problem of solving partial differential equations (in depth and time) for the temperature and turbulence quantities is reduced to solving ordinary differential equations for the time-dependent parameters that specify the evolving temperature profile. The result is a computationally efficient bulk model that incorporates much of the essential physics.

Empirical constants and parameters of the proposed model are estimated, using independent empirical and numerical data. Importantly, they should not be re-evaluated when the model is applied to a particular lake. The only lake-specific parameters are the lake depth, the optical characteristics of lake water, the temperature at the bottom of the thermally active layer of bottom sediments, and the depth of this layer. These external parameters are not part of the model physics, however. In this way, the model does not require re-tuning, a procedure that may improve an agreement with a limited amount of data but should generally be avoided as it greatly reduces the predictive capacity of a physical model.

The present report contains a brief overview of previous studies and a description of the lake model. Results from single-column numerical experiments with the proposed model, termed FLake, details of the implementation of FLake into the limited-area numerical weather prediction model COSMO, and results from numerical experiments with the coupled COSMO-FLake system are described elsewhere.

1 Introduction

Lakes significantly affect the structure of the atmospheric boundary layer and therefore the surface fluxes of heat, water vapour and momentum. This effect has not been systematically studied so far and is poorly understood. In most numerical weather prediction (NWP) models, the effect of lakes is either entirely ignored or is parameterized very crudely. At present, a large number of small-to-medium size lakes are indistinguishable sub-grid scale features. These lakes will become resolved scale features as the horizontal resolution is increased. Then, a physically sound model (parameterization scheme) is required to predict the lake surface temperature and the effect of lakes on the structure and transport properties of the atmospheric boundary layer[1]. Apart from being physically sound, a lake model must meet stringent requirements of computational economy.

There are several aspects of the problem. For one thing, the interaction of the atmosphere with the underlying surface is strongly dependent on the surface temperature and its time-rate-of-change. It is common for NWP models to assume that the water surface temperature can be kept "frozen" over the forecast period. That is, once the NWP model has been initialised, the surface temperature of the grid points of the type "water" is kept constant in time. The assumption is to some extent justified for seas and deep lakes. It is doubtful for small-to-medium size relatively shallow lakes, where short-term variations of the surface temperature (with a period of several hours to one day) reach several degrees. A large number of such lakes become resolved scale features as the horizontal resolution is increased. The use of a horizontal grid size of about three kilometres or even less will soon become a common practice in short-range weather forecast. In NWP models with coarser resolution, many small-to-medium size lakes remain sub-grid scale features. However, the presence of these lakes cannot be ignored due to their aggregate effect on the grid-scale surface fluxes. This also holds for climate models concerned with the time scales ranging from many days to many years.

Initialisation of the water-type grid points of an NWP model often presents considerable difficulties. In case the observational data for several water points are not available, these points are initialised by means of interpolation (often quite sophisticated) between the nearest water-type points for which the surface temperature is known (from satellite data or from in situ measurements). Such procedure is not too harmful for sea points. Large horizontal gradients of the sea surface temperature (SST) are comparatively rare, so that the interpolated SST is expected to be a reasonably good approximation of the actual SST. In contrast to open sea, lakes are enclosed water bodies of a comparatively small horizontal extent. The lake surface temperature is a result of a complex interplay of physical processes in the lake in question. It has little or nothing to do with the surface temperature obtained by means of interpolation between the alien water bodies.

Another important aspect of the problem is that lakes strongly modify the structure and the transport properties of the atmospheric boundary layer. A major outstanding question is the parameterization of the roughness of the water surface with respect to wind and to scalar quantities, such as potential temperature and specific humidity. A detailed consideration of this aspect of the problem is beyond the scope of the present report.

An interest in the problem of lakes has led to the development of several lake models (parameterization schemes) for use in NWP and climate studies. Three-dimensional lake models

[1]The terms "model" and "parameterization scheme" may be used interchangeably in this context. The term "parameterization scheme" is more often used in the NWP and climate modelling community to discriminate a component (module) of a complex modelling system from its host that is referred to as an NWP (climate) model.

account for both vertical and horizontal transport of momentum and heat and provide detailed information about the lake temperature structure. However, a very high computational cost limits their utility to only a few large lakes, such as Lake Victoria (Song et al. 2004), Laurentian Great Lakes (León et al. 2005), Great Slave Lake (León et al. 2007, Long et al. 2007) and Great Bear Lake (Long et al. 2007), and to research applications. The use of three-dimensional lake models (or ocean models customised for lakes) as lake parameterization schemes in NWP and other operational applications will most likely be impossible for some years to come. One-dimensional lake models range from the simplest one-layer slab models to rather sophisticated turbulence closure models based on the transport equations for the second-order turbulence moments. One-layer models characterise the entire water column by a single value of temperature, assuming a complete mixing down to the lake bottom (Ljungemyr et al. 1996), or to the bottom of a mixed layer of a fixed depth which may vary spatially (Goyette et al. 2000). Although this assumption results in a bulk model that is computationally very efficient, it is an oversimplification from the physical point of view. As most lakes are stratified over a considerable part of the year, neglecting the lake thermocline results in large errors in the surface temperature. Second-order turbulence closure models, e.g. models that carry transport equations for the turbulence kinetic energy (TKE) and its dissipation rate (Omstedt and Nyberg 1996, Omstedt 1999, Blenckner et al. 2002, Stepanenko 2005, Stepanenko et al. 2006) or for the TKE only (Tsuang et al. 2001)[2], may describe the lake thermocline with reasonable accuracy. These models are computationally rather expensive, however. Their use to treat a large number of lakes can hardly be afforded in operational applications. Hostetler (see Hostetler and Bartlein 1990, Hostetler 1991, Hostetler et al. 1993, Barrette and Laprise 2005) developed a lake model that uses an algebraic stability-dependent formulation for the turbulent heat conductivity and a convective adjustment procedure. As a lake parameterization scheme, that lake model was coupled to a number of atmospheric models. It enjoyed wide popularity in climate studies (Hostetler and Benson 1990, Hostetler 1991, Hostetler and Giorgi 1992, Bates et al. 1993, 1995, Hostetler et al. 1993, 1994, Bonan 1995, Small et al. 1999). MacKay (2005) developed a hybrid model, where the solution of the non-steady heat transfer equation on a numerical grid is combined with the bulk treatment of the upper mixed layer following Imberger (1985) and Spigel et al. (1986).

In the present report, a lake model capable of predicting the vertical temperature structure in lakes of various depth on the time scales from a few hours to many years is described. The model is based on a two-layer parameterization of the evolving temperature profile and on the integral energy budget for the layers in question. The structure of the stratified layer between the upper mixed layer and the basin bottom, the lake thermocline, is described using the concept of self-similarity (assumed shape) of the temperature-depth curve. The same concept is used to describe the temperature structure of the thermally active upper layer of bottom sediments and of the ice and snow cover. In this way, the problem of solving partial differential equations (in depth and time) for the temperature and turbulence quantities is reduced to solving ordinary differential equations for the time-dependent parameters that specify the temperature profile. This approach, that is based on what could be called "verifiable empiricism", offers a very good compromise between physical realism and computational economy. In Section 2, the concept of self-similarity of the temperature profile is outlined and a brief overview of previous studies along this line is given. A lake model is presented in Section 3. Conclusions are presented in Section 4.

[2]The model of Tsuang et al. (2001) is not strictly one dimensional as it incorporates a simplified scheme to account for horizontal advection of momentum, heat and turbulence kinetic energy.

2 Background

2.1 The Concept of Self-Similarity of the Temperature Profile

The concept of self-similarity of the temperature profile $\theta(z,t)$ in the thermocline was put forward by Kitaigorodskii and Miropolsky (1970) to describe the vertical temperature structure of the oceanic seasonal thermocline. The essence of the concept is that the dimensionless temperature profile in the thermocline can be fairly accurately parameterized through a "universal" function of dimensionless depth, that is

$$\frac{\theta_s(t) - \theta(z,t)}{\Delta\theta(t)} = \Phi_\theta(\zeta) \quad \text{at} \quad h(t) \le z \le h(t) + \Delta h(t). \tag{1}$$

Here, t is time, z is depth, $\theta_s(t)$ is the temperature of the upper mixed layer of depth $h(t)$, $\Delta\theta(t) = \theta_s(t) - \theta_b(t)$ is the temperature difference across the thermocline of depth $\Delta h(t)$, $\theta_b(t)$ is the temperature at the bottom of the thermocline, and $\Phi_\theta \equiv [\theta_s(t) - \theta(z,t)]\,/\Delta\theta(t)$ is a dimensionless "universal" function of dimensionless depth $\zeta \equiv [z - h(t)]\,/\Delta h(t)$ that satisfies the boundary conditions $\Phi_\theta(0) = 0$ and $\Phi_\theta(1) = 1$. In what follows, the arguments of functions dependent on time and depth are not indicated, unless it is indispensable. The temperature profile given by Eq. (1) is illustrated in Fig. 1.

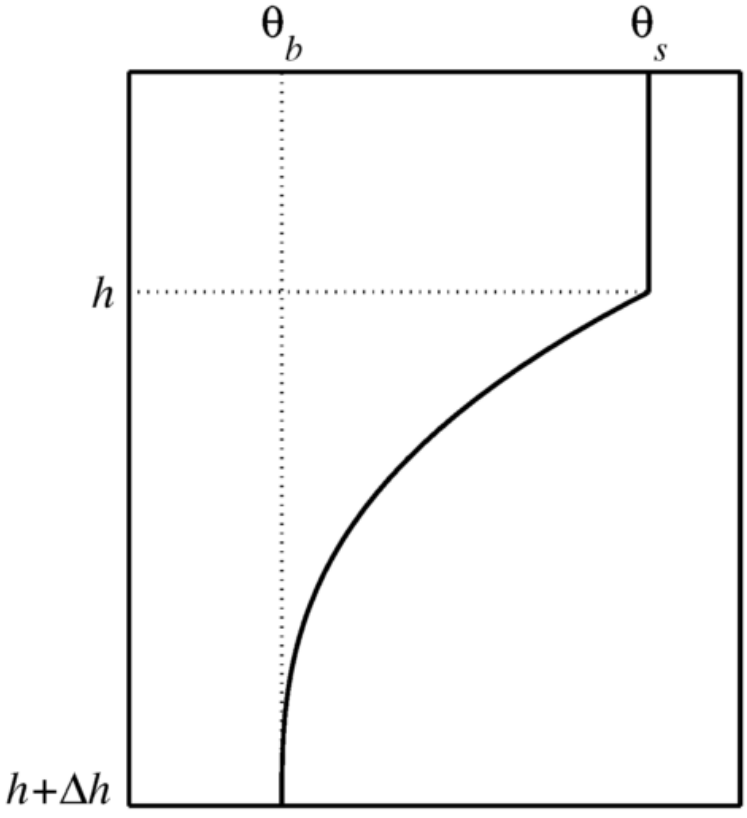

Figure 1: Schematic representation of the temperature profile in the upper mixed layer and in the thermocline. See text for notation.

The idea of self-similarity of the temperature profile in the thermocline can be traced back to the famous work of Munk and Anderson (1948). Although these authors did not present Eq. (1) in its explicit form, the following quotation is a qualitative statement of the idea (Munk and Anderson 1948, p. 276):

> ...the upper layers are stirred until an almost homogeneous layer is formed, bounded beneath by a region of marked temperature gradient, the thermocline. ...If the wind increases in intensity the thermocline moves downward, but the characteristic *shape* of the temperature-depth curve remains essentially unchanged. (Original authors' italic.)

In this connection, the work of Ertel (1954) should be mentioned. Ertel considered the formation and deepening of the thermocline in a fresh-water lake during the summer heating period, using an analytical solution to the linear heat transfer equation. He defined the thermocline ("thermische Sprungschicht" – the temperature jump layer, as termed in op. cit.) as a layer where the vertical temperature gradient exceeds 1 $\mathrm{K{\cdot}m^{-1}}$. Ertel did not present his results in the form given by Eq. (1). He found, however, that the ratio of the depth from the upper boundary of the thermocline to the bend point of the temperature profile to the depth from the bend point to the bottom of the thermocline is constant. In other words, the *shape* of the temperature-depth curve in the thermocline is independent of time.

The concept of self-similarity of the temperature profile in the thermocline can be considered as a natural extension of the concept of the temperature uniform mixed layer that has been successfully used in geophysical fluid dynamics over several decades. Indeed, using the mixed-layer temperature θ_s and its depth h as appropriate scales, the mixed-layer concept can be expressed as $\theta(z,t)/\theta_s(t) = \vartheta[z/h(t)]$, where a dimensionless function ϑ is simply a constant equal to one. The use of $\Delta\theta$ and Δh as appropriate scales of temperature and depth, respectively, in the thermocline leads to Eq. (1), where Φ_θ is not merely a constant but a more sophisticated function of ζ. It should be emphasised that neither the mixed-layer concept nor the concept of self-similarity of the thermocline is well justified theoretically. Both concepts heavily rely on empirical evidence and should therefore be considered phenomenological. However, this phenomenological approach appears to describe the observed temperature structure to a degree of approximation that is sufficient for many applications.

2.2 Empirical Evidence

In order to obtain an analytical approximation of the dimensionless function $\Phi_\theta(\zeta)$ in Eq. (1), Kitaigorodskii and Miropolsky (1970) took a geometrical approach similar to what is often referred to as the Pohlhausen method in the boundary-layer theory. They expressed Φ_θ as a fourth-order polynomial in ζ and invoked five boundary conditions to specify the polynomial coefficients. Apart from the conditions $\Phi_\theta(0) = 0$ and $\Phi_\theta(1) = 1$ that simply follow from the definition of Φ_θ and ζ, they assumed neutral temperature stratification at the bottom of the thermocline, $\Phi'_\theta(1) = 0$, and a smooth matching to the temperature profile in the underlying layer, $\Phi''_\theta(1) = 0$. Furthermore, they assumed that the temperature-depth curve has a maximum curvature at the upper boundary of the thermocline, $\Phi'''_\theta(0) = 0$. The resulting expression,

$$\Phi_\theta = \frac{8}{3}\zeta - 2\zeta^2 + \frac{1}{3}\zeta^4, \tag{2}$$

was tested against monthly-mean temperature profiles recorded at the ocean weather ships "Papa" (Kitaigorodskii and Miropolsky 1970) and "Tango" (Kitaigorodskii 1970).

One more polynomial approximation of $\Phi_\theta(\zeta)$ was proposed by Arsenyev and Felzenbaum (1977). These authors also took a geometrical approach (the Pohlhausen method) but, unlike Kitaigorodskii and Miropolsky (1970), did not make use of the condition $\Phi'''_\theta(0) = 0$. The

resulting third-order polynomial,

$$\Phi_\theta = 1 - (1-\zeta)^3, \tag{3}$$

has subsequently enjoyed wide popularity.

The concept of self-similarity of the temperature profile in the thermocline received support through laboratory studies (Linden 1975, Voropaev 1977, Wyatt 1978). Linden (1975) modified the Kitaigorodskii and Miropolsky (1970) expression (2) in order to account for the stable density stratification in a quiescent layer below the thermocline. He proposed the expression (in op. cit., it is given in terms of density)

$$\Phi_\theta = \zeta + (1-\Gamma)\left(\frac{5}{3}\zeta - 2\zeta^2 + \frac{1}{3}\zeta^4\right), \tag{4}$$

where $\Gamma = -(\Delta\theta/\Delta h)^{-1}(\partial\theta/\partial z)|_{h+\Delta h}$ is the temperature gradient just below the thermocline relative to the mean temperature gradient within the thermocline [by virtue of a smooth matching of the temperature profile in the thermocline and in the layer below, $\Gamma = \Phi'_\theta(1)$]. Equation (4) revealed a good agreement with data from measurements in a laboratory tank, where turbulence was generated by an oscillating grid.

Empirical data taken in natural conditions (Miropolsky et al. 1970, Nesterov and Kalatsky 1975, Kharkov 1977, Reshetova and Chalikov 1977, Efimov and Tsarenko 1980, Filyushkin and Miropolsky 1981, Mälkki and Tamsalu 1985, Tamsalu and Myrberg 1998) also lent support to the concept of self-similarity of the thermocline. However, the scatter of data around the temperature-depth curves proved to be quite large. Reshetova and Chalikov (1977) attempted to extend the self-similarity concept to parameterize the vertical profile of salinity in the ocean.

Filyushkin and Miropolsky (1981) noticed that the shape of the temperature-depth curve depends on the mixed-layer state. They proposed to differentiate between the two cases: the mixed-layer deepening, $dh/dt > 0$, and its stationary state or retreat, $dh/dt \leq 0$. Mälkki and Tamsalu (1985) developed the following empirical approximations for these two cases:

$$\Phi_\theta = \begin{cases} 1-(1-\zeta)^3 & \text{if} \quad dh/dt > 0 \\ 1-4(1-\zeta)^3+3(1-\zeta)^4 & \text{if} \quad dh/dt \leq 0. \end{cases} \tag{5}$$

These expressions were tested against data from measurements in the Baltic Sea (Mälkki and Tamsalu 1985, Tamsalu and Myrberg 1998). The first line of Eq. (5) that corresponds to the mixed-layer deepening coincides with Eq. (3) developed from simple geometrical arguments by Arsenyev and Felzenbaum (1977). In case of the mixed-layer stationary state or retreat, the form of the temperature-depth curve is essentially different. The temperature profiles in the thermocline and in the mixed layer match smoothly, and the vertical temperature gradient is a maximum within the thermocline, not at its upper boundary. Data taken in Lake Ladoga, Russia, and Lake Sevan, Armenia, corroborated the occurrence of two types of self-similar temperature profiles in the thermocline (Zilitinkevich 1991).

2.3 Theoretical Explanation

A plausible theoretical explanation for the observed self-similarity of the temperature profile in the thermocline was offered in case of the mixed-layer deepening (Barenblatt 1978, Turner 1978, Shapiro 1980, Zilitinkevich et al. 1988, Zilitinkevich and Mironov 1989, Mironov 1990, Zilitinkevich and Mironov 1992). These authors analysed the heat transfer equation

$$\frac{\partial\theta}{\partial t} = \frac{\partial}{\partial z}K_H\frac{\partial\theta}{\partial z}, \tag{6}$$

where K_H is the temperature conductivity (the heat conductivity divided by the density ρ and specific heat c of the medium in question). Introducing a vertical co-ordinate moving with the mixed layer-thermocline interface, $z' = z - h(t)$, they considered a travelling wave-type solution to Eq. (6). Assuming constant temperatures at the upper and lower boundaries of the thermocline, $\partial\theta_s/\partial t = \partial\theta_b/\partial t = 0$, Eq. (6) becomes

$$-\dot{h}\frac{d\theta}{dz'} = \frac{d}{dz'}K_H\frac{d\theta}{dz'}, \tag{7}$$

where $\dot{h} \equiv dh/dt > 0$ is the rate of the mixed-layer deepening.

Barenblatt (1978) took K_H to be constant and considered a solution to Eq. (7) in a half-space $z' > 0$. Using boundary conditions $\theta = \theta_s$ at $z' = 0$ and $\theta = \theta_b$ at $z' = \infty$, he obtained the solution

$$\Phi_\theta = 1 - \exp(-\dot{h}z'/K_H). \tag{8}$$

Since the thermocline has an infinite thickness, the above solution cannot be recast in terms of $\Phi_\theta(\zeta)$. However, Eq. (8) appears to be a fairly close approximation to the empirical polynomials proposed by Kitaigorodskii and Miropolsky (1970) and Arsenyev and Felzenbaum (1977) at certain values of $\dot{h}/K_H$.

Turner (1978) examined both the simplest case of $K_H = const$ and a more sophisticated case, where K_H is proportional to the vertical temperature gradient,

$$K_H = -\frac{\dot{h}l^2}{\Delta\theta}\frac{\partial\theta}{\partial z}, \tag{9}$$

l being a characteristic eddy length scale. Assuming $K_H \propto -\partial\theta/\partial z$, he added the factor $\dot{h}l^2/\Delta\theta$ to the r.h.s. of Eq. (9) "to be consistent dimensionally". In support of Eq. (9), Turner considered generation of turbulence by breaking internal gravity waves. He wrote (Turner 1978, p. 6): "It seems likely that the energy required to produce this addition mixing below the surface layer will be supplied by internal waves propagating into the gradient region, and then breaking. ... Clearly, the wave breaking and the density distribution must be intimately linked: for a given energy level breaking will occur preferentially in regions where the density gradient is high." Numerical experiments with a mixed-layer model (Kamenkovich and Kharkov 1975, Gill and Trefethen, unpublished manuscript referred to by Turner 1978) lend some support to this idea. They show an improved fit to ocean data if the effective temperature conductivity in the thermocline is taken proportional to the vertical temperature (density) gradient. Taking $l = const$ and using boundary conditions $\theta = \theta_s$ at $z = h$ and $\theta = \theta_b$ at $z = h + \Delta h$, and an additional condition $\partial\theta/\partial z = 0$ at $z = h + \Delta h$ that serves to determine l, the solution to Eqs. (7) and (9) is

$$\Phi_\theta = 1 - (1 - \zeta)^2, \qquad l = \frac{1}{2}\Delta h. \tag{10}$$

Obviously, it is difficult to give preference to the above expression for $\Phi_\theta(\zeta)$ over the expressions developed by Kitaigorodskii and Miropolsky (1970) and Arsenyev and Felzenbaum (1977), or vice versa, on purely empirical ground by virtue of a large scatter of empirical data.

Zilitinkevich et al. (1988) pointed out that Eq. (9) is not consistent with the proposed wave breaking mechanism of mixing in the thermocline, although the mechanism per se is physically credible. The point is that Eq. (9) does not contain the buoyancy parameter $\beta = g\alpha_T$, where g is the acceleration due to gravity and α_T is the thermal expansion coefficient, which must obviously be taken into account. Indeed, there would be no internal

gravity waves and no wave breaking mechanism of mixing were it not for the density changes associated with the temperature changes and not for the gravity that cause the buoyancy effects in a temperature-stratified fluid. Using β, $\partial\theta/\partial z$ and l as the governing parameters, Zilitinkevich et al. (1988) invoked dimensional arguments to obtain the following expression for the effective temperature conductivity in the thermocline:

$$K_H = l^2 N, \tag{11}$$

where $N = (-\beta\partial\theta/\partial z)^{1/2}$ is the buoyancy frequency (the constant of proportionality is incorporated into l). It is easy to verify that Eqs. (7) and (11) subject to the same boundary conditions as used by Turner (1978) have the following solution:

$$\Phi_\theta = 1 - (1-\zeta)^3, \qquad l = 3^{-3/4}(\beta\Delta\theta)^{-1/4}\Delta h^{3/4}\dot{h}^{1/2}. \tag{12}$$

The above expression for the temperature profile shape function $\Phi_\theta(\zeta)$ appears to coincide with the third-order polynomial (3) developed earlier from simple geometrical arguments by Arsenyev and Felzenbaum (1977) and on the basis of empirical data by Mälkki and Tamsalu (1985).

In the models of Turner (1978) and Zilitinkevich et al. (1988), the eddy length scale l was treated as a bulk quantity characteristic of the thermocline as a whole. Zilitinkevich and Mironov (1992, see also Zilitinkevich and Mironov 1989, and Mironov 1990) proposed to treat l as a depth-dependent quantity. To this end, they employed the transport equation for the turbulence kinetic energy in its stationary form,

$$\frac{\partial e}{\partial t} = -\frac{\partial F}{\partial z} - \beta\mathcal{Q} - \epsilon = 0, \tag{13}$$

where e is the TKE per unit mass, F is the vertical TKE flux (the sum of the third-order velocity correlations and the pressure-velocity correlation), $\mathcal{Q}$ is the vertical turbulent temperature flux, and ϵ is the TKE dissipation rate. The temperature flux is also referred to as the kinematic heat flux, that is the heat flux divided by the density ρ and specific heat c. A calligraphic letter is used to avoid confusion with the heat flux $Q = \rho c\mathcal{Q}$. The following expression that is known to hold in strongly stable layers (see e.g. Zeman and Tennekes 1977, Brost and Wyngaard 1978, Otte and Wyngaard 2001) was used to relate the length scale to the TKE:

$$l = \frac{e^{1/2}}{N}. \tag{14}$$

The problem was closed through the use of a down-gradient approximation for the fluxes,

$$\mathcal{Q} = -K_H\frac{\partial\theta}{\partial z}, \qquad F = -K_E\frac{\partial e}{\partial z}, \tag{15}$$

and the Kolmogorov-Heisenberg hypothesis for the eddy exchange coefficients and the TKE dissipation rate,

$$\frac{K_H}{C_H} = \frac{K_E}{C_E} = le^{1/2}, \qquad \epsilon = C_\epsilon\frac{e^{3/2}}{l}, \tag{16}$$

where C_H, C_E and C_ϵ are dimensionless constants.

Considering the problem in a half-space $z' > 0$, the travelling wave-type solution to Eqs. (7), (13), (14), (15) and (16) subject to boundary conditions $\theta = \theta_s$, $e = e_h$ at $z' = 0$ and $\theta = \theta_b$, $e = 0$ at $z' = \infty$ is

$$\Phi_\theta = 1 - \exp(E_* - E_*/\eta), \qquad 6^{1/2}\exp(-E_*)\int_\eta^1 \eta'^2\exp(E_*/\eta')d\eta' = \xi. \tag{17}$$

Here, $\eta^2 = e_h^{-1} e$ and $\xi = C_e^{-1/2} e_h^{-1/2} N_h z'$ are the dimensionless TKE and the dimensionless vertical co-ordinate, respectively, $E_* = C_H^{-1}(6C_e)^{1/2} e_h^{-1/2} \dot{h}$ is the dimensionless rate of the mixed-layer deepening, e_h and N_h are the TKE and the buoyancy frequency, respectively, at the mixed layer-thermocline interface $z = h$, and $C_e = C_E(C_H + C_\epsilon)^{-1}$ is a dimensionless constant. The solution (17) describes a family of the temperature-depth curves where the shape of the curve depends upon E_*. At $E_* \geq 2$, the vertical temperature gradient is a maximum at the mixed layer-thermocline interface, $z = h$, whereas at $E_* < 2$, the temperature gradient is a maximum at $z > h$. The temperature profile given by Eq. (17) is quite similar to the third-order polynomial (3) at certain values of E_*.

An extension of the $K_H = const$ solution to Eq. (7) was developed by Shapiro (1980). He assumed that the mixed-layer temperature θ_s and the rate of the mixed-layer deepening $\dot{h}$ do not remain constant, as in the case considered by Barenblatt (1978) and Turner (1978), but experience small-amplitude fluctuations. Then, an additional term appears on the r.h.s. of Eq. (7), namely $\left\langle \dot{h}'' \partial \theta_s'' / \partial z \right\rangle$, where the angle brackets denote an ensemble mean and a double prime denotes a fluctuation therefrom. An analysis of the resulting solution showed an increase of the temperature gradient just below the mixed layer-thermocline interface and an overall cooling of the thermocline as compared to the case of constant θ_s and $\dot{h}$ when the fluctuations of θ_s and of $\dot{h}$ are coherent.

The analytical travelling wave-type solutions considered above are conditioned by a constant rate of the mixed-layer deepening and constant temperatures at the upper and lower boundaries of the thermocline (the mean values of $\dot{h}$, θ_s and θ_b are constant although these quantities may experience high-frequency small-amplitude fluctuations, cf. Shapiro 1980). If these quantities are not constant but vary slowly with time, the analytical solutions are not exact but approximate. If these quantities undergo fast changes, a travelling wave-type solution to the heat transfer equation can no longer serve as a theoretical explanation for the observed self-similarity of the temperature profile in the thermocline. It should be pointed out that all the above theoretical models apply to the case of the mixed-layer deepening. No theoretical explanation for the self-similarity of the temperature profile in case of the mixed-layer stationary state or retreat has been offered so far. The self-similarity at $dh/dt \leq 0$ is based on the empirical evidence only and should therefore be considered purely phenomenological.

2.4 Bottom Sediments

A distinctive feature of shallow lakes is a strong thermal interaction between the water body and the bottom sediments. A sizable portion of the heat received from the atmosphere during spring and summer can be accumulated in the thermally active upper layer of bottom sediments. This heat is then returned back to the water column during autumn and winter, leading to a hysteresis-like behaviour of the seasonal temperature cycle of the water column-bottom sediment system. A straightforward approach to describe the evolution of the temperature structure of bottom sediments is to use the equation of heat transfer with a priori knowledge of the thermal diffusivity of sediments (see e.g. Gu and Stefan 1990, Fang and Stefan 1996, 1998, and references therein). The major shortcoming of this approach is that the thermal diffusivity is strongly dependent on the composition of the sediments and on the amount of organic matter they contain and is, therefore, rarely well known.

Golosov and Kreiman (1992) proposed an alternative way of describing the vertical temperature structure of bottom sediments. Their approach is based on a two-layer self-similar parametric representation of the evolving temperature profile in the sediments that is concep-
