tually similar to a parametric representation of the temperature profile in the thermocline. Observations suggest (a summary of observational studies is given in Ryanzhin 1997) that the temperature profile in the bottom sediments has the form of a travelling thermal wave. Typical temperature profiles in the lake bottom sediments are illustrated in Fig. 2. The wave starts at the water-sediment interface $z = D$ and propagates downward as the lake water and the bottom sediments are heated during spring and summer. When heating ceases and cooling sets in, a new wave starts at $z = D$. It propagates downward as the lake water and the sediments are cooled during autumn and winter, thus closing the annual cycle. The layer $D \le z \le L$, where seasonal temperature changes take place, is the thermally active layer of bottom sediments. Importantly, a characteristic *shape* of the temperature-depth curve remains approximately the same. Motivated by this empirical evidence, a two-layer parametric representation of the temperature profile in the bottom sediments was proposed by Golosov and Kreiman (1992) and further developed by Golosov et al. (1998). The expression of Golosov et al. (1998) reads

$$\theta(z,t) = \begin{cases} \theta_b(t) - [\theta_b(t) - \theta_H(t)]\,\Phi_{B1}(\zeta_{B1}) & \text{at} \quad D \le z \le H(t) \\ \theta_H(t) - [\theta_H(t) - \theta_L]\,\Phi_{B2}(\zeta_{B2}) & \text{at} \quad H(t) \le z \le L. \end{cases} \tag{18}$$

Here, θ_L is the (constant) temperature at the outer edge $z = L$ of the thermally active layer of the sediments, θ_H is the temperature at the depth H where the vertical temperature gradient is zero, and $\Phi_{B1} \equiv (\theta_b - \theta)/(\theta_b - \theta_H)$ and $\Phi_{B2} \equiv (\theta_H - \theta)/(\theta_H - \theta_L)$ are dimensionless functions of dimensionless depths $\zeta_{B1} \equiv (z - D)/(H - D)$ and $\zeta_{B2} \equiv (z - H)/(L - H)$, respectively. Using empirical polynomial approximations of $\Phi_{B1}(\zeta_{B1})$ and $\Phi_{B2}(\zeta_{B2})$, Golosov et al. (1998) developed a simple procedure for calculating the heat flux through the water-sediment interface. Simulations of the seasonal cycle of temperature in the bottom sediments of several lakes using that procedure showed a satisfactory agreement with observations (Golosov et al. 1998, Kondratiev et al. 1998). In the present study, the approach of Golosov and Kreiman (1992) and Golosov et al. (1998) is used to develop a simple parameterization for calculating the heat flux through the water-bottom sediment interface. It is presented in Section 3.3.

A plausible theoretical explanation for the observed self-similarity of the temperature profile in bottom sediments was offered by Mironov et al. (2003). Assuming a travelling wave-type behaviour of the temperature profile, these authors considered the temperature distribution in the layer from the water-bottom sediment interface $z = D$ to the depth $z = H$ penetrated by the wave. They showed that in the simplest case of constant temperature diffusivity K_H the heat transfer equation (6) subject to the boundary conditions $\Phi_{B1}(0) = 0$ and $\Phi_{B1}(1) = 1$ has an analytical solution in the form

$$\Phi_{B1} = \frac{\Pi_D}{\Pi_D - \Pi_H}\left(1 + \frac{\exp\left(-E\zeta_{B1}^2/4\right)}{\zeta_{B1}^{1/2}} \times \right.$$

$$\left. \left\{ P\left[\frac{W_{p,1/4}(E/2)}{M_{p,1/4}(E/2)} M_{p,1/4}(E\zeta_{B1}^2/2) - W_{p,1/4}(E\zeta_{B1}^2/2)\right] - \frac{\Pi_H}{\Pi_D}\exp(E/4) \right\} \right). \tag{19}$$

Here, $E = K_H^{-1}(H - D)dH/dt$ is the dimensionless rate of propagation of the thermal wave, $\Pi_D = K_H^{-1}(\theta_b - \theta_H)^{-1}(H - D)^2 d\theta_b/dt$ and $\Pi_H = K_H^{-1}(\theta_b - \theta_H)^{-1}(H - D)^2 d\theta_H/dt$ are the dimensionless time rates of change of the temperature at the water-sediment interface $z = D$ and of the temperature at the depth $z = H$ penetrated by the wave, respectively, M and W are the Whittaker functions (Abramowitz and Stegun 1964, Chapter 13), $p = -\left[2(\Pi_D - \Pi_H) + E\right]/4E$, $P = 2^{1/4}\pi^{-1/2}E^{-1/4}\Gamma\left[(2E + \Pi_D - \Pi_H)/2E\right]$, and Γ is the Gamma function.

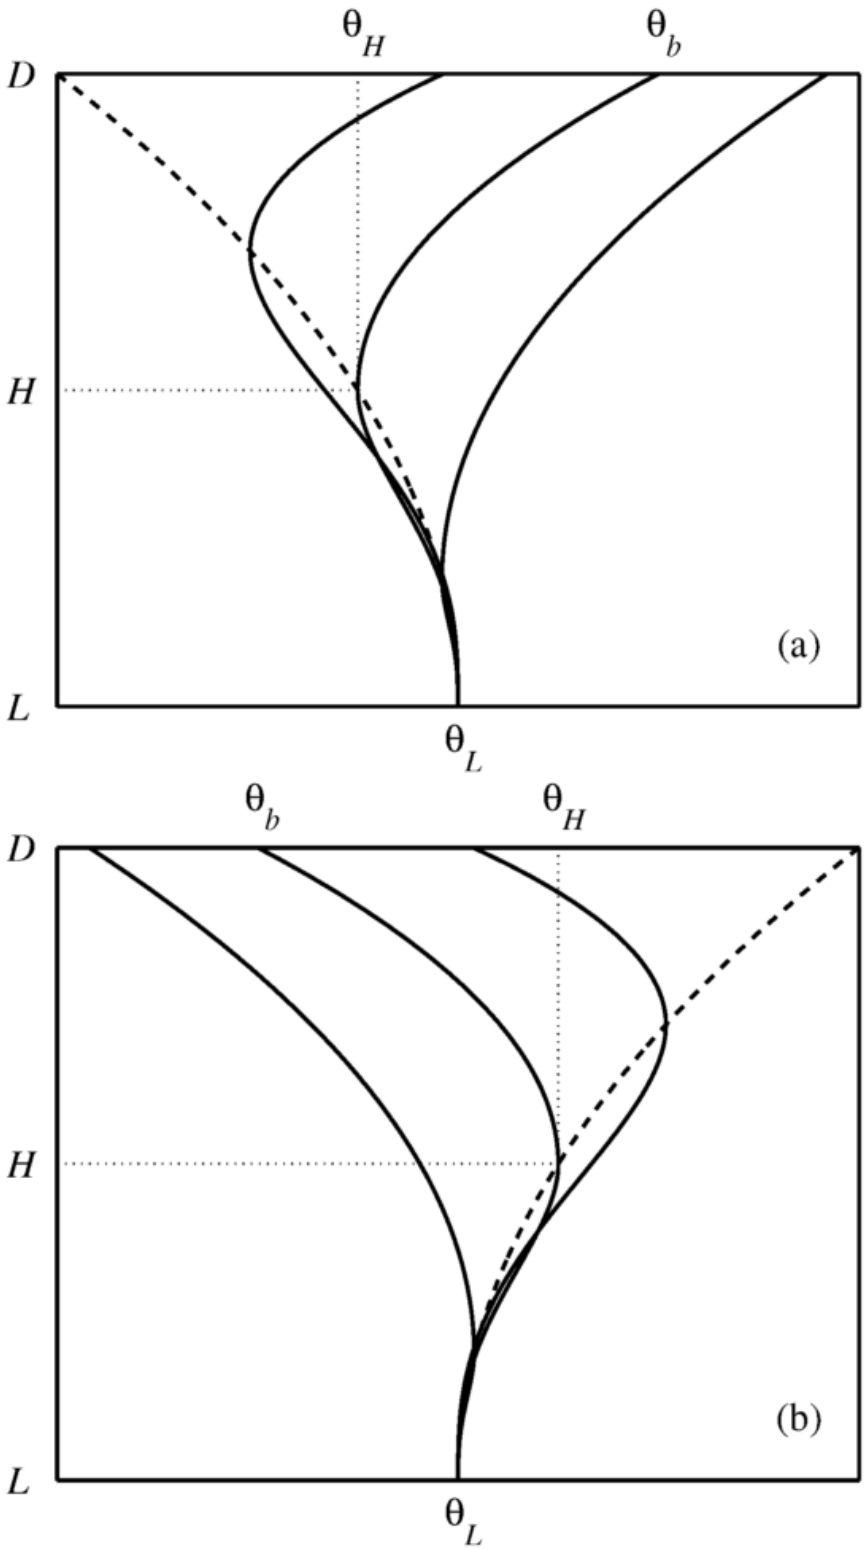

Figure 2: Schematic representation of the temperature profile in bottom sediments during periods of (a) heating and (b) cooling. Dashed curves show the initial temperature profiles, i.e. the profiles developed towards the end of the previous period of cooling (heating). See text for details.

The solution (19) is conditioned by a constant dimensionless propagation rate of the thermal wave and constant time rates of change of the temperature at the water-sediment interface and of the temperature at the depth penetrated by the wave. In case E, Π_D and Π_H are not constant but vary slowly with time, Eq. (19) is not exact but approximate. If these quantities undergo fast changes, the analytical solution (19) can no longer serve as a theoretical explanation for the observed self-similarity of the temperature profile in bottom sediments. Equation (19) appears to compare favourably with data from measurements in a number of lakes, with data from laboratory experiments and with a phenomenological polynomial approximation of the temperature profile in bottom sediments developed by Golosov et al. (1998) on the basis of empirical data.

2.5 Ice and Snow Cover

Many lakes are frozen over a considerable part of the year so that the atmosphere does not directly communicate with the lake water. The atmosphere-lake interaction occurs through the air-ice or, if snow is present, through the air-snow interface. An ice-snow model is therefore required to predict the surface temperature. Use of sophisticated ice models with rheology is a standard practice in climate modelling where the integration is performed over many decades. For NWP and related applications, a sophisticated dynamic-thermodynamic ice model is not required (and most often cannot be afforded because of its high computation cost). A simplified thermodynamic model is usually sufficient. Such model is developed in Section 3.4. As regards the thermodynamics of ice and snow, the model is broadly similar to most other models developed to date (summaries are given by e.g. Leppäranta 1993, and Launiainen and Cheng 1998). A distinguishing feature of the present model is the treatment of the heat transfer through the ice and snow. Most currently used ice and snow models carry the heat transfer equation that is solved on a finite-difference grid where the number of grid points and the grid spacing differ with the application. Here the integral, or bulk, approach is used. It is based on a parametric representation of the temperature profile within ice and snow and on the integral heat budgets of the ice and snow layers.

2.6 Applications

A number of computationally efficient models based on the self-similar representation of the temperature profile have been developed and successfully applied to simulate the evolution of the mixed layer and seasonal thermocline in the ocean (Kitaigorodskii and Miropolsky 1970, Miropolsky 1970, Kitaigorodskii 1970, Kamenkovich and Kharkov 1975, Arsenyev and Felzenbaum 1977, Kharkov 1977, Filyushkin and Miropolsky 1981). Filyushkin and Miropolsky (1981) assumed that both the temperature profile and the profile of the vertical heat flux in the thermocline can be represented in a self-similar form. We return to this issue in Section 3.2.1. The self-similarity concept has also been applied to model the atmospheric convectively mixed layer capped by the temperature inversion (Deardorff 1979, Fedorovich and Mironov 1995, Mironov 1999, Pénelon et al. 2001).

Models of the seasonal cycle of temperature and mixing in medium-depth fresh-water lakes, based on the self-similar representation of the evolving temperature profile, have been developed and successfully applied by Zilitinkevich and Rumyantsev (1990), Zilitinkevich (1991), Mironov et al. (1991), Zilitinkevich et al. (1992), Mironov (1992), Golosov et al. (1998), and Kondratiev et al. (1998). An attempt has been made to apply the above self-similarity concept to shallow lakes and to consider short-term (diurnal) variations of temperature and mixing conditions (Kirillin 2001a, 2001b). As different from the ocean and the atmo-

sphere, where the thermocline (capping inversion) is underlain (overlain) by a deep stably or neutrally stratified quiescent layer, the above lake models assume a two-layer temperature structure, where the thermocline extends from the bottom of the mixed layer down to the basin bottom. This assumption is fair for most lakes, except for very deep lakes such as Lake Baikal.

3 Model Description

In this section, a lake model based on a self-similar parametric representation (assumed shape) of the evolving temperature profile in the water column, in the bottom sediments, and in the ice and snow is developed. The same basic concept is used to describe the temperature structure of the four media in question (snow, ice, water, and bottom sediment). The lake model proposed by Mironov et al. (1991) is taken as a starting point. It is modified and further developed to account for specific features of shallow lakes and to consider both seasonal and diurnal variations of temperature and mixing conditions. The lake water is treated as a Boussinesq fluid, i.e. the water density is taken to be constant equal to the reference density except when it enters the buoyancy term in the TKE equation and the expression for the buoyancy frequency. The other thermodynamic parameters are considered constant except for the snow density and the snow heat conductivity (see Section 3.5.3 and Appendix B).

The model presented in what follows is a bulk model. It incorporates the heat budget equations for the layers in question. An entrainment equation for the depth of a convectively-mixed layer and a relaxation-type equation for the depth of a wind-mixed layer in stable and neutral stratification are developed on the basis of the TKE equation integrated over the mixed layer. Simple thermodynamic arguments are invoked to develop the evolution equations for the ice and snow depths. The resulting system of ordinary differential equations for the time-dependent prognostic quantities that characterise the evolving temperature profile, see Figs. 3 and 4, is closed with algebraic (or transcendental) equations for diagnostic quantities, such as the heat flux through the lake bottom and the equilibrium mixed-layer depth in stable or neutral stratification. Finally, we end up with a lake model that is computationally very efficient but still incorporates much of the essential physics.

3.1 Equation of State

We utilise the quadratic equation of state of the fresh water,

$$\rho_w = \rho_r \left[1 - \frac{1}{2} a_T \left(\theta - \theta_r \right)^2 \right], \tag{20}$$

where ρ_w is the water density, $\rho_r = 999.98 \approx 1.0 \cdot 10^3$ kg·m^{-3} is the maximum density of the fresh water at the temperature $\theta_r = 277.13$ K, and $a_T = 1.6509 \cdot 10^{-5}$ K^{-2} is an empirical coefficient (Farmer and Carmack 1981). Equation (20) is the simplest equation of state that accounts for the fact that the temperature of maximum density of the fresh water exceeds its freezing point $\theta_f = 273.15$ K. According to Eq. (20), the thermal expansion coefficient α_T and the buoyancy parameter β depend on the water temperature,

$$\beta(\theta) = g\alpha_T(\theta) = g a_T(\theta - \theta_r), \tag{21}$$

where $g = 9.81$ m·s^{-2} is the acceleration due to gravity.

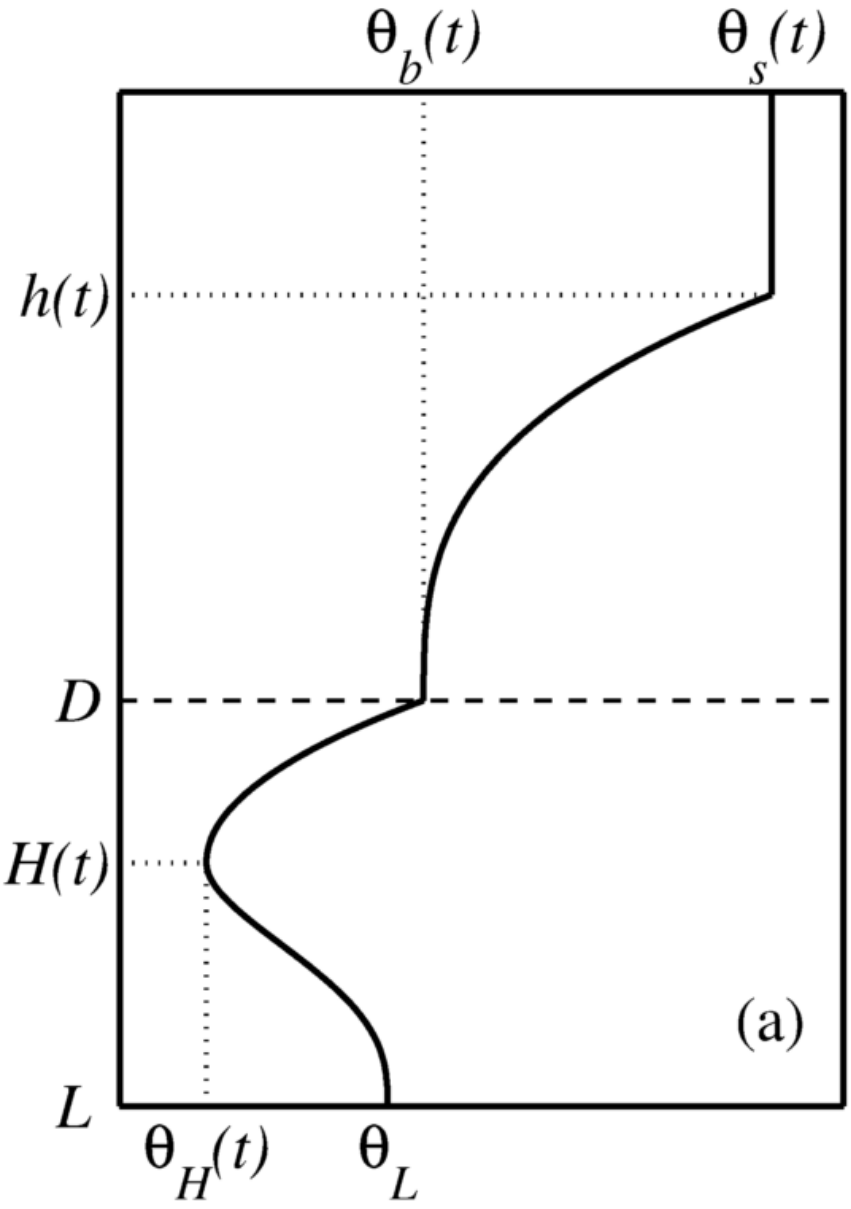

Figure 3: Schematic representation of the temperature profile in the mixed layer, in the thermocline, and in the thermally active layer of bottom sediments. The evolving temperature profile is specified by several time-dependent quantities. These are the mixed-layer temperature $\theta_s(t)$ and its depth $h(t)$, the temperature $\theta_b(t)$ at the water-bottom sediment interface, the shape factor $C_\theta(t)$ with respect to the temperature profile in the thermocline, the temperature $\theta_H(t)$ at the lower boundary of the upper layer of bottom sediments penetrated by the thermal wave, and the depth $H(t)$ of that layer. The temperature θ_L at the outer edge $z = L$ of the thermally active layer of bottom sediments is constant.

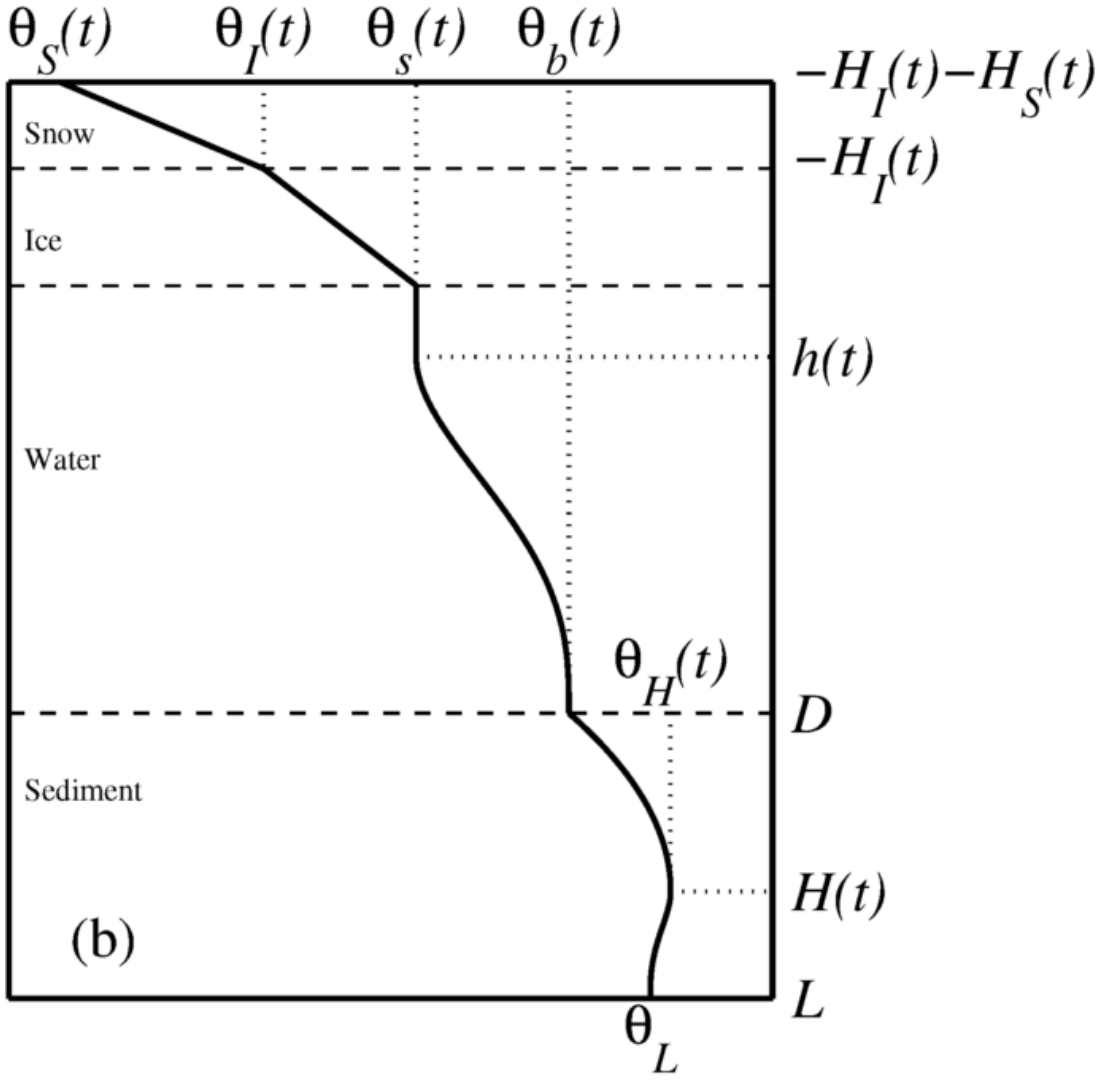

Figure 4: Apart from $\theta_s(t)$, $h(t)$, $\theta_b(t)$, $C_\theta(t)$, $\theta_H(t)$, and $H(t)$ (see Fig. 3), four additional quantities are computed in case the lake is covered by ice and snow. These are the temperature $\theta_S(t)$ at the air-snow interface, the temperature $\theta_I(t)$ at the snow-ice interface, the snow depth $H_S(t)$, and the ice depth $H_I(t)$.

3.2 The Water Temperature

3.2.1 Parameterization of the Temperature Profile and the Heat Budget

We adopt the following two-layer parameterization of the vertical temperature profile:

$$\theta = \begin{cases} \theta_s & \text{at} \quad 0 \le z \le h \\ \theta_s - (\theta_s - \theta_b)\Phi_\theta(\zeta) & \text{at} \quad h \le z \le D, \end{cases} \tag{22}$$

where $\Phi_\theta \equiv (\theta_s - \theta) / (\theta_s - \theta_b)$ is a dimensionless function of dimensionless depth $\zeta \equiv (z - h) / (D - h)$. The thermocline extends from the mixed-layer outer edge $z = h$ to the basin bottom $z = D$.

According to Eq. (22), h, D, θ_s, θ_b, and the mean temperature of the water column, $\overline{\theta} \equiv D^{-1} \int_0^D \theta dz$, are related through

$$\overline{\theta} = \theta_s - C_\theta(1 - h/D)(\theta_s - \theta_b), \tag{23}$$

where

$$C_\theta = \int_0^1 \Phi_\theta(\zeta) d\zeta \tag{24}$$

is the shape factor.

The parameterization of the temperature profile (22) should satisfy the heat transfer equation

$$\frac{\partial}{\partial t}(\rho c \theta) = -\frac{\partial}{\partial z}(Q + I), \tag{25}$$

where Q is the vertical turbulent heat flux, and I is the heat flux due to solar radiation.

Integrating Eq. (25) over z from 0 to D yields the equation of the total heat budget,

$$D\frac{d\overline{\theta}}{dt} = \frac{1}{\rho_w c_w}\left[Q_s + I_s - Q_b - I(D)\right], \tag{26}$$

where c_w is the specific heat of water, Q_s and I_s are the values of Q and I, respectively, at the lake surface, and Q_b is the heat flux through the lake bottom. The radiation heat flux I_s that penetrates into the water is the surface value of the incident solar radiation flux from the atmosphere multiplied by $1 - \alpha_w$, α_w being the albedo of the water surface with respect to solar radiation. The surface flux Q_s is a sum of the sensible and latent heat fluxes and the net heat flux due to long-wave radiation at the air-water interface.

Integrating Eq. (25) over z from 0 to h yields the equation of the heat budget in the mixed layer,

$$h\frac{d\theta_s}{dt} = \frac{1}{\rho_w c_w}\left[Q_s + I_s - Q_h - I(h)\right], \tag{27}$$

where Q_h is the heat flux at the bottom of the mixed layer.

Given the surface fluxes Q_s and I_s (these are delivered by the driving atmospheric model or are known from observations), and the decay law for the flux of solar radiation (Section 3.5.3), Eqs. (23), (26) and (27) contain seven unknowns, namely, h, $\overline{\theta}$, θ_s, θ_b, Q_h, Q_b and C_θ. The mixed layer depth, the bottom heat flux and the shape factor are considered in Section 3.2.2, Section 3.3 and Section 3.5.1, respectively. One more relation is required. Following Filyushkin and Miropolsky (1981, see also Tamsalu et al. 1997, and Tamsalu and Myrberg

1998), we assume that in case of the mixed layer deepening, $dh/dt > 0$, the profile of the vertical turbulent heat flux in the thermocline can be represented in a self-similar form. That is

$$Q = Q_h - (Q_h - Q_b)\Phi_Q(\zeta) \qquad \text{at} \;\; h \le z \le D, \tag{28}$$

where the shape function Φ_Q satisfies the boundary conditions $\Phi_Q(0) = 0$ and $\Phi_Q(1) = 1$. Equation (28) is suggested by the travelling wave-type solution to the heat transfer equation. If the mixed layer and the thermocline develop on the background of a deep stably or neutrally stratified quiescent layer (this situation is encountered in the ocean and in the atmosphere), the travelling wave-type solution shows that both the temperature profile and the profile of the turbulent heat flux are described by the same shape function, i.e. $\Phi_\theta(\zeta) = \Phi_Q(\zeta)$. In lakes, the thermocline usually extends from the bottom of the mixed layer down to the basin bottom. In this case, the travelling wave-type solution to the heat transfer equation also suggests self-similar profiles of the temperature and of the heat flux, however the relation between the shape functions $\Phi_\theta(\zeta)$ and $\Phi_Q(\zeta)$ is different. The issue is considered in Appendix A.

Integrating Eq. (25) with due regard for Eqs. (22) and (28) over z' from h to $z > h$, then integrating the resulting expression over z from h to D, we obtain

$$\frac{1}{2}(D-h)^2\frac{d\theta_s}{dt} - \frac{d}{dt}\left[C_{\theta\theta}(D-h)^2(\theta_s - \theta_b)\right] =$$

$$\frac{1}{\rho_w c_w}\left[C_Q(D-h)(Q_h - Q_b) + (D-h)I(h) - \int_h^D I(z)dz\right], \tag{29}$$

where

$$C_Q = \int_0^1 \Phi_Q(\zeta)d\zeta \tag{30}$$

is the shape factor with respect to the heat flux, and

$$C_{\theta\theta} = \int_0^1 d\zeta \int_0^{\zeta'} \Phi_\theta(\zeta')d\zeta' \tag{31}$$

is the dimensionless parameter. The analysis in Appendix A suggests that $C_Q = 2C_{\theta\theta}/C_\theta$.

In case of the mixed-layer stationary state or retreat, $dh/dt \le 0$, Eq. (28) is not justified. Then, the bottom temperature is assumed to be "frozen",

$$\frac{d\theta_b}{dt} = 0. \tag{32}$$

If $h = D$, then $\theta_b = \theta_s = \overline{\theta}$ and the mean temperature is computed from Eq. (26).

3.2.2 The Mixed-Layer Depth

Convection

Convective deepening of the mixed layer is described by the entrainment equation. This equation is conveniently formulated in terms of the dependence of the so-called entrainment ratio A on one or the other stratification parameter. The entrainment ratio is a measure of the entrainment efficiency. It is commonly defined as a negative of the ratio of the heat flux due to entrainment at the bottom of the mixed layer, Q_h, to an appropriate heat flux scale,

Q_*. In case of convection driven by the surface flux, where the forcing is confined to the boundary, the surface heat flux Q_s serves as an appropriate flux scale. This leads to the now classical Deardorff (1970a, 1970b) convective scaling, where h and $|h\beta Q_s/(\rho_w c_w)|^{1/3}$ serve as the scales of length and velocity, respectively.

The Deardorff scaling is unsuitable for convective flows affected by the solar radiation heating that is not confined to the boundary but is distributed over the water column. If the mixed-layer temperature exceeds the temperature of maximum density, convective motions are driven by surface cooling, whereas radiation heating tends to stabilise the water column, arresting the mixed layer deepening (Soloviev 1979, Mironov and Karlin 1989). Such regime of convection is encountered in the oceanic upper layer (e.g. Kraus and Rooth 1961, Soloviev and Vershinskii 1982, Price et al. 1986) and in fresh-water lakes (e.g. Imberger 1985). If the mixed-layer temperature is below that of maximum density, volumetric radiation heating leads to de-stabilisation of the water column and thereby drives convective motions. Such regime of convection is encountered in fresh-water lakes in spring. Convective mixing often occurs under the ice, when the snow cover overlying the ice vanishes and solar radiation penetrates down through the ice (e.g. Farmer 1975, Mironov and Terzhevik 2000, Mironov et al. 2002, Jonas et al. 2003).

In order to account for the vertically distributed character of the radiation heating, we make use of a generalised convective heat flux scale

$$Q_* = Q_s + I_s + I(h) - 2h^{-1}\int_0^h I(z)dz, \tag{33}$$

and define the convective velocity scale and the entrainment ratio as

$$w_* = \left[-h\beta(\theta_s)Q_*/(\rho_w c_w)\right]^{1/3}, \qquad A = -Q_h/Q_*, \tag{34}$$

respectively. In order to specify A, we employ the entrainment equation in the form

$$A + \frac{C_{c2}}{w_*}\frac{dh}{dt} = C_{c1}, \tag{35}$$

where C_{c1} and C_{c2} are dimensionless constants (the estimates of these and other empirical constants of the model are discussed in Section 3.5.2 and summarised in Appendix B). The second term on the l.h.s. of Eq. (35) is the spin-up correction term introduced by Zilitinkevich (1975). This term prevents an unduly fast growth of h when the mixed layer is shallow. If the spin-up term is small, Eq. (35) reduces to a simple relation $A = C_{c1}$ that proved to be a sufficiently accurate approximation for a large variety of geophysical and laboratory convective flows (Zilitinkevich 1991).

Equations (33), (34) and (35) should be used to compute the mixed-layer depth when the buoyancy flux $B_* = \beta(\theta_s)Q_*/(\rho_w c_w)$ is negative. The quantity $-hB_* \equiv w_*^3$ is a measure of the generation rate of the turbulence kinetic energy in a layer of depth h by the buoyancy forces (see a discussion in Mironov et al. 2002). A negative B_* indicates that the TKE is generated through convective instability. Otherwise, the TKE is lost to work against the gravity. This occurs when the density stratification is stable. A different formulation for the mixed-layer depth is then required.

Stable and Neutral Stratification

Mironov et al. (1991) used a diagnostic equation to determine the wind-mixed layer depth in stable and neutral stratification. That is, h was assumed to adjust to external forcing on a time scale that does not exceed the model time step. This assumption is fair if seasonal

changes of temperature and mixing conditions are considered and the model time step is typically one day. The assumption is likely to be too crude to consider diurnal variations. To this end, we utilise a relaxation-type rate equation for the depth of a stably or neutrally stratified wind-mixed layer. It reads

$$\frac{dh}{dt} = \frac{h_e - h}{t_{rh}}. \tag{36}$$

Here, h_e is the equilibrium mixed-layer depth, and t_{rh} is the relaxation time scale given by

$$t_{rh} = \frac{h_e}{C_{rh} u_*}, \tag{37}$$

where $u_* = |\tau_s/\rho_w c_w|^{1/2}$ is the surface friction velocity, τ_s being the surface stress, and C_{rh} is a dimensionless constant. A rate equation (36) with the relaxation time scale proportional to the reciprocal of the Coriolis parameter [that is a particular case of Eq. (37) with h_e specified through Eq. (38)] was favourably tested by Zilitinkevich et al. (2002) and Zilitinkevich and Baklanov (2002) against data from atmospheric measurements and was recommended for practical use.

In order to specify h_e, we make use of a multi-limit formulation for the equilibrium depth of a stably or neutrally stratified boundary layer proposed by Zilitinkevich and Mironov (1996). Based on the analysis of the TKE budget, these authors proposed a generalised equation for the equilibrium boundary-layer depth that accounts for the combined effects of rotation, surface buoyancy flux and static stability at the boundary-layer outer edge [Eq. (30) in op. cit.]. That equation reduces to the equations proposed earlier by Rossby and Montgomery (1935), Kitaigorodskii (1960) and Kitaigorodskii and Joffre (1988) in the limiting cases of a truly neutral rotating boundary layer, the surface-flux-dominated boundary layer, and the imposed-stability-dominated boundary layer, respectively. It also incorporates the Zilitinkevich (1972) and the Pollard, Rhines and Thompson (1973) equations that describe the intermediate regimes, where the effects of rotations and stratification essentially interfere and are roughly equally important. We adopt a simplified version of the Zilitinkevich and Mironov (1996) equation [Eq. (26) in op. cit.] that does not incorporate the Zilitinkevich (1972) and the Pollard et al. (1973) scales. It reads

$$\left(\frac{f h_e}{C_n u_*}\right)^2 + \frac{h_e}{C_s L} + \frac{N h_e}{C_i u_*} = 1, \tag{38}$$

where $f = 2\Omega \sin\phi$ is the Coriolis parameter, $\Omega = 7.29 \cdot 10^{-5}$ s^{-1} is the angular velocity of the earth's rotation, ϕ is the geographical latitude, L is the Obukhov length, N is the buoyancy frequency below the mixed layer, and C_n, C_s and C_i are dimensionless constants. A generalised formulation for the Obukhov length is used, $L = u_*^3/(\beta Q_*/\rho_w c_w)$, that accounts for the vertically distributed character of the solar radiation heating (note that the von Kármán constant is not included into the definition of L). A mean-square buoyancy frequency in the thermocline, $\overline{N} = \left[(D-h)^{-1} \int_h^D N^2 dz\right]^{1/2}$, is used as an estimate of N in Eq. (38).

One further comment is in order. Zilitinkevich et al. (2002, 2007) reconsidered the problem of the equilibrium stable boundary-layer depth. They concluded that the Zilitinkevich (1972) scale, $|u_* L/f|^{1/2}$, and the Pollard et al. (1973) scale, $u_*/|Nf|^{1/2}$, are the appropriate depth scales for the boundary layers dominated by the surface buoyancy flux and by the static stability at the boundary-layer outer edge, respectively. In other words, h_e depends on the Coriolis parameter no matter how strong the static stability. This is different from Eq. (38) where the limiting scales are L and u_*/N, respectively. The problem was further examined by Mironov and Fedorovich (2008). They showed that the above scales are particular cases of

more general power-law formulations, namely, $h/L \propto (|f|L/u_*)^{-p}$ and $hN/u_* \propto (|f|/N)^{-q}$ for the boundary layers dominated by the surface buoyancy flux and by the static stability at the boundary-layer outer edge, respectively. The Zilitinkevich (1972) and Pollard et al. (1973) scales are recovered with $p = 1/2$ and $q = 1/2$, whereas the Kitaigorodskii (1960) and Kitaigorodskii and Joffre (1988) are recovered with $p = 0$ and $q = 0$. Scaling arguments are not sufficient to fix the exponents p and q. They should be evaluated on the basis of experimental data. Available data from observations and from large-eddy simulations are uncertain. They do not make it possible to evaluate p and q to sufficient accuracy and to conclusively decide between the alternative formulations for the boundary-layer depth. Leaving the evaluation of p and q for future studies, we utilise Eq. (38). This simple interpolation formula is consistent with the complexity of the present lake model and is expected to be a sufficiently accurate approximation for most practical purposes.

One more limitation on the equilibrium mixed-layer depth should be taken into account. Consider the situation where the mixed-layer temperature exceeds the temperature of maximum density, the surface flux Q_s is negative, whereas the heat flux scale Q_* given by Eq. (33) is positive (this can take place if $-Q_s/I_s < 1$). A positive Q_* indicates the the mixed layer of depth h is statically stable. A negative Q_s, however, indicates that convective instability should take place, leading to the development of a convectively mixed layer whose deepening is arrested by the solar radiation heating. The equilibrium depth h_c of such mixed layer is given by (see e.g. Mironov and Karlin 1989)

$$Q_*(h_c) = Q_s + I_s + I(h_c) - 2h_c^{-1} \int_0^{h_c} I(z)dz = 0. \tag{39}$$

This regime of convection is encountered on calm sunny days. If the wind suddenly ceases, Eq. (38) predicts a very shallow stably-stratified equilibrium mixed layer to which the mixed layer of depth $h > h_e$ should relax. In fact, however, the mixed layer would relax towards a convectively mixed layer whose equilibrium depth is given by Eq. (39). In order to account for this constraint, we require that $h_e \geq h_c$ if $Q_*(h) > 0$ and $\theta_s > \theta_r$.

3.3 The Water - Bottom Sediment Interaction

3.3.1 Parameterization of the Temperature Profile and the Heat Budget

We adopt a two-layer parametric representation, Eq. (18), of the evolving temperature profile in the thermally active layer of bottom sediments proposed by Golosov et al. (1998). The parameterization (18) should satisfy the heat transfer equation (25), where the heat flux Q is due to molecular heat conduction and the bottom sediments are opaque to radiation. Integrating Eq. (25) over z from $z = D$ to $z = H$ with due regard for Eq. (18), we obtain

$$\frac{d}{dt}\left[(H-D)\theta_b - C_{B1}(H-D)(\theta_b - \theta_H)\right] - \theta_H \frac{dH}{dt} = \frac{1}{\rho_w c_w}\left[Q_b + I(D)\right], \tag{40}$$

where the heat flux at $z = H$ is zero by virtue of the zero temperature gradient there.

Integrating Eq. (25) over z from $z = H$ to $z = L$, we obtain

$$\frac{d}{dt}\left[(L-H)\theta_H - C_{B2}(L-H)(\theta_H - \theta_L)\right] + \theta_H \frac{dH}{dt} = 0, \tag{41}$$

where the heat flux at $z = L$ (the geothermal heat flux) is neglected.

The shape factors C_{B1} and C_{B2} are given by

$$C_{B1} = \int_0^1 \Phi_{B1}(\zeta_{B1})d\zeta_{B1}, \qquad C_{B2} = \int_0^1 \Phi_{B2}(\zeta_{B2})d\zeta_{B2}. \tag{42}$$

3.3.2 Heat Flux through the Bottom

The bottom heat flux Q_b is due to molecular heat conduction through the uppermost layer of bottom sediments. It can be estimated as the product of the negative of the temperature gradient at $z = D + 0$ and the molecular heat conductivity. The uppermost layer of bottom sediments is saturated with water. Its water content typically exceeds 90% and its physical properties, including the heat conductivity, are very close to the properties of the lake water. Then, the heat flux through the lake bottom is given by

$$Q_b = -\kappa_w \frac{\theta_H - \theta_b}{H - D} \Phi'_{B1}(0), \tag{43}$$

where κ_w is the molecular heat conductivity of water. This relation closes the problem.

It should be stressed that Eqs. (40), (41) and (43) do not contain the molecular heat conductivity of bottom sediments, a quantity that is rarely known to a satisfactory degree of precision. It is through the use of the integral (bulk) approach, based on the parameterization (18) of the temperature profile, that the molecular heat conductivity of bottom sediments is no longer needed.

3.4 Ice and Snow Cover

In this section, a two-layer thermodynamic (no rheology) model of the ice and snow cover is described. It is based on a self-similar parametric representation of the temperature profile within ice and snow and on the integral heat budgets of the ice and snow layers. The approach is, therefore, conceptually similar to the approach used above to describe the temperature structure of the mixed layer, of the lake thermocline, and of the thermally active layer of bottom sediments. Notice that the assumption about the shape of the temperature profile within the ice, the simplest of which is the linear profile, is either explicit or implicit in a number of ice models developed to date. A model of ice growth based on a linear temperature distribution was proposed by Stefan as early as 1891.

3.4.1 Parameterization of the Temperature Profile and the Heat Budget

We adopt the following parametric representation of the evolving temperature profile within ice and snow:

$$\theta(z,t) = \begin{cases} \theta_f - [\theta_f - \theta_I(t)]\Phi_I(\zeta_I) & \text{at} \quad -H_I(t) \le z \le 0 \\ \theta_I(t) - [\theta_I(t) - \theta_S(t)]\Phi_S(\zeta_S) & \text{at} \quad -[H_I(t) + H_S(t)] \le z \le -H_I(t). \end{cases} \tag{44}$$

Here, z is the vertical co-ordinate (positive downward) with the origin at the ice-water interface, H_I is the ice thickness, H_S is the thickness of snow overlaying the ice, θ_f is the fresh-water freezing point, θ_I is the temperature at the snow-ice interface, and θ_S is the temperature at the air-snow interface. Notice that the freezing point of salt water is a decreasing function of salinity. A model that accounts for this dependence and is applicable to the ice over salt lakes or seas is presented by Mironov and Ritter (2004). Dimensionless universal functions $\Phi_I \equiv (\theta_f - \theta)/(\theta_f - \theta_I)$ and $\Phi_S \equiv (\theta_I - \theta)/(\theta_I - \theta_S)$ of dimensionless depths $\zeta_I \equiv -z/H_I$ and $\zeta_S \equiv -(z + H_I)/H_S$, respectively, satisfy the boundary conditions $\Phi_I(0) = 0$, $\Phi_I(1) = 1$, $\Phi_S(0) = 0$, and $\Phi_S(1) = 1$.

According to Eq. (44), the heat fluxes through the ice, Q_I, and through the snow, Q_S, due to molecular heat conduction are given by

$$Q_I = -\kappa_i \frac{\theta_f - \theta_I}{H_I} \frac{d\Phi_I}{d\zeta_I}, \qquad Q_S = -\kappa_s \frac{\theta_I - \theta_S}{H_S} \frac{d\Phi_S}{d\zeta_S}, \tag{45}$$

where κ_i and κ_s are the heat conductivities of ice and snow, respectively.

The parameterization of the temperature profile (44) should satisfy the heat transfer equation (25). Integrating Eq. (25) over z from the air-snow interface $z = -(H_I + H_S)$ to just above the ice-water interface $z = -0$ with due regard for the parameterization (44), we obtain the equation of the heat budget of the snow-ice cover,

$$\frac{d}{dt}\{\rho_i c_i H_I [\theta_f - C_I(\theta_f - \theta_I)] + \rho_s c_s H_S [\theta_I - C_S(\theta_I - \theta_S)]\} - \rho_s c_s \theta_S \frac{d}{dt}(H_I + H_S) =$$

$$Q_s + I_s - I(0) + \kappa_i \frac{\theta_f - \theta_I}{H_I} \Phi_I'(0). \tag{46}$$

Here, ρ_i and ρ_s are the densities of ice and of snow, respectively, c_i and c_s are specific heats of these media, and Q_s and I_s are the values of Q and I, respectively, at the air-snow or, if snow is absent, at the air-ice interface. The radiation heat flux I_s that penetrates into the interior of snow-ice cover is the surface value of the incident solar radiation flux from the atmosphere multiplied by $1 - \alpha_i$, α_i being the albedo of the ice or snow surface with respect to solar radiation. The dimensionless parameters C_I and C_S, the shape factors, are given by

$$C_I = \int_0^1 \Phi_I(\zeta_I) d\zeta_I, \qquad C_S = \int_0^1 \Phi_S(\zeta_S) d\zeta_S. \tag{47}$$

The heat flux at the snow-ice interface is assumed to be continuous, that is

$$-\kappa_i \frac{\theta_f - \theta_I}{H_I} \Phi_I'(1) = -\kappa_s \frac{\theta_I - \theta_S}{H_S} \Phi_S'(0). \tag{48}$$

Equations (46) and (48) serve to determine temperatures at the air-snow and at the snow-ice interfaces, when these temperatures are below the freezing point, i.e. when no melting at the snow surface (ice surface, when snow is absent) takes place. During the snow (ice) melting from above, the temperatures θ_S and θ_I remain equal to the freezing point θ_f, and the heat fluxes Q_S and Q_I are zero.

3.4.2 Snow and Ice Thickness

The equations governing the evolution of the snow thickness and of the ice thickness are derived from the heat transfer equation (25) that incorporates an additional term on its right-hand side, namely, the term $f_M(z) L_f dM/dt$ that describes the rate of heat release/consumption due to accretion/melting of snow and ice. Here, M is the mass of snow or ice per unit area, L_f is the latent heat of fusion, and $f_M(z)$ is a function that satisfies the normalization conditions $\int_{H_I}^{H_I+H_S} f_M(z) dz = 1$ and $\int_0^{H_I} f_M(z) dz = 1$ for snow and ice, respectively.

The accumulation of snow is not computed within the ice-snow model. The rate of snow accumulation is assumed to be a known time-dependent quantity that is provided by the atmospheric model or is known from observations. Then, the evolution of the snow thickness during the snow accumulation and no melting is computed from

$$\frac{d\rho_s H_S}{dt} = \left(\frac{dM_S}{dt}\right)_a, \tag{49}$$

where $M_S = \rho_s H_S$ is the snow mass per unit area, and $(dM_S/dt)_a$ is the (given) rate of snow accumulation.

When the temperature θ_I at the upper surface of the ice is below the freezing point θ_f, the heat conduction through the ice causes the ice growth. This growth is accompanied by a release of heat at the lower surface of the ice that occurs at a rate $L_f dM_I/dt$, where $M_I = \rho_i H_I$ is the ice mass per unit area. The normalization function f_M is equal to zero throughout the snow-ice cover except at the ice-water interface where $f_M = \delta(0)$, $\delta(z)$ being the Dirac delta function. Integrating Eq. (25) from $z = -0$ to $z = +0$ with due regard for this heat release yields the equation for the ice thickness. It reads

$$L_f \frac{d\rho_i H_I}{dt} = Q_w + \kappa_i \frac{\theta_f - \theta_I}{H_I} \Phi'_I(0), \tag{50}$$

where Q_w is the heat flux in the near-surface water layer just beneath the ice. If the r.h.s. of Eq. (50) is negative, i.e. the negative of the heat flux in the water, Q_w, exceeds the negative of the heat flux in the ice, $Q_I|_{z=0}$, ice ablation takes place.

As the atmosphere heats the snow surface, the surface temperature eventually reaches the freezing point and the snow and ice melting sets in. This process is accompanied by a consumption of heat at rates $L_f d\rho_s H_S/dt$ and $L_f d\rho_i H_I/dt$ for snow and ice, respectively. Notice that the exact form of the normalization function f_M is not required by virtue of the normalization conditions considered above. Integrating Eq. (25) from $z = -(H_I + H_S) - 0$ to $z = -H_I$ with due regard for the heat loss due to snow melting and adding the (given) rate of snow accumulation yields the equation for the snow thickness,

$$L_f \frac{d\rho_s H_S}{dt} = -(Q_s + I_s) + I(-H_I) + L_f \left(\frac{dM_S}{dt}\right)_a + c_s \theta_f H_S \frac{d\rho_s}{dt}, \tag{51}$$

where the last term on the r.h.s. originates from the dependence of the snow density on the snow depth (see Section 3.5.3).

Integrating Eq. (25) from $z = -H_I$ to $z = +0$ with due regard for the heat loss due to ice melting yields the equation for the ice thickness,

$$L_f \frac{d\rho_i H_I}{dt} = Q_w + I(0) - I(-H_I), \tag{52}$$

If the ice melts out earlier than snow, the snow depth is instantaneously set to zero.

3.4.3 The Temperature Profile beneath the Ice

The simplest assumption is to keep the temperature profile unchanged over the entire period of ice cover. This assumption is fair for deep lakes, where the heat flux through the bottom is negligibly small. In shallow lakes, this assumption may lead to an underestimation of the mean temperature. The heat accumulated in the thermally active upper layer of bottom sediments during spring and summer is returned back to the water column during winter, leading to an increase of the water temperature under the ice. The water temperature under the ice can also increase due to heating by solar radiation penetrating down through the ice. The thermodynamic regimes encountered in ice-covered lakes are many and varied. Their detailed description requires a set of sophisticated parameterizations. The use of such parameterizations in the framework of the present lake model is, however, hardly justified. The point is that it is the snow (ice) surface temperature that communicates information to the atmosphere, the water temperature is not directly felt by the atmospheric surface layer. It is, therefore, not vital that the temperature regimes in ice-covered lakes be described in great detail. Only their most salient features should be accounted for, first of all, the heat budget of the water column.

When the lake is ice-covered, the temperature at the ice-water interface is fixed at the freezing $\theta_s = \theta_f$. In case the bottom temperature is less than the temperature of maximum density, $\theta_b < \theta_r$, the mixed-layer depth and the shape factor are kept unchanged, $dh/dt = 0$ and $dC_\theta/dt = 0$, the mean temperature $\overline{\theta}$ is computed from Eq. (26) and the bottom temperature θ_b is computed from Eq. (23). If the entire water column appears to be mixed at the moment of freezing, i.e. $h = D$ and $\theta_s = \overline{\theta} = \theta_b$, the mixed layer depth is reset to zero, $h = 0$, and the shape factor is set to its minimum value, $C_\theta = 0.5$ (see Section 3.5.1).

The heat flux from water to ice is estimated from

$$Q_w = -\kappa_w \frac{\theta_b - \theta_s}{D}, \tag{53}$$

if $h = 0$, and $Q_w = 0$ otherwise. Notice that the estimate of Q_w given by Eq. (53) and the shape factor $C_\theta = 0.5$ correspond to a linear temperature profile over the entire water column. A linear profile is encountered in ice-covered shallow lakes when $\theta_b < \theta_r$ and the heat flux is from the bottom sediments to the lake water.

As the bottom temperature reaches the temperature of maximum density, convection due to bottom heating sets in. To describe this regime of convection in detail, a convectively mixed layer whose temperature is close to θ_r, and a thin layer adjacent to the bottom, where the temperature decreases sharply from $\theta_b > \theta_r$ to θ_r, should be thoroughly considered. We neglect these peculiarities of convection due to bottom heating and adopt a simpler model where the bottom temperature is fixed at the temperature of maximum density, $\theta_b = \theta_r$. The mean temperature $\overline{\theta}$ is computed from Eq. (26). If $h > 0$, the shape factor C_θ is kept unchanged, and the mixed-layer depth is computed from Eq. (23). As the mixed-layer depth approaches zero, Eq. (23) is used to compute the shape factor C_θ that in this regime would increase towards its maximum value C_θ^{max}. The heat flux from water to ice is estimated from

$$Q_w = -\kappa_w \frac{\theta_b - \theta_s}{D} \max\left[1, \Phi'_\theta(0)\right], \tag{54}$$

if $h = 0$, and $Q_w = 0$ otherwise.

One more regime of convection is often encountered in ice-covered lakes. In late spring, the snow overlying the ice vanishes and solar radiation penetrates down through the ice. As the mixed-layer temperature is below that of maximum density, the volumetric radiation heating leads to de-stabilisation of the water column and thereby drives convective motions. Such regime of convection was analysed by Farmer (1975), Mironov and Terzhevik (2000), Mironov et al. (2002), and Jonas et al. (2003), among others. A parameterization of convection due to solar heating (e.g. a parameterization based on a bulk model developed by Mironov et al. 2002) can, in principle, be incorporated into the present model. We do not do so, however, considering that the major effect of convection beneath the ice is to redistribute heat in the vertical and that it takes place over a very limited period of time.

3.5 Empirical Relations and Model Constants

3.5.1 The Shape Functions

In the lake model proposed by Mironov et al. (1991), a polynomial approximation of the shape function with respect to the temperature profile in the thermocline was used. The temperature-depth curve was assumed to be bounded by the two limiting curves given by Eq. (5). The shape function $\Phi_\theta(\zeta)$ evolves towards the first line of Eq. (5) during the mixed-layer deepening, and towards the second line of Eq. (5) during the mixed-layer stationary

state or retreat. The corresponding limiting values of the shape factor C_θ are 0.75 and 0.6, respectively. The adjustment of the temperature-depth curve occurs on a certain relaxation time scale that was estimated on the basis of the similarity theory for stably stratified turbulent flows (see Mironov et al. 1991 for details).

Recall that the approximations (5) are based on the observational data taken in the Baltic Sea. Theoretical analysis of Zilitinkevich et al. (1988) also holds for the ocean or sea, where the thermocline is underlain by a deep quiescent layer. Shallow and medium-depth lakes usually have a two-layer temperature structure, where the thermocline extends from the bottom of the mixed layer down to the basin bottom. Empirical data indicate a greater variety of shapes of the temperature-depth curve in lakes than in the ocean or sea (Kirillin 2001a, 2001b). During the mixed-layer deepening, the dimensionless temperature gradient just below the mixed layer-thermocline interface and the shape factor often exceed their limiting values of $\Phi'_\theta(0) = 3$ and $C_\theta = 0.75$, respectively, suggested by the first line of Eq. (5). These findings are corroborated by the theoretical analysis in Appendix A. Based upon these empirical and theoretical findings, we allow a wider range of variation in Φ_θ.

We adopt the following polynomial approximation of the shape function $\Phi_\theta(\zeta)$ with respect to the temperature profile in the thermocline:

$$\Phi_\theta = \left(\frac{40}{3}C_\theta - \frac{20}{3}\right)\zeta + (18 - 30C_\theta)\,\zeta^2 + (20C_\theta - 12)\,\zeta^3 + \left(\frac{5}{3} - \frac{10}{3}C_\theta\right)\zeta^4. \tag{55}$$

The shape factor C_θ is computed from

$$\frac{dC_\theta}{dt} = \mathrm{sign}(dh/dt)\frac{C_\theta^{max} - C_\theta^{min}}{t_{rc}}, \qquad C_\theta^{min} \le C_\theta \le C_\theta^{max}, \tag{56}$$

where t_{rc} is the relaxation time scale, and sign is the signum function, $\mathrm{sign}(x)=-1$ if $x \le 0$ and $\mathrm{sign}(x)=1$ if $x > 0$. The minimum and maximum values of the shape factor are set to $C_\theta^{min} = 0.5$ and $C_\theta^{max} = 0.8$. The shape function $\Phi_\theta(\zeta)$ given by Eq. (55) is illustrated in Fig. 5. As seen from the figure, the dimensionless temperature profiles lie in the area bounded by the lower and the upper solid curves. During the mixed-layer deepening, $dh/dt > 0$, the temperature profile evolves towards the limiting curve, characterised by a maximum value of the shape factor, $C_\theta^{max} = 0.8$, and the maximum value of the dimensionless temperature gradient at the upper boundary of the thermocline, $\Phi'_\theta(0) = 4$. During the mixed-layer stationary state or retreat, $dh/dt \le 0$, the temperature profile evolves towards the other limiting curve, characterised by a minimum value of the shape factor, $C_\theta^{min} = 0.5$, and the zero temperature gradient at the upper boundary of the thermocline, $\Phi'_\theta(0) = 0$. Notice that $C_\theta^{min} = 0.5$ is consistent with a linear temperature profile that is assumed to occur under the ice when the bottom temperature is less than the temperature of maximum density (see Section 3.4.3).

According to Eq. (55), the dimensionless parameter $C_{\theta\theta}$ defined through Eq. (31) is given by

$$C_{\theta\theta} = \frac{11}{18}C_\theta - \frac{7}{45}. \tag{57}$$

The relaxation time t_{rc} is estimated from the following scaling arguments. The time t_{rc} is basically the time of the evolution of the temperature profile in the thermocline from one limiting curve to the other, following the change of sign in dh/dt. Then, a reasonable scale for t_{rc} is the thermal diffusion time through the thermocline, that is a square of the thermocline thickness, $(D-h)^2$, over a characteristic eddy temperature conductivity, K_{H*}. With due regard for the stable stratification in the thermocline, K_{H*} is estimated from Eqs. (14) and (16). Using a mean-square buoyancy frequency in the thermocline, $\overline{N} =$

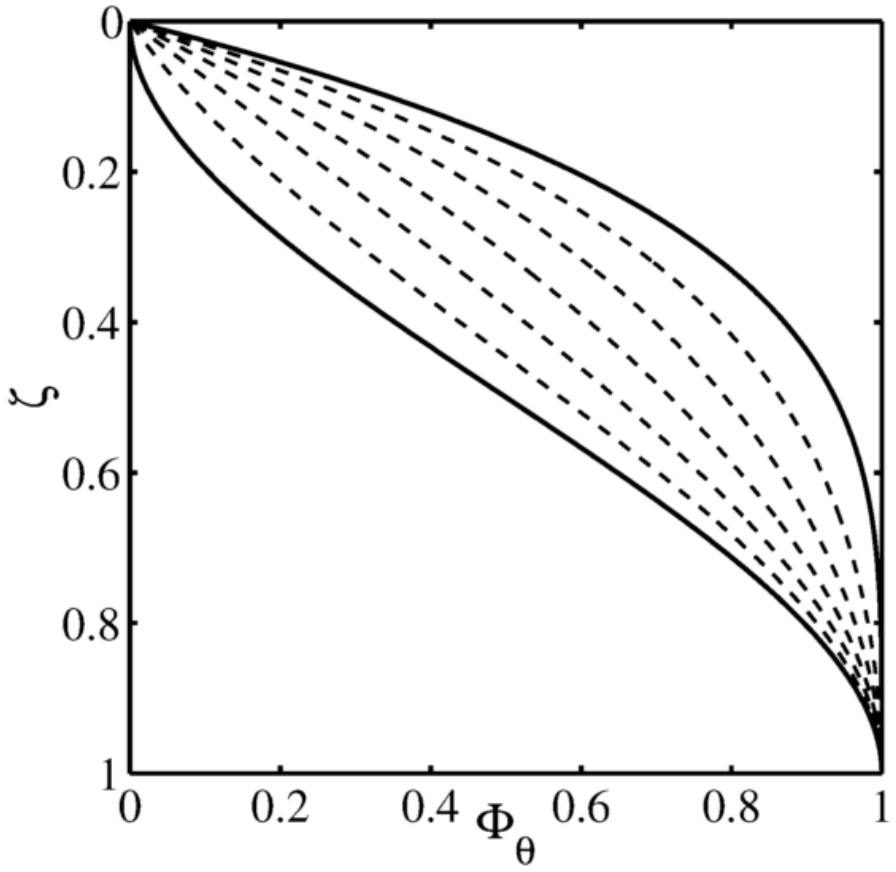

Figure 5: The fourth-order polynomial approximation of the shape function $\Phi_\theta(\zeta)$ with respect to the temperature profile in the thermocline. The curves are computed from Eq. (55) with seven different values of the shape factor C_θ ranging from $C_\theta = C_\theta^{min} = 0.5$, lower solid curve, to $C_\theta = C_\theta^{max} = 0.8$, upper solid curve, $\Delta C_\theta = 0.05$ apart.

$\left[(D-h)^{-1}\int_h^D N^2 dz\right]^{1/2}$, as an estimate of N and assuming that the TKE in the thermocline scales either on the convective velocity w_*, Eq. (34), or on the surface friction velocity u_*, we propose

$$t_{rc} = \frac{(D-h)^2\overline{N}}{C_{rc}u_T^2}, \qquad u_T = \max(w_*, u_*), \tag{58}$$

where C_{rc} is a dimensionless constant estimated at 0.003 (this value may be altered as new information becomes available).

We adopt the following polynomial approximations of the shape functions $\Phi_{B1}(\zeta_{B1})$ and $\Phi_{B2}(\zeta_{B2})$ with respect to the temperature profile in bottom sediments (cf. Golosov et al. 1998):

$$\Phi_{B1} = 2\zeta_{B1} - \zeta_{B1}^2, \qquad \Phi_{B2} = 6\zeta_{B2}^2 - 8\zeta_{B2}^3 + 3\zeta_{B2}^4. \tag{59}$$

which are the simplest polynomials that satisfy a minimum set of constraints. The conditions $\Phi_{B1}(0) = \Phi_{B2}(0) = 0$ and $\Phi_{B1}(1) = \Phi_{B2}(1) = 1$ follow from the definition of ζ_{B1}, ζ_{B2}, Φ_{B1}, and Φ_{B2}. The conditions $\Phi'_{B1}(1) = \Phi'_{B2}(0) = \Phi'_{B2}(1) = 0$ provide a zero temperature

gradient at the depths $z = H$ and $z = L$, and the condition $\Phi''_{B2}(1) = 0$ follows from the requirement that the temperature θ_L at the outer edge $z = L$ of the thermally active layer of the sediments is constant in time. The shape functions given by Eq. (59) are illustrated in Fig. 6. The shape factors that correspond to Eq. (59) are $C_{B1} = 2/3$ and $C_{B2} = 3/5$.

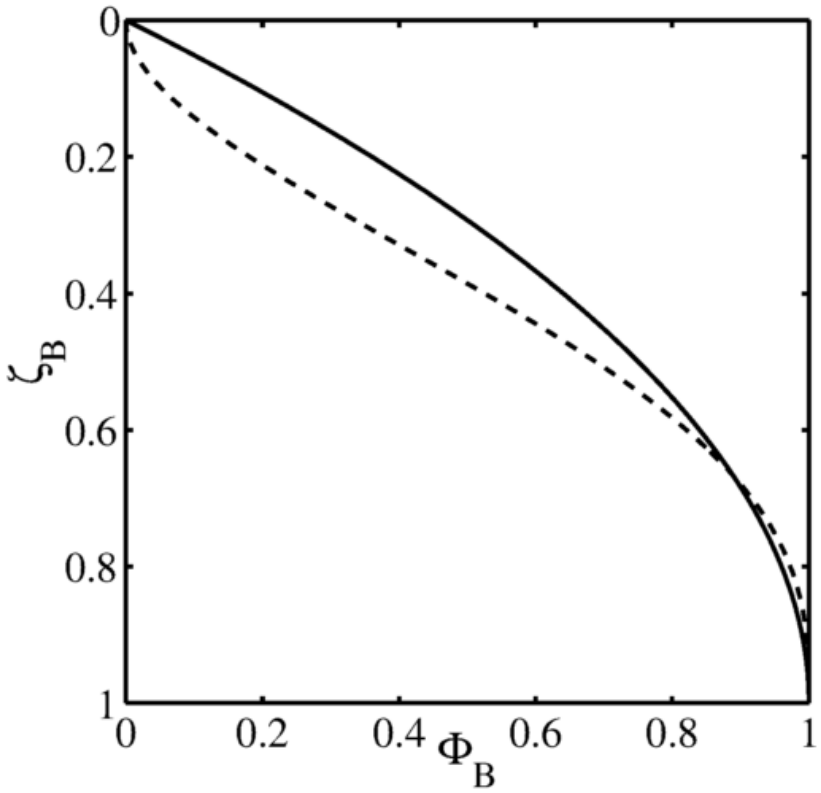

Figure 6: The polynomial approximations of the shape functions $\Phi_{B1}(\zeta_{B1})$, solid curve, and $\Phi_{B2}(\zeta_{B2})$, dashed curve, with respect to the temperature profile in bottom sediments. The curves are computed from Eq. (59).

As a zero-order approximation, the simplest linear temperature profile within snow and ice can be assumed, $\Phi_S(\zeta_S) = \zeta_S$ and $\Phi_I(\zeta_I) = \zeta_I$. This gives $C_S = C_I = 1/2$. Although a linear profile is a good approximation for thin ice, it is likely to result in a too thick ice in cold regions, where the ice growth takes place over a long period, and in a too high thermal inertia of thick ice. A slightly more sophisticated approximation was developed by Mironov and Ritter (2004) who assumed that the ice thickness is limited by a certain maximum value H_I^{max} and that the rate of ice growth approaches zero as H_I approaches H_I^{max} (the snow layer over the ice was not considered). They proposed

$$\Phi_I = \left[1 - \frac{H_I}{H_I^{max}}\right]\zeta_I + \left[(2 - \Phi_{*I})\frac{H_I}{H_I^{max}}\right]\zeta_I^2 + \left[(\Phi_{*I} - 1)\frac{H_I}{H_I^{max}}\right]\zeta_I^3, \tag{60}$$

where Φ_{*I} is a dimensionless constant. The shape factor that corresponds to Eq. (60) is

$$C_I = \frac{1}{2} - \frac{1}{12}(1 + \Phi_{*I})\frac{H_I}{H_I^{max}}. \tag{61}$$

The physical meaning of the above expressions can be elucidated as follows. The relation $\Phi'_I(0) = 1 - H_I/H_I^{max}$ that follows from Eq. (60) ensures that the ice growth is quenched

as the ice thickness approaches its maximum value. Equation (61) suggests that the shape factor C_I decreases with increasing ice thickness. A smaller C_I means a smaller relative thermal inertia of the ice layer of thickness H_I [the absolute thermal inertia is measured by the term $C_I H_I$ that enters the l.h.s. of Eq. (46)]. This is plausible as it is mostly the upper part of thick ice, not the entire ice layer, that effectively responds to external forcing. For use in the global numerical weather prediction model GME of the German Weather Service, Mironov and Ritter (2004) proposed an estimate of $H_I^{max} = 3$ m. This value is typical of the central Arctic in winter. The allowable values of Φ_{*I} lie in the range between -1 and 5. $\Phi_{*I} > 5$ yields an unphysical negative value of C_I as the ice thickness approaches H_I^{max}. $\Phi_{*I} < -1$ gives C_I that increases with increasing H_I. There is no formal proof that this may not occur, but it is very unlikely. A reasonable estimate is $\Phi_{*I} = 2$. With this estimate C_I is halved as H_I increases from 0 to H_I^{max}. Notice that the linear temperature profile is recovered as $H_I/H_I^{max} \ll 1$, i.e. when the ice is thin. The polynomial (60) is illustrated in Fig. 7.

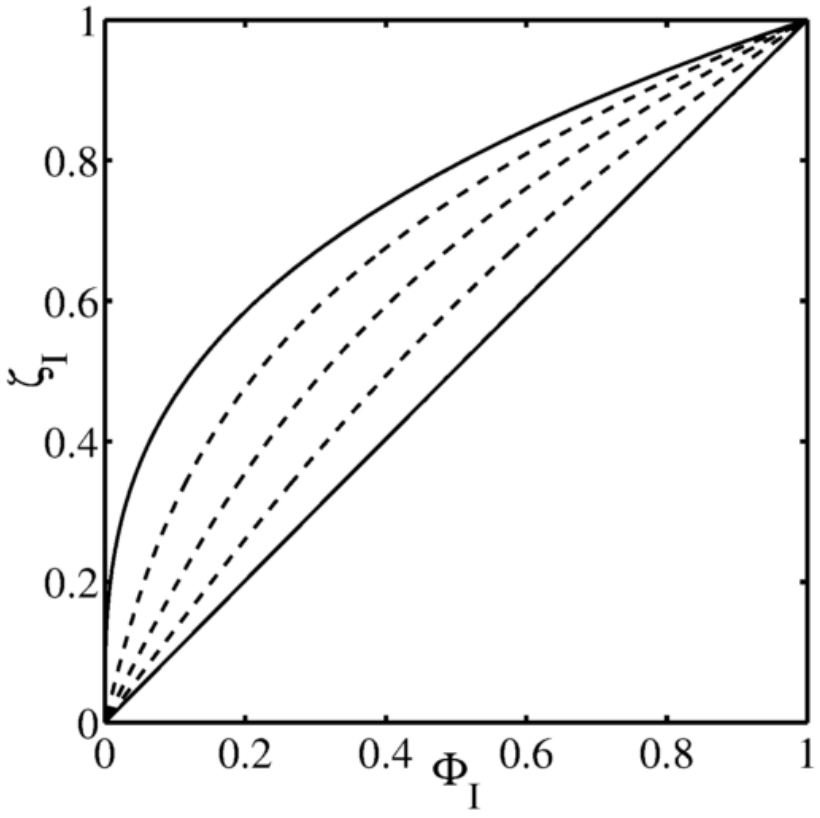

Figure 7: The approximation of the temperature profile shape function $\Phi_I(\zeta_I)$ given by Eq. (60). The curves are computed with $\Phi_{*I} = 2$ and (from right to left) $H_I/H_I^{max} = 0.01$, $H_I/H_I^{max} = 0.25$, $H_I/H_I^{max} = 0.5$, $H_I/H_I^{max} = 0.75$ and $H_I/H_I^{max} = 1.0$.

One further comment is in order regarding the shape functions Φ_θ, Φ_{B1}, Φ_{B2}, Φ_S and Φ_I. These functions have been determined using a geometrical approach (the Pohlhausen method). The essence of the approach is to use a polynomial approximation of the function in question and to invoke a minimum set of physical constraints to determine the polynomial coefficients. In spite of the utter simplicity of this approach, it often yields very accurate results. Prominent examples are the boundary-layer similarity models developed by Long

(1974) and Zilitinkevich (1989a, 1989b).

It should be stressed that, although the shape functions are useful in that they provide a continuous temperature profile trough the snow, ice, water and bottom sediments, their exact shapes are not required in the present model. It is not $\Phi_\theta(\zeta)$, $\Phi_{B1}(\zeta_{B1})$, $\Phi_{B2}(\zeta_{B2})$, $\Phi_S(\zeta_S)$ and $\Phi_I(\zeta_I)$ per se, but the shape factors C_θ, C_{B1}, C_{B2}, C_S and C_I, and the dimensionless gradients $\Phi'_\theta(0)$, $\Phi'_{B1}(0)$, $\Phi'_S(0)$, $\Phi'_I(0)$ and $\Phi'_I(1)$, that enter the model equations. The estimates of these parameters are summarised in Table 1 (Appendix B).

3.5.2 Constants in the Equations for the Mixed-Layer Depth

The estimates of $C_{c1} = 0.2$ and $C_{c2} = 0.8$ in Eq. (35) were recommended by Zilitinkevich (1991). They were obtained using laboratory, atmospheric and oceanic data. Apart from being commonly used in mixed-layer models of penetrative convection driven by the surface buoyancy flux, these values were successfully used by Mironov and Karlin (1989) to simulate day-time convection in the upper ocean that is driven by surface cooling but inhibited by radiation heating, and by Mironov and Terzhevik (2000) and Mironov et al. (2002) to simulate spring convection in ice-covered lakes where convective motions are driven by volumetric radiation heating of the water at temperature below the temperature of maximum density (Mironov et al. 2002 used $C_{c2} = 1.0$). A slightly modified estimate of $C_{c1} = 0.17$ was obtained by Fedorovich et al. (2004) from large-eddy simulation data. We adopt the estimates of $C_{c1} = 0.17$ and $C_{c2} = 1.0$ for use in the equation of convective entrainment.

For use in Eq. (38) for the equilibrium mixed-layer depth in stable or neutral stratification, we adopt the estimates of $C_n = 0.5$, $C_s = 10$ and $C_i = 20$ obtained by Zilitinkevich and Mironov (1996). The estimates of C_s and C_i are based on a limited amount of data and may need to be slightly altered as new (and better) data become available. The estimate of C_n was corroborated by the results from further studies (Zilitinkevich and Esau 2002, 2003) and is reliable.

The estimates of the dimensionless constant C_{rh} in the relaxation-type rate equation for the depth of a stably or neutrally stratified wind-mixed layer, Eqs. (36) and (37), are not abundant. Kim (1976) and Deardorff (1983) recommended that the value of $C_{rh} = 0.28$ be used to describe entrainment into a homogeneous fluid. The same value was used by Zeman (1979), and a slightly lower value of $C_{rh} = 0.26$ by Zilitinkevich et al. (1979). The rate equations given by Khakimov (1976) and Zilitinkevich et al. (2002) use the reciprocal of the Coriolis parameter as the relaxation time scale. Their rate equations suggest the values of $C_{rh} = 0.45$ and $C_{rh} = 0.5$, respectively. A similar form of the rate equation was proposed earlier by Deardorff (1971) who used a much lower value of $C_{rh} = 0.025$. We adopt an estimate of $C_{rh} = 0.03$ suggested by the sensitivity experiments with the present lake model (keeping in mind that this value may need to be altered).

The estimates of dimensionless constants in the equations for the mixed-layer depth are summarised in Table 1 (Appendix B).

3.5.3 Thermodynamic Parameters

The exponential approximation of the decay law for the flux of solar radiation is commonly used in applications. It reads

$$I(t,z) = I_s(t) \sum_{k=1}^{n} a_k \exp[-\gamma_k(z + H_S + H_I)], \tag{62}$$

where I_s is the surface value of the solar radiation heat flux multiplied by $1-\alpha$, α being the albedo of the water, ice or snow surface with respect to solar radiation, n is the number of wavelength bands, a_k are fractions of the total radiation flux for different wavelength bands, and $\gamma_k(z)$ are attenuation coefficients for different bands. The attenuation coefficients are piece-wise constant functions of height, i.e. they have different values for water, ice and snow but remain depth-constant within these media. The optical characteristics of water are lake-specific and should be estimated in every particular case. Rough estimates of a_k and γ_k for ice and snow are given by Launiainen and Cheng (1998).

The lake model includes a number of thermodynamic parameters. They are summarised in Table 2 (Appendix B). These thermodynamic parameters can be considered constant except for the snow density and the snow heat conductivity that depend, among other things, on the snow thickness and the snow age. As a first approximation, the following empirical formulations (Heise et al. 2003) can be used that relate ρ_s and κ_s to the snow thickness:

$$\rho_s = \min\left\{\rho_s^{max}, |1 - H_S\Gamma_{\rho_s}/\rho_w|^{-1}\,\rho_s^{min}\right\}, \tag{63}$$

where $\rho_s^{min} = 100$ kg·m^{-3} and $\rho_s^{max} = 400$ kg·m^{-3} are minimum and maximum values, respectively, of the snow density, and $\Gamma_{\rho_s} = 200$ kg·m^{-4} is an empirical parameter, and

$$\kappa_s = \min\left\{\kappa_s^{max}, \kappa_s^{min} + H_S\Gamma_{\kappa_s}\rho_s/\rho_w\right\}, \tag{64}$$

where $\kappa_s^{min} = 0.2$ J·m^{-1}·s^{-1}·K^{-1} and $\kappa_s^{max} = 1.5$ J·m^{-1}·s^{-1}·K^{-1} are minimum and maximum values, respectively, of the snow heat conductivity, and $\Gamma_{\kappa_s} = 1.3$ J·m^{-2}·s^{-1}·K^{-1} is an empirical parameter.

4 Conclusions

A lake model suitable to predict the vertical temperature structure in lakes of various depths on time scales from a few hours to many years is developed. The model, termed FLake, is based on a two-layer parametric representation of the evolving temperature profile and on the integral budget of energy for the layers in question. The structure of the stratified layer between the upper mixed layer and the basin bottom, the lake thermocline, is described using the concept of self-similarity (assumed shape) of the temperature-depth curve. The same concept is used to describe the temperature structure of the thermally active upper layer of bottom sediments and of the ice and snow cover. An entrainment equation is used to compute the depth of a convectively-mixed layer. A relaxation-type equation is used to compute the wind-mixed layer depth in stable and neutral stratification, where a multi-limit formulation for the equilibrium mixed-layer depth accounts for the effects of the earth's rotation, of the surface buoyancy flux, and of the static stability in the thermocline. Both mixing regimes are treated with due regard for the volumetric character of solar radiation heating. Simple thermodynamic arguments are invoked to develop the evolution equations for the ice and snow depths. Using the integral (bulk) approach, the problem of solving partial differential equations (in depth and time) for the temperature and turbulence quantities is reduced to solving ordinary differential equations for the time-dependent parameters that specify the evolving temperature profile. The result is a computationally efficient lake model that incorporates much of the essential physics.

It must be emphasised that the empirical constants and parameters of FLake are not application-specific. That is, once they have been estimated using independent empirical and numerical data, they should not be re-evaluated when the model is applied to a particular lake. There are, of course, lake-specific external parameters, such as depth to the

bottom and optical characteristics of water, but these are not part of the model physics. In this way FLake does not require "re-tuning", a procedure that may improve an agreement with a limited amount of data and is sometimes justified. This procedure should, however, be considered as a bad practice and must be avoided whenever possible as it greatly reduces the predictive capacity of a physical model (Randall and Wielicki 1997).

Apart from the depth to the bottom and the optical characteristics of lake water, the only lake-specific parameters are the depth L of the thermally active layer of bottom sediments and the temperature θ_L at that depth. These parameters should be estimated only once for each lake, using observational data or empirical recipes (e.g. Fang and Stefan 1998). In a similar way, the temperature at the bottom of the thermally active soil layer and the depth of that layer are estimated once and then used in an NWP model as two-dimensional external-parameter arrays.

The proposed lake model is intended for use, first of all, in NWP and climate models as a module (parameterization scheme) to predict the lake surface temperature. Apart from NWP and climate modelling, practical applications where simple bulk models are favoured over more accurate but more sophisticated models (e.g. second-order turbulence closures) include modelling aquatic ecosystems. For ecosystem modelling, a sophisticated physical module is most often not required because of insufficient knowledge of chemistry and biology.

5 Appendices

Appendix A. Temperature Profile in the Lake Thermocline – A Self-Similar Travelling Wave-Type Solution

In Section 2.3, a travelling wave-type self-similar solution to the heat transfer equation obtained by Zilitinkevich et al. (1988) is discussed. These authors analysed the heat transfer equation in the form

$$\partial\theta/\partial t = -\partial\mathcal{Q}/\partial z, \tag{A.1}$$

where $\mathcal{Q}$ is the vertical turbulent temperature flux, subject to the boundary conditions

$$\theta = \theta_s \quad \text{at} \quad z = h, \qquad \theta = \theta_b \quad \text{at} \quad z = h + \Delta h. \tag{A.2}$$

They assumed that the temperatures at the upper and lower boundaries of the thermocline are constant, $\theta_s = const$ and $\theta_b = const$, the mixed layer deepens at a constant rate, $dh/dt \equiv \dot{h} = const > 0$, whereas the thickness of the thermocline does not change with time, $d\Delta h/dt = 0$. Then, the heat transfer equation (A.1) takes the form

$$\dot{h}d\theta/d\zeta = d\mathcal{Q}/d\zeta, \tag{A.3}$$

where $\zeta = (z-h)/\Delta h$ is the dimensionless depth. In order to close the problem, Zilitinkevich et al. (1988) used the down-gradient formulation for the temperature flux, $\mathcal{Q} = -K_H\partial\theta/\partial z$, and the expression $K_H = l^2N$ for the effective temperature conductivity in the thermocline, where l is the eddy length scale. Taking $l = const$, they invoked an additional condition $\partial\theta/\partial z = 0$ at $z = h + \Delta h$ to determine l. The solution to the problem reads

$$\Phi_\theta = 1 - (1-\zeta)^3, \qquad l = 3^{-3/4}(\beta\Delta\theta)^{-1/4}\Delta h^{3/4}\dot{h}^{1/2}. \tag{A.4}$$

The temperature profile shape function Φ_θ is given by the third-order polynomial in ζ. This polynomial was developed earlier by Arsenyev and Felzenbaum (1977) on the basis of simple geometrical arguments and by Mälkki and Tamsalu (1985) on the basis of data from measurements in the Baltic Sea.

The Zilitinkevich et al. (1988) solution (A.4) is conditioned by the assumption $d\Delta h/dt = 0$. This situation is illustrated in Fig. 8(a). It is characteristic of the ocean or sea, where the mixed layer grows into a neutrally stratified deep quiescent layer, whereas the thickness of the thermocline remains approximately unchanged. In lakes, the thermocline is usually pressed against the basin bottom so that an increase of the mixed-layer thickness is accompanied by a decrease of the thickness of the thermocline, $dh/dt = -d\Delta h/dt$. This situation is illustrated in Fig. 8(b). With $dh/dt = -d\Delta h/dt = const > 0$, the heat transfer equation (A.1) takes the form

$$\dot{h}(1-\zeta)d\theta/d\zeta = d\mathcal{Q}/d\zeta. \tag{A.5}$$

It is easy to verify that Eq. (A.5) subject to the same boundary conditions and closure relations as used by Zilitinkevich et al. (1988) possesses a solution in the form

$$\Phi_\theta = 1 - (1-\zeta)^5, \qquad l = 180^{-1/4}(\beta\Delta\theta)^{-1/4}\Delta h^{3/4}\dot{h}^{1/2}. \tag{A.6}$$

Equations (A.4) and (A.6) reveal a number of differences between the lake thermocline that is pressed against the bottom and the ocean thermocline that is underlain by a deep neutrally

stratified quiescent layer. The eddy length scale l characteristic of the lake thermocline is $(20/3)^{1/4}$ times smaller than l characteristic of the ocean thermocline. The temperature profile in the lake thermocline is characterised by a sharper temperature gradient near the thermocline top. The dimensionless temperature gradients at the top of the thermocline, $-(\Delta\theta/\Delta h)^{-1}(\partial\theta/\partial z)|_{z=h} \equiv \Phi'_\theta(0)$, $\Delta\theta = \theta_s - \theta_b$ being the temperature difference across the thermocline, are $\Phi'_\theta(0) = 5$ for the lake and $\Phi'_\theta(0) = 3$ for the ocean. The temperature profile shape factor is $C_\theta = 5/6$ for the lake and $C_\theta = 3/4$ for the ocean.

As Eq. (A.3) suggests, the self-similar oceanic thermocline is characterised by the shape function $\Phi_\theta \equiv (\theta_s - \theta)/(\theta_s - \theta_b)$ with respect to the temperature that coincides with the shape function $\Phi_Q \equiv (\mathcal{Q}_h - \mathcal{Q})/(\mathcal{Q}_h - \mathcal{Q}_b)$ with respect to the temperature (heat) flux. For the lake thermocline, the relation between Φ_θ and Φ_Q is more sophisticated. Equation (A.5) yields

$$\Phi_Q(\zeta) = C_\theta^{-1}\left[(1-\zeta)\Phi_\theta(\zeta) + \int_0^\zeta \Phi_\theta(\zeta')d\zeta'\right]. \tag{A.7}$$

The above relation suggests that the dimensionless shape-function parameters C_Q, $C_{\theta\theta}$ and C_θ defined by Eqs. (30), (31) and (24), respectively, are related through $C_Q = 2C_{\theta\theta}/C_\theta$.

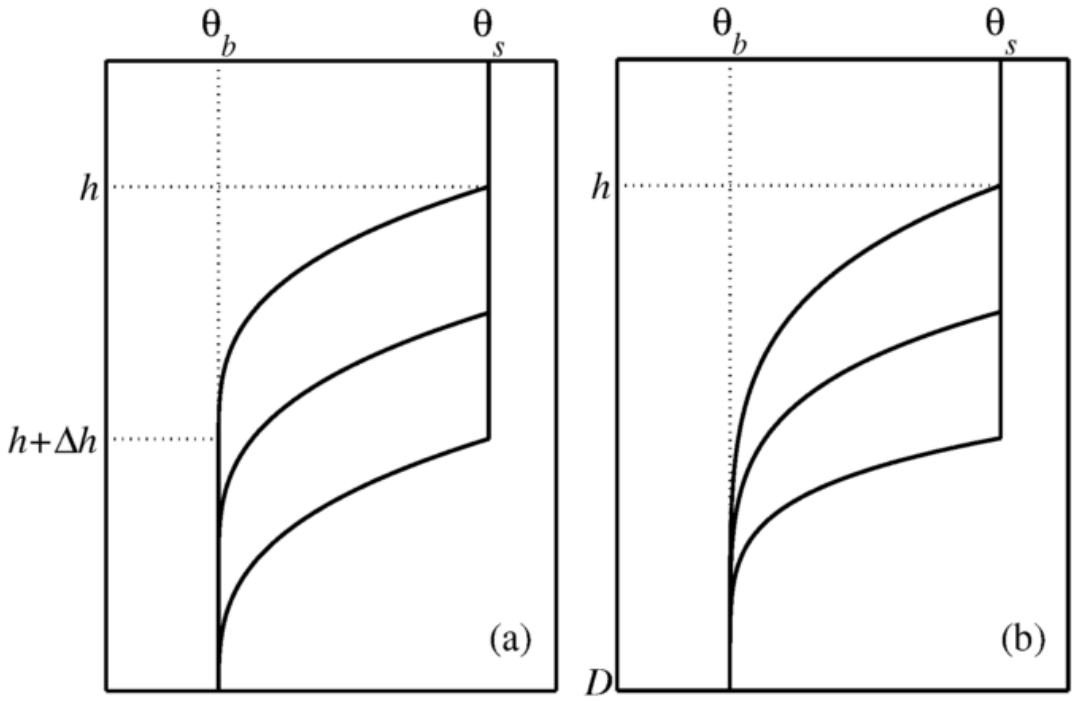

Figure 8: Self-similar temperature profile during the mixed-layer deepening. (a) In a neutrally stratified deep ocean, the mixed-layer depth increases, $dh/dt > 0$, whereas the depth of the thermocline remains constant, $d\Delta h/dt = 0$. (b) In lakes, the thermocline is pressed against the bottom, $\Delta h = D - h$, so that $dh/dt = -d\Delta h/dt$.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIM, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA), and Russia (ROSHYDROMET). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the COSMO-Model relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

2 Main achievements 4

3 Applications of the GPU and single precision capability 7

4 Lessons learned and outlook 7

Executive summary

Efficient use of high-performance computing (HPC) systems is key to enable higher resolution, larger computational domains, more complex physical parametrizations, or more ensemble members. Due to the end of Moore's Law, HPC systems achieve higher performance via a massive increase in processor cores accompanied by a stagnant or decreasing clock frequency and by employing specialized hardware such as GPUs. The main outcomes of this project are a GPU-capable version of the COSMO model and the possibility to run the model in single precision. Both developments have been merged into the official release of the model and are already in use by several members of the COSMO community. The port to GPU was achieved by using a domain-specific language (DSL) for the dynamics and OpenACC compiler directives for the other components of the model. The resulting code is about a factor 3-4x faster on current state-of-the-art GPUs as compare to traditional multi-core CPUs.

1 Introduction

Numerical weather prediction can greatly benefit from progress in computational technology by increasing resolution, model complexity or the number of ensemble members in probabilistic prediction system. In the recent years, performance increase in hardware stems from massive increase in the number of processing units (cores) and specialized hardware such as Graphics Processing Units (GPUs). In order to benefit from current hardware, scientific models need to be adapted. The aim of the POMPA project was to prepare the COSMO model for these hardware architectures and render it performance portable across architectures. The project leveraged efforts from the High Performance and High Productivity Computing (HP2C) initiative and the Platform for Advanced Scientific Computing (PASC) in Switzerland which addressed these challenges.

The following actions were planned in the project:

- Holistic performance analysis and documentation (Task 1)
- Improve generic scalability of the current model implementation:
  - Redesign memory layout and data structures for better cache awareness and easier load-balancing (Task 2)
  - Optimization of current parallelization and introduction of a hybrid parallelization employing MPI and OpenMP (Task 3)
  - Improve performance of I/O (Task 4)
  - Develop a switchable singe/double precision model version (Task 8)
- Explore emerging technologies:
  - Design a new implementation of the dynamical core optimized for multi-core processors and GPUs (Task 5)
  - Re-engineering the implementation of the physical parametrizations (Task 6)
  - Develop a GPU-capable version of COSMO (Task 7)

This report provides only a general overview of the main outcomes of the POMPA project, while further details can be found in several papers and reports published during this project

which are referenced thereafter in particular. In Sec. 2 we discuss main achievements of the projects associated with the different tasks. In Sec. 3 we present the lessons learned during this work and finally some overview and recommendation for future work are discussed.

2 Main achievements

The performance analysis of the model (Task 1) shows that for a typical application most of the computational time (60%) is spend in the dynamical core, which only represents a relatively small fraction of the code (20%), see Fig. 1. Most of the optimizations therefore focused on this part and a re-write using a Domain Specific Language (DSL) was considered.

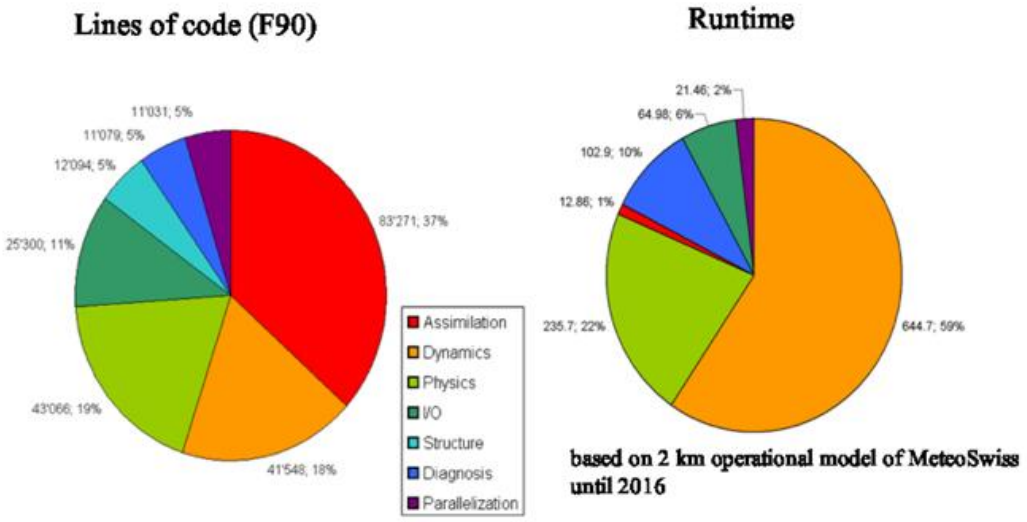

Figure 1: COSMO components timing.

The DSL approach allows a separation of concerns between the user code and the hardware specific optimizations which are implemented in a so-called back-end. A given user code is in principle portable to and efficient on all architectures supported by the library that implements the DSL. The COSMO dynamical core was re-written using the STELLA Library which was developed as part of the project and for which an x86 CPU and a GPU back-end have been implemented. A detailed description of the STELLA library can be found in [Gysi 2015]. The CPU back-end employs OpenMP for threading (Task 3 and 5) while the GPU back-end relies on the CUDA language (Task 5). The specific data storage layout is hidden from the STELLA user allowing to change the underlying data structures for optimal performance on a given target hardware architecture (Task 2). Furthermore the library relies heavily on cache optimizations (Task 2).

For an application such as COSMO which has low compute intensity, i.e. low number of floating-point operations as compared to memory accesses, having only the dynamical core running on GPU is not a performant solution for running on an hybrid GPU system. This would indeed require costly synchronization between the host CPU and the GPU at every time steps which would counteract all performance gains obtained by using GPUs. It was therefore decided to adopt a so-called full GPU port strategy which means that every component of the model reading or writing three dimensional fields needs to run on the GPU see Fig. 2. The dynamics and communication are ported to GPU using the DSL while a

compiler-based directive approach OpenACC (Task 7) is considered [Lapillonne 2014]. A detailed description of the COSMO GPU port can be found in [Fuhrer 2014].

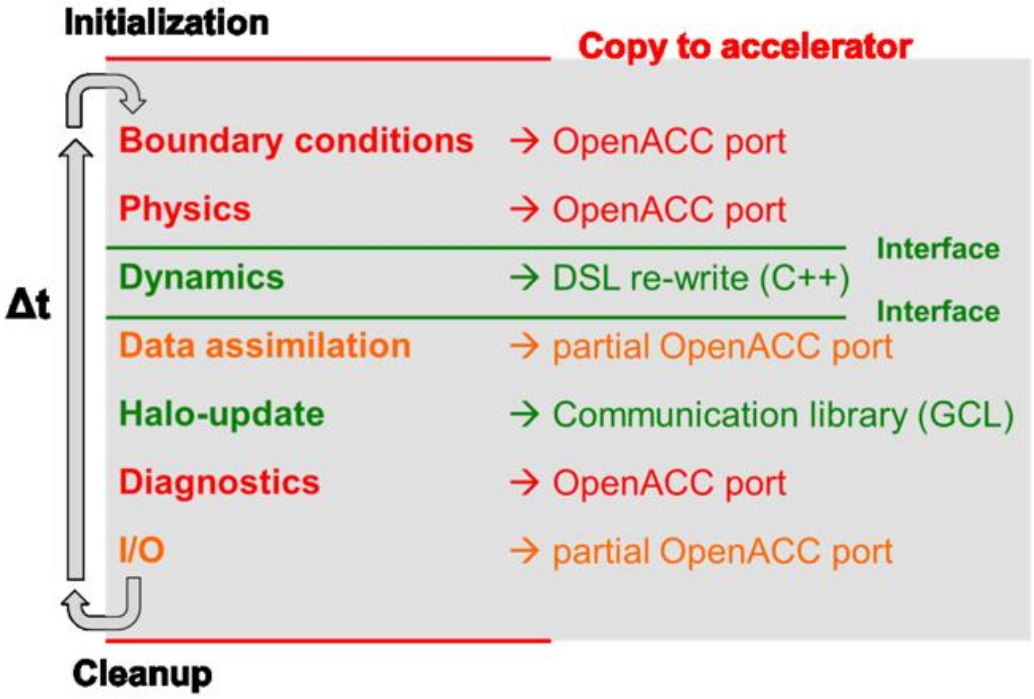

Figure 2: COSMO time loop. Full GPU port strategy.

The GPU capability of COSMO are available from COSMO version 5.6 on for the COSMO community. When comparing the runtime of COSMO on CPU and GPUs of similar generation the code runs typically 3 to 5 time faster on GPU (Fig. 3).

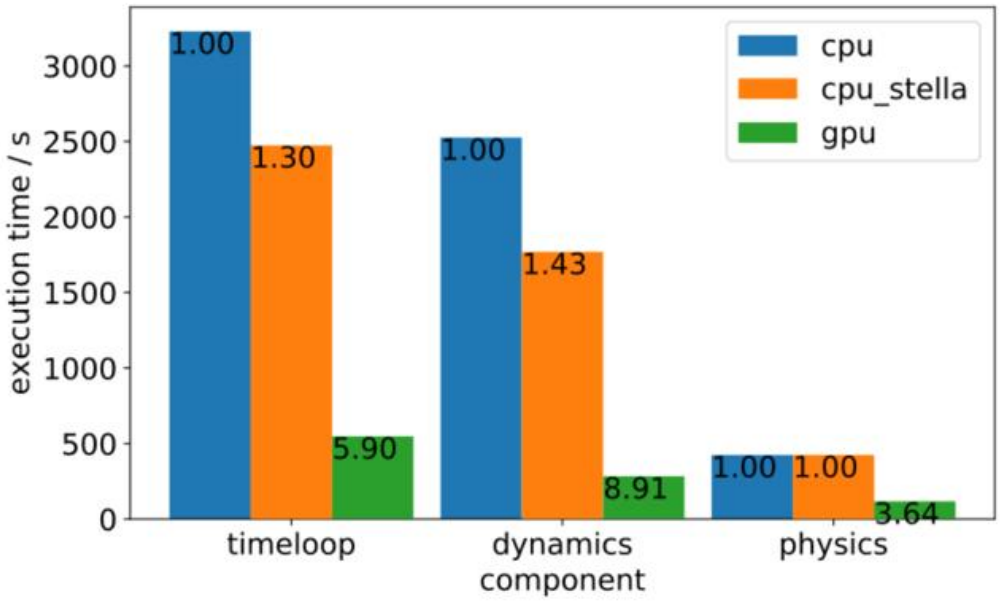

Figure 3: Performance comparison of a COSMO-1 6h benchmark on Piz Daint supercomputer. The CPU benchmark is run on 32 Intel Haswell (12 cores - Xeon E5-2690 v3) CPUs while the GPU is run using 32 P100 Nvidia cards. The speedup as compared to the reference Fortran code (i.e. without the DSL dynamics) is given inside the bars. The code used is COSMO 5.6 release-candidate.

In parallel to the GPU port, the physical parametrizations have been restructured to be shared with the ICON model using a block format (Task 6). This can in principle improve performance on CPU since it could increase cache reuse between the different parametrizations. This gain is however counterbalanced by the fact that one needs to copy the input and output data from the original ijk COSMO data structure to the block format. This change has a neutral effect on performance, but allows to share physics between the ICON and COSMO model.

The COSMO code was furthermore adapted to run using single precision floating point number (Task 8), in addition to double precision. A detailed description of the required adaptation can be found in [Rudisuhli 2014]. This provides an additional performance improvement ranging from a speed up factor of 1.2x to 1.3x depending on the architecture.

Finally, although the C++ dynamical core is making use of OpenMP parallelization on CPU, the rest of the code also had to be ported to OpenMP (Task 3). As compared to a flat MPI parallelization, introducing threading using OpenMP in the Fortran part did not lead to significant performance improvements. Unless more aggressive optimizations such as blocking would be introduced in the Fortran code (which would significantly reduce the maintainability and readability of the code), it was to be expected that a memory bandwidth bound code would not yield significant performance improvements. As a consequence, the changes introduced for hybrid MPI+OpenMP parallelism were not prioritized high enough to be introduced into the official version of the COSMO code.

3 Applications of the GPU and single precision capability

The COSMO model is run operationally at MeteoSwiss on GPU-based hardware and in single precision since 2016. The high performance computing system employs a fat-node design with multiple GPUs per CPU socket. From the operational point of view the use of a GPU system did not bring new issues, and the system is running stably as compared to the previous CPU only operational system. Currently, the system is being upgraded by a system with a similar fat node design but latest-generation hardware. The COSMO-LEPS ensemble forecast run at ECMWF is running in single precision, the performance gain associated with switching from single precision to double precision has enabled to run more ensemble members. Several groups at ETH Zurich are running the COSMO model on GPUs for climate applications on the Piz Daint supercomputer. This allowed researchers to run high-resolution (2-km) simulations on continental scale domain [Leutwyler 2016]

4 Lessons learned and outlook

With the advent of GPU-accelerated systems, the days where vendors would port applications to a specific hardware architecture within the framework of a procurement benchmark are over and the load of maintaining a code base that is ready to run on different hardware architectures has been shifted to the code maintainers and developers. Since hardware architectures are evolving rapidly and the lifetime of a supercomputer typically is between 3-6 years, this requires a tight collaboration with institutions and individuals who have an in-depth understanding of and outlook on developments in the HPC hardware sector.

As a side effect of this project the development infrastructure of COSMO has been greatly improved. The GPU as well as single/double precision capability of the model have increased the maintenance complexity, such that manual testing is not an option anymore. The Jenkins continuous integration platform is now being used to automatically test the main source code as well as development branches on all supported hardware architectures and floating point precision using the COSMO technical testsuite. The code is now hosted on the development infrastructure github which provides a modern interface for software development and in particular allows for online code reviews. Without these tools, the project could not have been such a success, and this type of infrastructure and workflow should be used in the future in the COMO community.

For the port to GPUs different technologies have been used. The OpenACC compiler directives have proven to be very efficient for incrementally porting large existing code bases. It also has the advantage of being moderately intrusive, as compared to a full re-write, and is well accepted by the developer community. On the other hand, adding directives to an existing legacy code make the code much harder to maintain. Indeed, several targets need now to be supported but the Fortran code does not provide component or unit testing functionality such that bugs introduced with changes or associated to a new compiler version require considerable amount of time to be identified. Further, the OpenACC programming model has proven not to be very robust, with the few compilers that support it introducing regressions when new versions come out. Cray has decided to drop support for OpenACC in the future and thus currently the only compiler supporting OpenACC is the PGI compiler owned by NVIDIA. An alternative implementation of OpenACC exists in GCC, but is not in a state that can be used for production. For some components, optimizations for GPU have adverse effects on CPU performance such that either the CPU performance has been given priority, or separate code for GPU has been introduced using ifdef pre-processor macro.

For the most critical component ported with OpenACC a source-to-source translation tool CLAW [Clement 2018], doing automatic code transformation, has been also used.

The STELLA DSL approach has proven successful to achieve performance portability. However, the project has shown that acceptance of this new technology by the end user (dycore developer) is very limited. In fact, there are currently two versions of the COSMO dynamical core in the official code, namely the Fortran and the DSL version. One possible reason for this is that the resulting C++ code is rather complex to handle for someone used to pure Fortran code. In addition, because of time constraints on both the DSL developer and end dycore user the exchange while developing the library was very limited, such that the final product did not meet the expectation of the end user. For a future project we recommend more focus and the usability of such a DSL approach as well as a better integration between the DSL developers and the end-users.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

For any comments and questions, please contact the editor:

1 Preface

This Technical Report describes a new implementation of the computation of radar reflectivity values on the native model grid points, which will soon become available in the COSMO-Model together with the new Efficient Modular VOlume scanning RADar forward Operator (EMVORADO).

While the abovementioned computation of grid point reflectivities is one of several processing steps within the EMVORADO, it can also be used on its own, without the "full" EMVORADO-simulation of polar volumetric radar data. In that sense, it is a replacement for the presently very simple Rayleigh-type 'DBZ' computation available in the COSMO module `pp_utilities.f90`, which is currently used for output diagnosis in the COSMO `GRIBOUT`-namelist(s). Well, "replacement" is not entirely correct, because the present method will still be available as one of several options. The new options are the more accurate (and more expensive) Mie-scattering, but also two new variants of Rayleigh-type approximations of different complexity and cost, which differ from the current simple one mainly by a better treatment of partially melted particles (the famous radar "bright band").

The present report is restricted to this "stand-alone" aspect. It covers the theoretical aspects of the unattenuated equivalent radar reflectivity factor (loosely called "reflectivity"), including the refractive index of hydrometeors, which is the basic material parameter, which determines the interaction with electromagnetic radiation. The latter possesses various possible and uncertain definitions for the ice-water-air-mixture of partially melted particles. Moreover, details of the implementation of these aspects into the new libraries `radar_mielib_vec.f90` and `radar_mie_lm_vec.f90` are described, before the report concludes with an exhaustive sensitivity study on the various (and uncertain!) choosable options for the backscattering cross section of partially melted particles.

Although developed in the framework of the COSMO-model, the new libraries can in principle be coupled to any other NWP model.

I have written most contents of this report alongside the code development during my Post-Doc time at the Institute of Meteorology and Climate Research, Tropospheric Branch (IMK-TRO), Karlsruhe Institute of Technology (KIT) in Germany. This work started in early 2005, when I first came into contact with numerical modeling and the COSMO-model, and was largely finished by 2010 when I started at Deutscher Wetterdienst. In 2005, the model still had its traditional name "Lokalmodell" LM, and I preserved this acronym at many places in the code in order to not forget the roots.

Later, together with Yuefei Zeng and Dorit Jerger (PhD-projects with financial support through DWD's Extramural Reserach Programme) as well as our mentor Klaus-Dieter Beheng from IMK-TRO, we built the full EMVORADO-framework on top. But this is a different story.

Ulrich Blahak

2 Introduction

The program package `radar_mielib` provides Fortran-90 routines for the calculation of gridbox values of the equivalent radar reflectivity factor from model output based on Mie-scattering functions as well as Rayleigh approximation. Water drops and a variety of different kinds of dry and melting ice particles are considered (graupel, snow, cloud ice, hail).

Whereas `radar_mielib` contains quite general subroutines, the library `radar_mie_lm` provides the necessary interface routines to use them with the Lokalmodell (LM) of the German Weather Service (DWD) together with the two-moment bulk microphysical scheme of Seifert and Beheng (2006) or the standard one-moment bulk microphysical schemes.

Note that in calculating gridbox values, propagation effects (extinction) and the spatial averaging properties (beam function) of radar systems are not considered. The neglect of attenuation confines the applicability of the calculated reflectivity values to quantitative comparisons at radar wavelengths with negligible attenuation only, e.g., S-band, or to situations or research questions where attenuation is not of primary importance. At shorter wavelengths (C-band, X-band) those effects have to be kept in mind when comparing with real radar data. The shorter the wavelength the stronger is attenuation. However, calculation of the extinction cross section is contained in the basic scattering routines in `radar_mielib`, but is not used further by routines in `radar_mielib` and `radar_mie_lm` which build upon them. Only a full radar forward operator, considering true ray paths from the antenna through the atmosphere, could make use of this information.

Special emphasis is given to the description of melting ice particles. It is well known, however, that this is a highly underdetermined problem, since, on one hand, the particles shapes are different from spherical and, on the other hand, the effective refractive index of the particle material (mixture of ice, water, and air) is very sensitive to the type and topology of mixture and the particles bulk density. Moreover, there is no absolutely precise theoretical description of the effective refractive index of such complex mixtures like in snow- and graupel particles — consequently, a large number of formulas for different applications are on the market.

In `radar_mielib`, the problem is tackled by providing routines for 3 different mixing formulas for the refractive index (Maxwell-Garnett, Wiener, Bruggemann), whereas only spherical shapes are considered. In case of Mie-scattering, also a concentric two-layer-sphere particle model is implemented, which can be used for, e.g., snowflakes and melting hail- and graupel particles. Moreover, different melting topologies are considered, e.g., accumulation of meltwater on the outside or fully soaked particles, melting taking place only on the outside or partly within the ice structure. Combining the tools leaves one with an infinite number of possibilities to describe a melting particle. Especially the Maxwell-Garnett mixing rule allows 15 different refractive index values for a single set of ice-water-air volume fractions. From this it can clearly be seen that there is a large natural variability, which has to be considered when comparing calculated with measured radar reflectivities. Sensitivity studies with the help of the tools from `radar_mielib` at least provide a lower bound for this high variability.

In the following sections, the tools of `radar_mielib` are described in detail. To facilitate their proper use, calculated backscatter coefficients for different types of melting particles (snow, graupel and hail) as a function of the degree of melting and particle mass are presented, considering about 800 different combinations of particle types and mixing rules. The different particle types are taken from the cloud microphysical schemes of the COSMO-model (formerly "Lokalmodell" (LM) of the German Weather Service (DWD) — the standard 1-moment scheme as well as the 2-moment scheme of Seifert and Beheng (2006).

3 Factors contributing to the radar "bright band"

There are different (and sometimes competing) factors contributing to the observed radar bright band:

- Backscattering of single melting particles is enhanced in the presence of meltwater.
- Thinning of the number densitiy (number of particles per volume of air) by increasing fall speed with increasing degree of melting reduces backscattering.
- Upper part of the melting layer: particle breakup is dominant.
  Lower part: particle coalescence is dominant.

It should be emphasized that the backscattering enhancement of single melting particles treatable by the routines in `radar_mielib` is only one of several processes contributing to the observed radar bright band. Therefore, the results presented later in Section 8 about backscattering cross sections of single particles as function of the degree of melting attribute only to this part of the reflectivity maximum.

4 Theoretical basis

In this section formulas are collected to calculate the unattenuated equivalent radar reflectivity factor Z_e from model output which are implemented in `radar_mielib`. To simulate a real radar measurement, also attenuation, beam propagation and the beam smoothing function would have to be included, which is omitted here.

4.1 Equivalent radar reflectivity factor

Consider the assumption of incoherent single scattering beeing the dominant effect in radar backscattering. Then, the equivalent radar reflectivity factor is commonly defined as

$$Z_e \;=\; \frac{\lambda_0^4}{\pi^5\;|K_{w,0}|^2}\;\int\limits_0^\infty \sigma_b(D)\,N(D)\,dD \quad , \tag{1}$$

where λ_0 is the radar wavelength, $N(D)$ the particle size distribution as a function of the (spherical) particle diameter D, and σ_b denotes the backscattering cross section of a particle having diameter D. $|K_{w,0}|$ is a reference value of the dielectric factor used in the radar software, usually taken as 0.93 (water, $T = 0°$C, $lambda_0 \approx 5 - 10$ cm). $N(D)$ depends also on time and location, but the explicit dependence is omitted for brevity.

Z_e would be output by a radar in case of a homogeneous spatial hydrometeor distribution across the range cell and no attenuation on the path to the cell. Written in the above notation, it is implicitly assumed that there is a unique relation between size (D) and $\sigma_b(D)$ as it is the case for water drops to a good degree of approximation. Taking into account also ice particles complicates the description, since then, this uniqueness breaks down and we have to extend the dependencies of N and σ to particle shape and particle effective refractive index ($\sigma_b(\text{shape}, D, \lambda_0, m)$).

As a compromise, one might define different types of ice hydrometeors (e.g., graupel, snow, hail) in a way that for these subtypes, a unique relation of σ and D exists. Then, Z_e is the sum of the contribution of each hydrometeor type. In fact, current microphysical descriptions in numerical weather prediction models classify ice hydrometeors in different types in a way to also let σ only depend on D.

As an example, the procedure to calculate Z_e from the output of a two-moment bulk microphysical scheme is as follows:

- $f(D)$: assume certain master function for $N(D)$, e.g., a four-parametric generalized gamma distribution. 2 free parameters are then deduced from the model predicted two moments (e.g., hydrometeor number- and mass density), and the other two parameters have to be fixed.
- Hydrometeors are a mixture of ice, air and water.
  - Choose appropriate formula to calculate m as a function of T, λ, material, density and the degree of melting f_{melt}. For this, several state-of-the-art effective medium approximations could be used, but this is always a delicate choice. A huge uncertainty and variability has to be expected there.
  - If the microphysics scheme does not predict f_{melt}, it has to be estimated from whatever information is available (temperature, particle size, etc.). This is a particularly difficult thing especially if there is no information about the particles history. Temperature and ventilation factors along backwards trajectories would be desireable for this task but are very costly to determine.
- σ_b: apply Mie-scattering (one- or twolayered sphere) or Rayleigh-Approximation to calculate σ_b.
- $Z_e = \sum$ (all hydrometeor categories)

For the LM, these tasks are accomplished by interface subroutines in the library `radar_mie_lm`, building on the more general tools provided by `radar_mielib`.

4.2 Extinction

For completeness, the formula for the twoway attenuation coefficient k_2 is given here:

$$k_2 \;=\; \frac{20}{\ln 10} \int_0^\infty \sigma_{ext}(D)\, N(D)\, dD \quad . \tag{2}$$

σ_{ext} is the extinction cross section, depending on D as well as λ_0. Applying Lambert-Beer's extinction law, integration of k_2 along the radar beam yields the attenuation factor. Again, there are issues about beam smoothing and propagation path which render an accurate calculation from model data very difficult and costly (apart from considering different hydrometeor types).

The calculation of σ_{ext} is implemented in all basic scattering subroutines but is not used further up to now (2008). This could however be extended by users who whish to develop, e.g., a complete radar simulator including propagation effects.

4.3 Backscattering and extinction by spheres

Consider a plane parallel electromagnetic wave incident on a spherical object with refractive index m (complex) different to that of the surrounding medium, m_0 (real, no extinction). The Mie-solution of maxwells equations at a large distance from the scatterer leads to the formula for σ_b,

$$\sigma_b \;=\; \frac{4\,\pi}{k^2} \left| \sum_{n=1}^{\infty} (-1)^n \left(n + \frac{1}{2}\right) (a_n \,-\, b_n) \right|^2 \quad . \tag{3}$$

a_n und b_n are the socalled Mie scattering coefficients of order n which depend only on the Mie-parameter $\alpha = \pi\lambda_0 m_0/D$ and the relative refractive index m/m_0 of the particle

material. They in turn involve spherical bessel functions of the arguments α and $\alpha m/m_0$ and are omitted here.

As an alternative, a_n and b_n can be efficiently calculated by recurrence formulas derived by, e.g., Deirmendjian (1969) or Bohren and Huffman (1983). These formulas themselves build on recurrence relations for the involved spherical bessel functions. The subroutine `SPHERE_SCATTER_BH()` of `radar_mielib` makes use of these relations.

A further simplification is the so called **Rayleigh-approximation** for particles having D small compared to λ_0. Series expansions of a_n and b_n in equation (3) and retention of only the leading term yield the approximation

$$\sigma_b \;=\; \frac{\pi^5}{\lambda_0^4}\left|\frac{m^2-1}{m^2+2}\right|^2 D^6 \;=\; \frac{\pi^5}{\lambda_0^4}\,|K|^2\;D^6 \qquad \text{with}\;\; \frac{m^2-1}{m^2+2} \;=\; K \tag{4}$$

where m_0 is set to 1 (air), so m/m_0 reduces to just m. K is called the dielectric factor. The Validity of the approximation depends on the Mie parameter and m/m_0. Generally, larger m/m_0 yield a more restrictive size criterion. For water spheres a comparison of exact formula and approximation yields $D < \lambda_0/20$, for ice spheres $D < \lambda_0/5$. Bohren and Huffman (1983) formulate the condition as $|m/m_0|\,\pi D_k/\lambda_0 \ll 1$.

When the particles are very small compared with the wavelength, the Rayleigh-approximation is also valid for nonspherical particles. The smaller the particle the less important is its shape. D has then to be taken as the diameter of the volume equivalent sphere.

In case of $m = \text{const.}$ (e.g., for water drops or dry ice spheres) and application of the Rayleigh approximation for σ_b, Z_e is simply given by the 6. moment of the size distribution $N(D)$,

$$Z_e \;=\; \frac{|K_w|^2}{|K_{w,0}|^2}\int\limits_0^\infty D^6\,N(D)\,dD \quad , \tag{5}$$

where water drops have been assumed in the formula without loss of generality. Z_e is equivalent to the 6. Moment of the size distribution of (hypothetically) measured water drops, which explaines the name "equivalent reflectivity factor". In cases of $N(D)$ beeing a certain type of function (e.g., a generalized gamma distribution), the integral in (5) can be solved analytically, involving gamma functions.

The extinction coefficient σ_{ext} for spherical particles is given by

$$\sigma_{ext} \;=\; \frac{4\,\pi}{k^2}\,\Re\left\{\sum_{n=1}^{\infty}\left(n+\frac{1}{2}\right)\,(a_n\,+\,b_n)\right\} \quad . \tag{6}$$

A similar approximation as in equation (4) yields

$$\sigma_{ext} \;=\; \frac{\pi^2}{\lambda_0}\Im\{-K\}\;D^3 \;+\; \frac{2}{3}\,\frac{\pi^5}{\lambda_0^4}\,|K|^2\;D^6 \quad , \tag{7}$$

with K having the same meaning as in equation (4). Two terms have been retained here since they might be of same order in certain situations. The first term describes the losses by absorption, second term the losses by scattering in all directions.

In case of a small water drop σ_{ext} is dominated by the absorption term (example with subscript $_w$ for water: $\lambda_0 = 1$ cm, $m_w = 4.97 - 2.79i$ (10°C) after Ray (1972), $|K_w|^2 = 0.91$, $\Im\{-K\} = 0.07$, $D = 0.1$ mm $\Rightarrow$ absorption term $= 7 \cdot 10^{-11}$ m^2, scattering term $= 3 \cdot 10^{-14}$ m^2, geometrical cross section $= 8 \cdot 10^{-9}$ m^2. In case of small ice particles both

Figure 1: Convention for the refractive indices m_0, m_1, m_2 and for the radii r_1, r_2 in the calculation of the scattering functions for a two-layered sphere.

terms are important, since $\Im\{-K_i\} \ll |K_i|^2$ (subscript $_i$ for ice). Ice absorbs microwave radiation much less than water.

For water droplets in the microwave region, the approximation (7) is only valid for $D < \lambda_0/100$, whereas for ice spheres $D < \lambda_0/2$, which is by far less restrictive. The same rule of thumb as in the case of backscattering applies here as well: the larger $|m/m_0|$, the more restrictive is the size criterion on D. As soon as the particles contain water in any volume fraction, one should not calculate σ_{ext} by the above approximation, but with the exact formula (6).

4.4 Backscattering and extinction by two-layered spheres

Today, exact solutions to the scattering problem of N-layered spheres are available which reduce to the classical Mie-formula for a simple sphere. Since some hydrometeors like melting hail (ice core, spongy ice/water-shell) can be well approximated by a two-layered sphere, formulas for backscattering- and extinction cross sections for this configuration are included into `radar_mielib` as well.

As in the case of simple spheres, important parameters are the two Mie-parameters

$$\alpha_1 = \frac{2\,\pi\,r_1\,m_0}{\lambda_0} \quad ; \qquad \alpha_2 = \frac{2\,\pi\,r_2\,m_0}{\lambda_0} \quad . \tag{8}$$

defined by the shell and core radii r_1 and r_2, resp., as well as the corresponding relative refractive indices m_1 and m_2 (see Figure 1).

Depending on these parameters, the scattering coefficients a_n and b_n can be calculated analytically and then plugged into equation (3) and (6). To this end, formulas for a_n and b_n given by, e.g., Kerker (1969) are implemented into `radar_mielib` (subroutine `COATEDSPHERE_SCATTER()`) or, as a second alternative, an efficient subroutine making advantage of the recurrence relations for the spherical Bessel and Hankel functions given in the appendix of Bohren and Huffman (1983) is provided (subroutine `COATEDSPHERE_SCATTER_BH()`). The rather long and cumbersome formulas for a_n and b_n are omitted here. We refer the reader to the cited literature.

Note that numerical instabilities in calculating Bessel-functions by utilizing efficient recurrence relations (as is done here) are known to be problematic in case of large arguments to the Bessel functions. In the `radar_mielib`-subroutine `COATEDSPHERE_SCATTER()`, backward recurrence for the Bessel- and Hankel functions (programs taken from Zhang and Jin, 1996) are utilized, which is more stable than the forward recurrence implemented into subroutine `COATEDSPHERE_SCATTER_BH()`. However, `COATEDSPHERE_SCATTER()` is slower than `COATEDSPHERE_SCATTER_BH()`. Application of these routines to hydrometeor scattering in the microwave region should not be problematic, so both routines can be used.

4.5 Refractive index of hydrometeors

Up to this point, general formulas for the computation of the backscatter- and extinction cross section of spherical particles were given. An important parameter herein is the complex refractive index of the particle material $m = m' + im''$ (m_1, m_2 for the two-layered

sphere), which will be presented in the next sections. m is connnected to the relative dielectric constant $\epsilon = \epsilon' + i\epsilon''$ by the relation $\epsilon = m^2$. Note that in this paper the convection with negative imaginary part of m and ϵ is used which corresponds to a timefactor $\exp(i\omega t)$ in the description of electromagnetic waves. Under the assumption $\epsilon'' < 0$, $m'' < 0$ the following conversion formulas apply:

$$\epsilon' = m'^2 - m''^2 \tag{9}$$

$$\epsilon'' = 2\, m'\, m'' \tag{10}$$

$$m' = \sqrt{\frac{\sqrt{\epsilon'^2 + \epsilon''^2} + \epsilon'}{2}} \tag{11}$$

$$m'' = -\sqrt{\frac{\sqrt{\epsilon'^2 + \epsilon''^2} - \epsilon'}{2}} \quad . \tag{12}$$

The last two equations define the principal arm of the complex root function, as it is implemented also in most programming languages.

Hydrometeors consist of air, ice and/or water, so values of m for these materials are needed. For air, $m = 1$ is a very good approximation. For ice and water, m basically depends on wavelength and temperature. With these values, pure water and ice particles can be treated. These are given in subsubsection 4.5.1 and 4.5.2.

Things get by far more complicated in the case of dry snow particles (mixture of ice and air) or melting snow particles (mixture of ice, air and water). Here the task is to find an effective value m_{eff}, which leads to the same scattering functions when applied in the Mie-formulae that are observed for the mixture particle, whose scattering pattern highly depends on the topology of the mixture. This is a very difficult task, and consequently, there are a lot of mixing formulas on the market applicable to certain special situations. A general solution to the problem seems to be not existent. Moreover, mixing rules applicable for backscattering might not be applicable for extinction and vice versa (e.g., for granular mixtures with spatially inhomogeneous material distribution), since it is sometimes not possible to describe the directional scattering by a single value of m_{eff}.

In subsubsection 4.5.4 to subsubsection 4.5.6, some mixing formulas are presented which are currently used by the radar meteorological community for the mixture topologies encountered in dry and melting hydrometeors.

4.5.1 Water

Two models (formulas) for the complex index of refraction of water, m_w, are implemented into `radar_mielib` as functions. They give m_w as a function of wavelength λ_0 and temperature T. The first is the model of Ray (1972), which is applicable to the temperature range from -10°C to 30°C and to the wavelength range of about 1 mm to 1 m. Figure 2 depicts the real and imaginary parts of m_w for this model as a function of λ_0 and T. One clearly sees the anomaleous dispersion signal connected to a classical Debye relaxation mode in the microwave region. With higher frequency (shorter wavelength) the real part drops down reflecting an increase in propagation phase speed, whereas in the same frequency range, the imaginary part has a distinct maximum, reflecting strong absorption. The complete formulas of Ray (1972) also contain several rotational and absorption bands in the infrared region, parameterized as gaussian peaks, but this is omitted in the `radar_mielib` function. Only the formulas (5) and (6) of Ray (1972) are used, which limits the applicability to the microwave region.

Another model is given by Liebe et al. (1991) with a slightly different application range, namely 300 μm $< \lambda_0 <$ 0.3 m and -3°C $< T <$ 30°C. Figure 3 shows the real and imaginary parts of m_w for this model. The prominent Debye relaxation mode is also present here, as it should.

A comparison of both models can be found in Figure 4 for a temperature of 25°C, together with a model based on measurements of Segelstein (1981). The latter is only available for the temperature of 25°C. Nearly no differences between these descriptions are visible the wavelength range 5 mm to 20 cm, so all descriptions equally can be used in the microwave region, all giving similar results. Looking at other temperatures, nearly no differences between Rays and Liebes model can be found for the wavelength range 1 cm to 10 cm. At larger wavelength, the imaginary part is larger for Rays model, whereas at shorter wavelengths, the opposite is found. Liebes model should be used for $\lambda_0 <$ 1 cm, whereas both models are applicable from 1 cm to 10 cm, and Rays model is better from 10 cm to 1 m.

4.5.2 Ice

For the complex refractive index of ice, m_i, three models are available in `radar_mielib`. The first is again a model of Ray (1972), from the same paper as previously the model for water. The corresponding real and imaginary parts of m_i are depicted in Figure 5 as functions of λ_o and T. The range of validity is given by the author to be 0.001 m $< \lambda_0 <$ 10^7 m and -20°C $< T <$ 0°C. Ray (1972) deduced it from then available measurements from the literature, but not fulfilling the Kramers-Kronig-relations (see, e.g., Bohren and Huffman, 1983), as criticized, e.g., by Warren (1984). The use of this model is therefore not recommended.

As a second and better model, the descrete m_i-tables given by Warren (1984) are implemented, as shown in Figure 6. The author critically and carefully reviewed the existing measurements in literature, combined with own measurements to deduce his lookup tables. Here the Kramers-Kronig-relations are fulfilled. Values of m_i at intermediate values of λ_0 and T are linearily interpolated. In the original paper, the range of validity is given as 45 nm $< \lambda_0 <$ 8.6 m and -60°C $< T <$ 0°C.

Third, the formula of Mätzler (1998) is available (see Figure 7). The author gives the range of validity as 0.1 mm $< \lambda_0 <$ 30 m and -250°C $< T <$ 0°C.

Can't show picture #8 because `tr28_ub2-pics.pdf` not found. Create it from `tr28_ub2.dvi` using `dvips` and `ps2pdf`!

Can't show picture #9 because `tr28_ub2-pics.pdf` not found. Create it from `tr28_ub2.dvi` using `dvips` and `ps2pdf`!

Figure 8: Comparison of the complex refractive index of ice as function of wavelength in m at temperatures of -2°C (solid lines) and -20°C (dashed lines) for 3 different formulations. **Upper panel:** real part. **Lower panel:** imaginary part. **Black:** Ray (1972), **blue:** Warren (1984), **red:** Mätzler (1998).

While very similar for the real part of m_i, it can be seen from Figure 8 that especially the model of Ray (1972) predicts a totally different behaviour of the imaginary part of m_i with wavelength than the other two models. Here, the models of Warren (1984) and Mätzler (1998) are in qualitative agreement, but Mätzler (1998) gives lower values of the imaginary part up to a factor of 8 compared to Warren (1984). The author of this document feels not to be in a position to recommend using one or the other, but using the model of Ray (1972) is not recommended because of the abovementioned reasons.

4.5.3 Mixtures of ice, air and water

In literature, many different formulations of the refractive index of a mixture material are presented termed "Effective Medium Approximations" (EMA). Mostly they have their origin in the field of physical chemistry. It is a very old concept dating back to the late 19th century but nevertheless still an actual topic in research. In the meteorological community dealing with radar measurements, mostly three formulations are used which are also part of `radar_mielib`. These will be introduced in the following subsections.

The general problem is to find an effective value for the refractive index m_{eff} of a mixture material leading to the same scattering pattern when replacing the actual mixture particle by a homogeneous particle and measuring/ calculating the scattering functions by some theory using m_{eff}. Many theoretical and experimental attempts can be found in literature, but we cannot go into detail here. A starting point for further study could be the book of Bohren and Huffman (1983) or the article of shortciteNstroud1978.

It is immediately clear that such a technique inevitably gets complicated or leads to errors when applying it to particles which are not truly homogeneously mixed (mixture may have a macroscale topography) and/or when at least one of the mixture components is a strong dielectric like water. Some EMAs may be valid only for extinction or scattering in a certain direction depending on the method of their derivation.

4.5.4 Mixtures of ice, air and water — Wieners formula

Otto Wiener (1912) presented a quite general theory for a homogeneous mixture of inclusions (grains, fibres, layers, etc.) of N materials which are embedded in a homogeneous background medium with dielectric constant ϵ_0. In case of spherical inclusions, he states

$$\frac{\epsilon_{eff} - \epsilon_0}{\epsilon_{eff} + f\,\epsilon_0} \;=\; \sum_{j=1}^{N} p_j \, \frac{\epsilon_j - \epsilon_0}{\epsilon_j + f\,\epsilon_0} \quad . \tag{13}$$

p_j denotes the relative volume fraction of the species j on the overall particle volume,

$$p_j \;=\; \frac{V_j}{V_m}, \quad \text{where} \;\; V_m \;= \text{Volume of mixture particle} \tag{14}$$

and ϵ_j is its dielectric constant. **Note that in fact N+1 materials are contained in the mixture!** The parameter f in general depends on the shape, orientation, mutual distance and alignment within the mixture body. Let us denote the partial volume fraction of the background medium with p_0 and the partial volume by V_0, then it is

$$p_0 + \sum_{j=1}^{N} p_j \;=\; 1 \qquad \text{and} \qquad V_0 + \sum_{j=1}^{N} V_j \;=\; V_m \tag{15}$$

A good review of the original paper by Wiener is given by Lichtenecker (1926).

Formula (13) was derived under the assumption of a mixture of equally shaped and equally sized inclusions of N species into the background medium. In order to be applicable, one has to specify a value for the parameter f. Wiener (1912) showed that this can be accomplished under the following constraints:

- All inclusions have to be sufficiently separated so that the electromagnetic field inbetween can be regarded as homogeneous. This implies $p_0 > 0$ (in fact $p_0 \gg p_1, p_2$) so that the condition of large grain separation distances can be fullfilled.
- ϵ_0 has to be either the largest or the smallest value of all ϵ_x involved and it has to be significantly different to the adjacent ϵ_x.
- Isotropic distribution of the grains within the matrix medium.

Under these circumstances the parameter f depends largely only on the shape of the inclusions and attains the value 2 for spherical inclusions (Wiener then denotes f by "Formzahl" — shape number). A more detailed discussion of these constraints can be found in the original literature. However, since the classical derivations were done for real ϵ_x, it remains somehow unclear how to formulate these constraints for complex ϵ_x.

Often a seemingly similar formula is used by the radarmeteorological community in a way to set $\epsilon_0 = 1$ (vacuum, air) (see e.g., the review article by Oguchi (1983)) and at the same time assuming that there is no contribution of the background medium to the particles volume ($p_0 = 0$). The formula then reduces to an older formula (Lorenz-Lorentz, Clausius, Mosotti et others, see, e.g., Wiener, 1912 or Lichtenecker, 1926),

$$\frac{\epsilon_{eff} - 1}{\epsilon_{eff} + u} = \sum_{j=1}^{N} p_j \frac{\epsilon_j - 1}{\epsilon_j + u} \tag{16}$$

$$\sum_{j=1}^{N} p_j = 1 \quad .$$

In the following, formula (16) is referred to as Oguchis[1] formula. Oguchi (1983) designates the parameter u as shape parameter, similar to f in equation (13), and states that in case of spherical inclusions u attains the value 2.

The problem with this formula is that in neglecting the partial volume of the background medium, the assumption of mutual "large enough" distances between the inclusions is violated and the formula seems not to be applicable in general. Debye (1929) therefore restricts the formula to weak dielectrics and to the case of molecular mixtures which he regards as suspended spheres (single atoms) in vacuum (same argumentation in Bohren and Huffman (1983)). It is clearly not applicable to a melting ice particle with low air contribution since water is a strong dielectric. This was also found experimentally by Joss and Aufdermaur (1965).

However, when the background medium within the particle is air ($\epsilon_0 = 1$) with a considerable volume fraction and the particle is a mixture of ice and air (dry snow flake, graupel), the formula might be applicable since ice is a weak dielectric. The mixing term containing the air volume in (16) then vanishes and a "classical" formula used by radar meteorologists for many years (e.g., Battan, 1973) is recovered (also by appropiately using formula (13), which corroborates the validity of (16) for this special case).

[1]Oguchi (1983) wrongly attributes equation (16) to Otto Wiener, whereas the latter showed in his 1912 paper, why and under what circumstances this formula is not applicable. Wiener derived equation (13) instead, among formulas for other mixing topologies.

4.5.5 Mixtures of ice, air and water — Maxwell-Garnetts formula

Maxwell-Garnetts formula (Maxwell Garnett, 1904) is a special case of a more general formulation, see Stroud (1975), in the limiting case of small spherical inclusions of random size suspended in a background medium ("matrix"), similar as is the Wiener-formula, except for the random size. (In fact, it will be shown later in this section to be exactly equal to Wieners formula in case of spherical inclusions.)

Bohren and Huffman (1983) derive the following formulation similar to the original paper of Maxwell Garnett (1904)

$$\epsilon_{eff} = \frac{p_1 \epsilon_1 + \sum_{j=2}^{N} p_j \beta_j \epsilon_j}{p_1 - \sum_{j=2}^{N} p_j \beta_j} \tag{17}$$

$$\beta_j = \frac{3\epsilon_1}{\epsilon_j + 2\epsilon_1} \quad , \tag{18}$$

where p_j denotes again the relative volume fraction of the species j on the overall particle volume,

$$p_j = \frac{V_j}{V_m}, \quad \text{where } V_m = \text{Volume of mixture particle} \tag{19}$$

and ϵ_j is its dielectric constant. It is

$$\sum_{j=1}^{N} p_j = 1 \quad .$$

in this case. Here, index 1 corresponds to the matrix medium and indices larger than 1 denote inclusion materials.

Bohren and Battan (1982) extended this model to spheroidal inclusions, which have random size, which are randomly oriented within the matrix medium and which have random principal axes ratios (shapes). For this, only the coefficients β_j have to be replaced by

$$\beta_j = \frac{2\epsilon_1}{\epsilon_j - \epsilon_1} \left(\frac{\epsilon_j}{\epsilon_j - \epsilon_1} \ln\left(\frac{\epsilon_j}{\epsilon_1}\right) - 1 \right) \quad . \tag{20}$$

The complex logarithm denotes the principal arm. Note that this formulation is not invariant to a change in the matrix-species, but it is invariant to interchange the inclusions.

In case of a three-component mixture (as is the case with melting snow and graupel particles), formula (17) leads to numerous possibilities to specify matrix and inclusions. There are 3 possibilities to specify one material as matrix and the other two as inclusions. 12 additional possibilities arise by a two-fold application of a two-component mixture: one material is regarded as the matrix (3 possibilities), whereas the inclusion itself is regarded as a two-component mixture with 2 possibilities to specify matrix and inclusion. This leads to 6 possibilities. Changing further the roles of matrix and inclusion for the hosting material and the two-component sub-mixture, another 6 possibilities arise. Every possibility leads to different results. The degree of freedom (and the uncertainty about what to do) is therefore very large. In addition spherical and spheroidal inclusions can be discriminated, further doubling the number of possible choices.

An interesting comparison to the Wiener-formula can be made in rewriting equation (17) for spherical inclusions (β_j with equation (4.5.5)). After some manipulation,

$$\frac{\epsilon_{eff} - \epsilon_1}{\epsilon_{eff} + 2\epsilon_1} = \sum_{j=2}^{N} p_j \frac{\epsilon_j - \epsilon_1}{\epsilon_j + 2\epsilon_1} \quad . \tag{21}$$

Changing the index convention to Wieners formula ($1 \to 0$, $N \to N-1$) leads to the formula

$$\frac{\epsilon_{eff} - \epsilon_0}{\epsilon_{eff} + 2\epsilon_0} = \sum_{j=1}^{N} p_j \frac{\epsilon_j - \epsilon_0}{\epsilon_j + 2\epsilon_0} \quad . \tag{22}$$

Now the species 1 to N are the inclusions and the species 0 is the matrix. Comparing to equation (13) with $f = 2$ (spherical inclusions), both formulas turn out to be exactly equal. Therefore, the same constraints concerning the applicability as for the Wiener-formula also apply to Maxwell-Garnetts fromula. In particular, in the case of $p_1 \to 0$, the matrix material vanishes and the Maxwell-Garnett formula might no longer be applicable. In this case, another formula might be better suited, which will be described in subsubsection 4.5.6. On the other hand, Wieners formula with $f = 2$ does not require the spherical inclusions to be all of equal size.
In recent studies, mainly the Maxwell-Garnett formulation with the assumption of randomly oriented and randomly shaped small spheroidal inclusions is preferred in the literature, but with different assumptions about matrix and inclusions.

4.5.6 Mixtures of ice, air and water — Bruggemann formula

Another limiting case of the more general formulation of Stroud (1975) is the formula given by Bruggemann (1935),

$$\sum_{j=1}^{N} p_j \frac{\epsilon_j - \epsilon_{eff}}{\epsilon_j + 2\epsilon_{eff}} = 0 \tag{23}$$

$$p_j = \frac{V_j}{V_m}, \quad \text{where } V_m = \text{Volume of mixture particle}$$

$$\sum_{j=1}^{N} p_j = 1 \quad .$$

It is applicable for a homogeneous mixture of subscale macroscopic granules of different materials (index j) in "dense packing" configuration without giving a special meaning to one of the component materials (Chýlek and Srivastava, 1983). In that sense, the mixing topology assumed for this formula might be regarded as the limiting case of vanishing matrix material (cf. end of subsubsection 4.5.5). It is based on an approximation of the Mie forward scattering function $S_1(0) = S_2(0)$ for the single granules in that only the leading term with coefficient a_1 in equation (3) is retained. The single granules therefore have to be very small compared to the wavelength. Formula (23) is invariant to interchanging the species, as is Oguchis formula (16).
The implicit equation (23) leads to the problem of finding the roots of a complex polynomial of order N in ϵ_{eff}. After the fundamental theorem of algebra there are exactly N complex roots. For $N \leq 3$ there exist analytical solutions ($N = 3$: Cardani's formula, e.g.), and for $N > 3$, these can be found, e.g., iteratively by Laguerre's method (Press et al., 2001).
However, only one of these roots has physical meaning and can be assigned to $m_{eff} = \sqrt{\epsilon_{eff}}$. Usually, the constraints of a negative imaginary part of ϵ_{eff} (by convention in `radar_mielib`) together with the real part of ϵ_{eff} beeing inbetween the range of real parts of the ϵ_j, the physical meaningful root ϵ_{eff} can be identified, at least for a three-component mixture of ice, air and water, as is needed for our purpose.

5 Routines in `radar_mielib`

To calculate Z_e by integration of equation (1) (Page 7), information about the particle size distribution and about the backscattering cross section σ_b as function of particle type, size and degree of melting is needed, which in turn requires information about the effective particle refractive index m_{eff}. The theoretical basics for σ_b (one- and two-layered Mie scattering, Rayleigh approximation) and m_{eff} were briefly discussed in earlier sections, and, in particular, different EMA approximations for m_{eff} were summarized. Up to now and in the remainder of this document, the particle size distributions itself are not treated in detail, since their proper treatment depends strongly on the application: for a bin microphysical scheme resolving explicitely the size distributions of different hydrometeor types, no assumptions have to be drawn about it, whereas for a bulk microphysical scheme, usually a parametric function prototype ("master function" approach) is chosen whose free parameters are diagnosed from model variables. Therefore, the main focus of this document is on the properties of single particles, whereas the integration over the entire size distribution is left for the user.

Before we turn to more detailed investigations of the differences caused by applying different combinations of EMA formulations and melting models for single particles (one-layered or two-layered spheres, different mixing material assumptions) in subsequent sections, a complete list of subroutines and functions from `radar_mielib` will be given in the following subsections providing tools for calculation of σ_b and m_{eff} of single particles.

Later in Section 6, the library `radar_mie_lm` is exemplified to show how these tools can be combined for reflectivity calculations in a mesoscale NWP-model. `radar_mie_lm` provides interface reflectivity calculation subroutines for the LM.

5.1 Refractive index of pure ice and water

5.1.1 `FUNCTION m_complex_water_ray (lambda, T)`

```
INTEGER, PARAMETER    :: kinddp = KIND(1.0d0)
COMPLEX(kind=kinddp)  :: m_complex_water_ray
DOUBLE PRECISION      :: T, lambda
```

Description:

Refractive index of water after Ray (1972), see subsubsection 4.5.1 on Page 12.
Valid for -10°C $< T <$ 30°C, 0.001 m $< \lambda_0 <$ 1 m.

Input parameters:

`kinddp`	kind parameter for double precision
`lambda`	radar wavelength in m
`T`	temperature in °C

Example:

```
mwater = m_complex_water_ray(0.055, 10.0)
```

5.1.2 FUNCTION m_complex_water_liebe (lambda, T)

```
INTEGER, PARAMETER    :: kinddp = KIND(1.0d0)
COMPLEX(kind=kinddp)  :: m_complex_water_liebe
DOUBLE PRECISION      :: T, lambda
```

Description:

Refractive index of water after Liebe et al. (1991), see subsubsection 4.5.1 on Page 12.
Valid for -3°C $< T <$ 30°C, 0.0003 m $< \lambda_0 <$ 0.3 m.

Input parameters:

`kinddp`	kind parameter for double precision
`lambda`	radar wavelength in m
`T`	temperature in °C

Example:

```
mwater = m_complex_water_liebe(0.055, 10.0)
```

5.1.3 FUNCTION m_complex_ice_ray (lambda, T)

```
INTEGER, PARAMETER    :: kinddp = KIND(1.0d0)
COMPLEX(kind=kinddp) :: m_complex_ice_ray
DOUBLE PRECISION      :: T, lambda
```

Description:

Refractive index of ice after Ray (1972), see subsubsection 4.5.2 on Page 13.
Valid for -20°C $< T <$ 0°C, 0.001 m $< \lambda_0 <$ 10^7m.

Input parameters:

`kinddp`	kind parameter for double precision
`lambda`	radar wavelength in m
`T`	temperature in °C

Example:

```
mice = m_complex_ice_ray(0.055, -10.0)
```

5.1.4 FUNCTION m_complex_ice_warren (lambda, T)

```
INTEGER, PARAMETER   :: kinddp = KIND(1.0d0)
COMPLEX(kind=kinddp) :: m_complex_ice_warren
DOUBLE PRECISION     :: T, lambda
```

Description:

Refractive index of ice after Warren (1984), see subsubsection 4.5.2 on Page 13.
Valid for -60°C $< T <$ 0°C, $45 \cdot 10^{-9}$ m $< \lambda_0 <$ 8.6 m.

Input parameters:

`kinddp`	kind parameter for double precision
`lambda`	radar wavelength in m
`T`	temperature in °C

Example:

```
mice = m_complex_ice_warren(0.055, -10.0)
```

5.1.5 FUNCTION m_complex_ice_maetzler (lambda, T)

```
INTEGER, PARAMETER    :: kinddp = KIND(1.0d0)
COMPLEX(kind=kinddp) :: m_complex_ice_maetzler
DOUBLE PRECISION      :: T, lambda
```

Description:

Refractive index of ice after Mätzler (1998), see subsubsection 4.5.2 on Page 13.
Valid for -250°C $< T <$ 0°C, 0.0001 m $< \lambda_0 <$ 30 m.

Input parameters:

`kinddp`	kind parameter for double precision
`lambda`	radar wavelength in m
`T`	temperature in °C

Example:

```
mice = m_complex_ice_maetzler(0.055, -10.0)
```

5.2 Refractive index of mixture materials

5.2.1 FUNCTION m_complex_oguchi (vol1, vol2, vol3, m1, m2, m3, fehler)

```
INTEGER, PARAMETER    :: kinddp = KIND(1.0d0)
COMPLEX(kind=kinddp) :: m_complex_oguchi
COMPLEX(kind=kinddp) :: m1, m2, m3
DOUBLE PRECISION      :: vol1, vol2, vol3
INTEGER, INTENT(out) :: fehler
```

Description:

Refractive index m_{eff} of a three-component mixture material after Oguchi (1983), see equation (16) in subsubsection 4.5.4 on Page 15.

Input parameters:

`kinddp`	kind parameter for double precision
`m1, m2, m3`	complex index of refraction for the three mixture components 1, 2 and 3
`vol1, vol2, vol3`	corresponding volume fractions (conform with p_1, p_2, p_3 from equation (16), $\sum p_j \stackrel{!}{=} 1$)

Output parameters:

`m_complex_oguchi`	complex refractive index m_{eff} of the mixture material, function result
`fehler`	error status (side effect): 0 = no error, 1 = error encountered

Example:

```
mmix = m_complex_oguchi(0.5, 0.3, 0.2, mwater, mice, mair, errorflag)
```

5.2.2 FUNCTION m_complex_maxwellgarnett (vol1, vol2, vol3, m1, m2, m3, inclusionstring, fehler)

```
INTEGER, PARAMETER   :: kinddp = KIND(1.0d0)
COMPLEX(kind=kinddp) :: m_complex_maxwellgarnett
COMPLEX(kind=kinddp) :: m1, m2, m3
DOUBLE PRECISION     :: vol1, vol2, vol3
CHARACTER(len=*)     :: inclusionstring
INTEGER, INTENT(out) :: fehler
```

Description:

Refractive index of a three-component mixture material after Maxwell Garnett (1904), see subsubsection 4.5.5 on Page 16. Both formulas for spherical (equation (18)) and spheroidal (equation (20)) inclusions are implemented and can be chosen via a keyword parameter. The choice which material is the matrix and which are the inclusions is done via the order number of the material: No. 1 denotes the matrix, No. 2 and 3 represent the inclusions (see below).

Input parameters:

`kinddp`	kind parameter for double precision
`m1, m2, m3`	complex index of refraction for the three mixture components 1, 2 and 3. Index 1 denotes the matrix material and 2 and 3 represent the inclusions
`vol1, vol2, vol3`	corresponding volume fractions (conform with p_1, p_2, p_3 from equation (17), $\sum p_j \stackrel{!}{=} 1$)
`inclusionstring`	A string constant to choose if spherical or spheroidal inclusions should be assumed: `'spherical'` — spherical inclusions `'spheroidal'` — spheroidal inclusions

Output parameters:

`m_complex_maxwellgarnett`	complex refractive index m_{eff} of the mixture material, function result
`fehler`	error status (side effect): 0 = no error, 1 = error encountered

Example:

```
mmix = m_complex_maxwellgarnett(0.5, 0.3, 0.2, mwater, mice, mair, 'spheroidal', errorflag
```

5.2.3 FUNCTION m_complex_bruggemann (volair, volice, volwater, mair, mice, mwater, fehler)

```
INTEGER, PARAMETER   :: kinddp = KIND(1.0d0)
COMPLEX(kind=kinddp) :: m_complex_bruggemann
COMPLEX(kind=kinddp) :: mair, mice, mwater
DOUBLE PRECISION     :: volair, volice, volwater
INTEGER, INTENT(out) :: fehler
```

Description:

Refractive index of a three-component mixture of air, ice and water after Bruggemann (1935), see equation (23) in subsubsection 4.5.6 on Page 17.

Note: This routine is especially designed for mixtures of air, ice and water!

Input parameters:

`kinddp`	kind parameter for double precision
`mair, mice, mwater`	complex index of refraction for air, ice and water
`volair, volice, volwater`	corresponding volume fractions (conform with p_1, p_2, p_3 from equation (23), $\sum p_j \stackrel{!}{=} 1$)

Output parameters:

`m_complex_bruggemann`	complex refractive index m_{eff} of the mixture material, function result
`fehler`	error status (side effect): 0 = no error, 1 = error encountered

Example:

```
mmix = m_complex_bruggemann(0.5, 0.3, 0.2, mwater, mice, mair, errorflag)
```

5.2.4 FUNCTION get_m_mix (m_a, m_i, m_w, volair, volice, volwater, mixingrulestring, matrixstring, inclusionstring, fehler)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
COMPLEX(kind=kinddp)              :: get_m_mix
COMPLEX(kind=kinddp), INTENT(in)  :: m_a, m_i, m_w
DOUBLE PRECISION, INTENT(in)      :: volair, volice, volwater
CHARACTER(len=*), INTENT(in)      :: mixingrulestring
CHARACTER(len=*), INTENT(in)      :: matrixstring
CHARACTER(len=*), INTENT(in)      :: inclusionstring
INTEGER, INTENT(out)              :: fehler
```

Description:

Interface routine to the basic functions `m_complex_oguchi()`, `m_complex_maxwellgarnett()` and `m_complex_bruggemann()` for a three-component mixture. Three keyword parameter strings determine, which mixingrule and, if necessary, which matrix material should be chosen. **Note: This routine is especially designed for mixtures of air, ice and water!**

Input parameters:

`kinddp`	kind parameter for double precision
`m_a, m_i, m_w`	complex index of refraction for air, ice and water, resp.
`volair, volice, volwater`	corresponding volume fractions (conform with p_1, p_2, p_3 from equation (23), $\sum p_j \stackrel{!}{=} 1$)

`mixingrulestring`	A string constant to choose the mixing rule:
	`'oguchi'` — `m_complex_oguchi()`, spherical inclusions
	`'maxwellgarnett'` — `m_complex_maxwellgarnett()`
	`'bruggemann'` — `m_complex_bruggemann()`

`matrixstring`	In case of `mixingrulestring = 'maxwellgarnett'`, choice of the matrix material: `'air'` — air `'ice'` — ice `'water'` — water
`inclusionstring`	A string constant to choose if spherical or spheroidal inclusions should be assumed: `'spherical'` — spherical inclusions `'spheroidal'` — spheroidal inclusions

Output parameters:

`get_m_mix`	complex refractive index m_{eff} of the mixture material, function result
`fehler`	error status (side effect): 0 = no error, 1 = error encountered

Example:

```
mmix = get_m_mix(mair, mice, mwater, 0.2, 0.3, 0.5, 'maxwellgarnett', &
                 'ice', 'spheroidal', errorflag)
```

5.2.5 FUNCTION get_m_mix_nested (m_a, m_i, m_w, volair, volice, volwater, mixingrulestring, hoststring, matrixstring, inclusionstring, hostmatrixstring, hostinclusionstring, kumfehler)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
COMPLEX(kind=kinddp)              :: get_m_mix_nested
COMPLEX(kind=kinddp), INTENT(in)  :: m_a, m_i, m_w
DOUBLE PRECISION, INTENT(in)      :: volair, volice, volwater
CHARACTER(len=*), INTENT(in)      :: mixingrulestring
CHARACTER(len=*), INTENT(in)      :: hoststring
CHARACTER(len=*), INTENT(in)      :: matrixstring
CHARACTER(len=*), INTENT(in)      :: inclusionstring
CHARACTER(len=*), INTENT(in)      :: hostmatrixstring
CHARACTER(len=*), INTENT(in)      :: hostinclusionstring
INTEGER, INTENT(out)              :: kumfehler
```

Description:

Interface routine to the basic functions `m_complex_oguchi()`, `m_complex_maxwellgarnett()` and `m_complex_bruggemann()` for a three-component mixture. The difference to `get_m_mix()` (subsubsection 5.2.4) is that, once a particular mixing rule is chosen, additionally a twofold mixing of two two-component mixtures is possible. This offers for the Maxwell-Garnett rule 30 different choices in total. If this twofold mixing is specified, first m_{eff} of a mixture of two of the three components is calculated ("inner" mixing material), and later, this effective medium is mixed with the remaining third compontent ("outer" mixture). **Note that the twofold application of two two-component mixtures with different mixing rules is not implemented so far.** In case of Bruggemann- and Oguchi-rule, it does not make any difference if choosing the three-component or twofold two-component mixing.

Six keyword parameter strings determine, which mixingrule and (if necessary) if twofold two-component or three-component mixture with which matrix material(s) should be chosen (see below for details). **Note: This routine is especially designed for mixtures of air, ice and water!**

Input parameters:

`kinddp`	kind parameter for double precision
`m_a, m_i, m_w`	complex index of refraction for air, ice and water, resp.
`volair, volice, volwater`	corresponding volume fractions (conform with p_1, p_2, p_3 from equation (23), $\sum p_j \stackrel{!}{=} 1$)

`mixingrulestring`	A string constant to choose the mixing rule:
	`'oguchi'` — `m_complex_oguchi()`, spherical inclusions
	`'maxwellgarnett'` — `m_complex_maxwellgarnett()`
	`'bruggemann'` — `m_complex_bruggemann()`

`hoststring`	Determines which material should be the hosting ("outer") material in a twofold two-component mixture or if a three-component mixture should be chosen: `'none'` — onefold three-component mixture `'air'` — air `'ice'` — ice `'water'` — water

`matrixstring`
: In case of twofold two-component mixture (`hoststring` $\neq$ `'none'`) and Maxwell-Garnett mixing rule, choice of the matrix material of the "inner" mixture:
`'air'` — air
`'ice'` — ice
`'water'` — water
(not equal to `hoststring`!)

  In case of three-component mixture (`hoststring = 'none'`), the usual choice of the matrix material:
`'air'` — air
`'ice'` — ice
`'water'` — water

`inclusionstring`
: A string constant to choose if spherical or spheroidal inclusions should be assumed (in case of twofold two-component mixture, for the "inner" mixture):
`'spherical'` — spherical inclusions
`'spheroidal'` — spheroidal inclusions

`hostmatrixstring`
: In case of `mixingrulestring = 'maxwellgarnett'` and twofold two-component mixture, choice of the matrix material of the "outer" mixture (no meaning in case of `hoststring = 'none'`):
`'air'` — air
`'ice'` — ice
`'water'` — water
`'airice'` — air/ice-mixture
`'airwater'` — air/water-mixture
`'icewater'` — ice/water-mixture

`hostinclusionstring`
: In case of twofold two-component mixture, for the "outer" mixture, a string constant to choose if spherical or spheroidal inclusions should be assumed:
`'spherical'` — spherical inclusions
`'spheroidal'` — spheroidal inclusions

Note that not all combinations of these six keyword parameter strings does make sense. Nonsense combinations will lead to an error ($m_{eff} = -999.99$), a corresponding error message and `kumfehler` $\neq$ `0`.

Output parameters:

`get_m_mix`
: complex refractive index m_{eff} of the mixture material, function result

`kumfehler`
: error status (side effect): 0 = no error, 1 = error encountered

Example:

```
mmix = get_m_mix_nested(mair, mice, mwater, 0.2, 0.3, 0.5, &
             'maxwellgarnett', 'air', 'water', 'spherical', &
             'icewater', 'spheroidal', errorflag)
```

5.3 Backscattering cross section for single precipitation particles

5.3.1 SUBROUTINE MIE_DRY_GRAUPEL (x_g,a_geo,b_geo,m_i,lambda,C_back, mixingrulestring, matrixstring, inclusionstring)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
DOUBLE PRECISION, INTENT(in)      :: x_g, lambda, a_geo, b_geo
COMPLEX(kind=kinddp), INTENT(in) :: m_i
CHARACTER(len=*), INTENT(in)      :: mixingrulestring
CHARACTER(len=*), INTENT(in)      :: matrixstring
CHARACTER(len=*), INTENT(in)      :: inclusionstring
DOUBLE PRECISION, INTENT(out)     :: C_back
```

Description:

Backscattering cross section σ_b (Mie-scattering) of a dry graupel/snow/hail particle, assumed as a **sphere of homogeneous ice-air mixture material**. The particle bulk density is derived from the inverse mass-size-relation (40) with coefficients a_{geo} and b_{geo} assuming spherical shape. `mixingrulestring`, `matrixstring` and `inclusionstring` determine the effective medium approximation used to calculate the effective refractive index of the particles, which is done by function `get_m_mix` (Subsection 5.2).

For relatively small particles, the Rayleigh approximation can be applied instead by using subroutine `RAYLEIGH_DRY_GRAUPEL()` (subsubsection 5.3.2).

Input parameters:

`kinddp`	kind parameter for double precision
`x_g`	Mass of particle in kg (without air fraction)
`a_geo`	Coefficient a_{geo} of the inverse mass-size-relation (40)
`b_geo`	Coefficient b_{geo} of the inverse mass-size-relation (40)
`m_i`	Complex refractive index of ice
`lambda`	Radar wavelength in m

`mixingrulestring`	A string constant to choose the mixing rule:
	`'oguchi'` — `m_complex_oguchi()`, spherical inclusions
	`'maxwellgarnett'` — `m_complex_maxwellgarnett()`
	`'bruggemann'` — `m_complex_bruggemann()`

`matrixstring`	In case of `mixingrulestring = 'maxwellgarnett'`, choice of the matrix material: `'air'` — air `'ice'` — ice `'water'` — water (does not make sense here)
`inclusionstring`	A string constant to choose if spherical or spheroidal inclusions should be assumed: `'spherical'` — spherical inclusions `'spheroidal'` — spheroidal inclusions

Output parameters:

`C_back`	Backscattering cross section σ_b in m^2

Example:

```
CALL MIE_DRY_GRAUPEL(2.3e-3, a_geo, b_geo, m_i, 0.055, C_back, &
     'maxwellgarnett', 'ice', 'spheroidal')
```

5.3.2 SUBROUTINE RAYLEIGH_DRY_GRAUPEL (x_g,a_geo,b_geo,m_i,lambda,C_back, mixingrulestring, matrixstring, inclusionstring)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
DOUBLE PRECISION, INTENT(in)      :: x_g, lambda, a_geo, b_geo
COMPLEX(kind=kinddp), INTENT(in) :: m_i
CHARACTER(len=*), INTENT(in)      :: mixingrulestring
CHARACTER(len=*), INTENT(in)      :: matrixstring
CHARACTER(len=*), INTENT(in)      :: inclusionstring
DOUBLE PRECISION, INTENT(out)     :: C_back
```

Description:

Backscattering cross section σ_b (Rayleigh approximation) of a dry graupel/snow/hail particle, assumed as a **sphere of homogeneous ice-air mixture material**. The particle bulk density is derived from the inverse mass-size-relation (40) with coefficients a_{geo} and b_{geo} assuming spherical shape. `mixingrulestring`, `matrixstring` and `inclusionstring` determine the effective medium approximation used to calculate the effective refractive index of the particles, which is done by function `get_m_mix` (Subsection 5.2).

Input parameters:

`kinddp`	kind parameter for double precision
`x_g`	Mass of particle in kg (without air fraction)
`a_geo`	Coefficient a_{geo} of the inverse mass-size-relation (40)
`b_geo`	Coefficient b_{geo} of the inverse mass-size-relation (40)
`m_i`	Complex refractive index of ice
`lambda`	Radar wavelength in m

`mixingrulestring`	A string constant to choose the mixing rule:
	`'oguchi'` — `m_complex_oguchi()`, spherical inclusions
	`'maxwellgarnett'` — `m_complex_maxwellgarnett()`
	`'bruggemann'` — `m_complex_bruggemann()`

`matrixstring`	In case of `mixingrulestring = 'maxwellgarnett'`, choice of the matrix material: `'air'` — air `'ice'` — ice `'water'` — water (does not make sense here)
`inclusionstring`	A string constant to choose if spherical or spheroidal inclusions should be assumed: `'spherical'` — spherical inclusions `'spheroidal'` — spheroidal inclusions

Output parameters:

`C_back`	Backscattering cross section σ_b in m^2

Example:

```
CALL RAYLEIGH_DRY_GRAUPEL(2.3e-3, a_geo, b_geo, m_i, 0.055, C_back, &
     'maxwellgarnett', 'ice', 'spheroidal')
```

5.3.3 SUBROUTINE MIE_DRYHAIL (x_h,a_geo,b_geo,m_i,lambda,C_back)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
DOUBLE PRECISION, INTENT(in)      :: x_h, lambda, a_geo, b_geo
COMPLEX(kind=kinddp), INTENT(in) :: m_i
DOUBLE PRECISION, INTENT(out)     :: C_back
```

Description:

Backscattering cross section σ_b (Mie-scattering) of a dry hail particle, assumed as a **homogeneous ice sphere**. It is an approximation to `MIE_DRY_GRAUPEL()` (subsubsection 5.3.1) in the sense that although the particle bulk density is permitted to deviate from pure ice, but solid ice is assumed for the particles refractive index (m_i). The purpose of this is to save computation time in case of high density ice particles. Therefore, this routine is only applicable to particle types whose coefficients a_{geo} and b_{geo} of the inverse mass-size-relation (40) represent nearly solid ice particles.

For smaller particles, the Rayleigh approximation can be applied by subroutine `RAYLEIGH_DRY_GRAUPEL` instead (subsubsection 5.3.2).

Input parameters:

`kinddp`	kind parameter for double precision
`x_h`	Mass of hail particle in kg
`a_geo`	Coefficient a_{geo} of the inverse mass-size-relation (40)
`b_geo`	Coefficient b_{geo} of the inverse mass-size-relation (40)
`m_i`	Complex refractive index of ice
`lambda`	Radar wavelength in m

Output parameters:

`C_back`	Backscattering cross section σ_b in m^2

Example:

```
CALL MIE_DRYHAIL(2.3e-3, a_geo, b_geo, m_i, 0.055, C_back)
```

5.3.4 SUBROUTINE MIE_DRYSNOW (x_s,a_geo,b_geo,m_i,lambda,C_back, mixingrulestring, matrixstring, inclusionstring)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
DOUBLE PRECISION, INTENT(in)      :: x_s, lambda, a_geo, b_geo
COMPLEX(kind=kinddp), INTENT(in) :: m_i
CHARACTER(len=*), INTENT(in)      :: mixingrulestring
CHARACTER(len=*), INTENT(in)      :: matrixstring
CHARACTER(len=*), INTENT(in)      :: inclusionstring
DOUBLE PRECISION, INTENT(out)     :: C_back
```

Description:

Backscattering cross section σ_b (Mie-scattering) of a dry graupel/snow/hail particle, assumed as a **sphere of homogeneous ice-air mixture material**. The particle bulk density is derived from the inverse mass-size-relation (40) with coefficients a_{geo} and b_{geo} assuming spherical shape. `mixingrulestring`, `matrixstring` and `inclusionstring` determine the effective medium approximation used to calculate the effective refractive index of the particles, which is done by function `get_m_mix` (Subsection 5.2).

For smaller particles, the Rayleigh approximation can be applied by using subroutine `RAYLEIGH_DRY_GRAUPEL` instead (subsubsection 5.3.2).

The only difference to subroutine `MIE_DRY_GRAUPEL` (subsubsection 5.3.1) is that a equivalent spherical diameter threshold of 10^{-12} m is used instead of 10^{-6} m below which C_back is set to 0 to save computation time.

Input parameters:

`kinddp`	kind parameter for double precision
`x_s`	Mass of particle in kg (without air fraction)
`a_geo`	Coefficient a_{geo} of the inverse mass-size-relation (40)
`b_geo`	Coefficient b_{geo} of the inverse mass-size-relation (40)
`m_i`	Complex refractive index of ice
`lambda`	Radar wavelength in m

`mixingrulestring`	A string constant to choose the mixing rule:
	`'oguchi'` — `m_complex_oguchi()`, spherical inclusions
	`'maxwellgarnett'` — `m_complex_maxwellgarnett()`
	`'bruggemann'` — `m_complex_bruggemann()`

`matrixstring`	In case of `mixingrulestring = 'maxwellgarnett'`, choice of the matrix material: `'air'` — air `'ice'` — ice `'water'` — water (does not make sense here)
`inclusionstring`	A string constant to choose if spherical or spheroidal inclusions should be assumed: `'spherical'` — spherical inclusions `'spheroidal'` — spheroidal inclusions

Output parameters:

`C_back`	Backscattering cross section σ_b in m^2

Example:

```
CALL MIE_DRYSNOW(3.4e-5, a_geo, b_geo, m_i, 0.055, C_back, &
     'maxwellgarnett', 'ice', 'spheroidal')
```

5.3.5 SUBROUTINE MIE_DRYSNOW_TWOSPH (x_s,a_geo,b_geo,m_i,radienverh,lambda,C_back, mixingrulestring_shell, matrixstring_shell, inclusionstring_shell, mixingrulestring_core, matrixstring_core, inclusionstring_core)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
DOUBLE PRECISION, INTENT(in)      :: x_s, lambda, a_geo, b_geo
DOUBLE PRECISION, INTENT(in)      :: radienverh
COMPLEX(kind=kinddp), INTENT(in) :: m_i
CHARACTER(len=*), INTENT(in)      :: mixingrulestring_shell
CHARACTER(len=*), INTENT(in)      :: matrixstring_shell
CHARACTER(len=*), INTENT(in)      :: inclusionstring_shell
CHARACTER(len=*), INTENT(in)      :: mixingrulestring_core
CHARACTER(len=*), INTENT(in)      :: matrixstring_core
CHARACTER(len=*), INTENT(in)      :: inclusionstring_core
DOUBLE PRECISION, INTENT(out)     :: C_back
```

Description:

Backscattering cross section σ_b (Mie-scattering) of a dry snowflake, assumed as a **two-layered sphere of homogeneous ice-air mixture material in each layer, the core having higher bulk density than the shell (see Subsection 7.2).** The overall particle bulk density is derived from the inverse mass-size-relation (40) with coefficients a_{geo} and b_{geo} assuming spherical shape. Note that b_{geo} has to represent a decreasing bulk density with size.

To model a snowflake by a two-layered sphere with a denser core and a less dense shell, additional information is necessary to assign the different bulk densities to core and shell, preserving overall particle mass. To this end, as additional parameter, the ratio of the inner to the outer sphere radius, `radienverh`, has to be specified with a value between 0 and 1. With this parameter, the procedure discribed later in Subsection 7.2 on Page 71 is applied to assign different bulk densities to core and shell.

Further, the input parameters `mixingrulestring_shell`/ `mixingrulestring_core`, `matrixstring_shell`/ `matrixstring_core` and `inclusionstring_shell`/ `inclusionstring_core` determine the effective medium approximation used to calculate the effective refractive index of the particles shell/ core, which is done by function `get_m_mix` (Subsection 5.2).

This routine uses the formulae of Bohren and Huffman (1983) for the backscattering cross section of a two-layered sphere (subroutine `COATEDSPHERE_SCATTER_BH()`), see Subsection 4.4.

Input parameters:

`kinddp`	kind parameter for double precision
`x_s`	Mass of particle in kg (without air fraction)
`a_geo`	Coefficient a_{geo} of the inverse mass-size-relation (40)
`b_geo`	Coefficient b_{geo} of the inverse mass-size-relation (40)
`radienverh`	Ratio of the inner to the outer sphere radius
`m_i`	Complex refractive index of ice
`lambda`	Radar wavelength in m

`mixingrulestring_shell/` `mixingrulestring_core`	String constants to choose the mixing rule:
	`'oguchi'` — `m_complex_oguchi()`, spherical inclusions
	`'maxwellgarnett'` — `m_complex_maxwellgarnett()`
	`'bruggemann'` — `m_complex_bruggemann()`

`matrixstring_shell/` `matrixstring_core`	In case of `mixingrulestring = 'maxwellgarnett'`, choice of the matrix material: `'air'` — air `'ice'` — ice `'water'` — water (does not make sense here)
`inclusionstring_shell/` `inclusionstring_core`	String constants to choose if spherical or spheroidal inclusions should be assumed: `'spherical'` — spherical inclusions `'spheroidal'` — spheroidal inclusions

Output parameters:

`C_back`	Backscattering cross section σ_b in m^2

Example:

```
CALL MIE_DRYSNOW_TWOSPH(3.4e-5, a_geo, b_geo, m_i, 0.055, C_back, &
     'maxwellgarnett', 'air', 'spheroidal', &
     'maxwellgarnett', 'ice', 'spheroidal')
```

5.3.6 SUBROUTINE MIE_WATERSPH_WETHAIL (x_h,fmelt,m_i,m_w,lambda,C_back)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
DOUBLE PRECISION, INTENT(in)      :: x_h, fmelt, lambda
DOUBLE PRECISION, INTENT(out)     :: C_back
COMPLEX(kind=kinddp), INTENT(in) :: m_i, m_w
```

Description:

Backscattering cross section σ_b of a melting hail particle, assumed as a **solid spherical ice core with spherical water coating**, calculated by the two-sphere Mie-formulae. Here, the formulae of Kerker (1969) are applied (subroutine `COATEDSPHERE_SCATTER()`), see Subsection 4.4.

To speed up computation (but with some loss of stability), the **subroutine** `MIE_WATERSPH_WETHAIL_BH()` can be used instead with exactly the same input- and output parameters. This routine utilizes the formulae of Bohren and Huffman (1983) (subroutine `COATEDSPHERE_SCATTER_BH()`) instead of Kerker (1969), see Subsection 4.4.

Input parameters:

`kinddp`	kind parameter for double precision
`x_h`	Mass of hail particle in kg
`fmelt`	degree of melting, $f_{melt} = x_w/x_h$ (x_w = mass of water contained in the particle)
`m_i`	Complex refractive index of ice
`m_w`	Complex refractive index of water
`lambda`	Radar wavelength in m

Output parameters:

`C_back`	Backscattering cross section σ_b in m^2

Example:

```
CALL MIE_WATERSPH_WETHAIL(2.3e-3, 0.7, m_i, m_w, 0.055, C_back)
```

Example sensitivity studies:

The dependence of σ_b on the degree of melting and on particle size for a specific temperature of $T = 5°C$ is studied in detail in Subsection 8.18 on Page 107.

5.3.7 SUBROUTINE MIE_SPONGY_WETHAIL (x_h,fmelt,f_water,m_i,m_w,lambda,C_back, mixingrulestring, matrixstring, inclusionstring)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
DOUBLE PRECISION, INTENT(in)      :: x_h, fmelt, f_water, lambda
COMPLEX(kind=kinddp), INTENT(in) :: m_i, m_w
CHARACTER(len=*), INTENT(in)      :: mixingrulestring
CHARACTER(len=*), INTENT(in)      :: matrixstring
CHARACTER(len=*), INTENT(in)      :: inclusionstring
DOUBLE PRECISION, INTENT(out)     :: C_back
```

Description:

Backscattering cross section σ_b of a melting hail particle, assumed as a **solid spherical ice core with a spherical coating of a "spongy" ice-water mixture**, calculated by the two-sphere Mie-formulae. Here, the formulae of Kerker (1969) are applied (subroutine `COATEDSPHERE_SCATTER()`), see Subsection 4.4. The mass fraction of water (`f_water`) in the outer spongy shell has to be preset and is held fixed throughout the melting process, as long as the inner ice core is not completely melted. After the inner core has completely vanished, `f_water` is increased automatically to represent now the melted fraction of the remaining homogeneous spherical particle.

It seems reasonable to assume larger values of `f_water` during later melting stages (larger `fmelt`) than for earlier melting stages (small `fmelt`).

To speed up computation (but with some loss of stability), the **subroutine** `MIE_SPONGY_WETHAIL_BH()` can be used instead with exactly the same input- and output parameters. This routine utilizes the formulae of Bohren and Huffman (1983) (subroutine `COATEDSPHERE_SCATTER_BH()`) instead of Kerker (1969), see Subsection 4.4.

Input parameters:

`kinddp`	kind parameter for double precision
`x_h`	Mass of hail particle in kg
`fmelt`	Degree of melting, $f_{melt} = x_w/x_h$ (x_w = mass of water contained in the particle)
`f_water`	Mass fraction of water in the outer spongy shell ($x_{water}/(x_{ice} + x_{water})$)
`m_i`	Complex refractive index of ice
`m_w`	Complex refractive index of water
`lambda`	Radar wavelength in m

`mixingrulestring`	A string constant to choose the mixing rule for the ice-water shell:
	`'oguchi'` — `m_complex_oguchi()`, spherical inclusions
	`'maxwellgarnett'` — `m_complex_maxwellgarnett()`
	`'bruggemann'` — `m_complex_bruggemann()`

`matrixstring`	In case of `mixingrulestring = 'maxwellgarnett'`, choice of the matrix material for the ice-water shell: `'air'` — air (does not make sense here) `'ice'` — ice `'water'` — water
`inclusionstring`	A string constant to choose if spherical or spheroidal inclusions should be assumed for the ice-water shell: `'spherical'` — spherical inclusions `'spheroidal'` — spheroidal inclusions

Output parameters:

`C_back`	Backscattering cross section σ_b in m^2

Example:

```
CALL MIE_SPONGY_WETHAIL(2.3e-3, 0.7, 0.5, m_i, m_w, 0.055, C_back)
```

Example sensitivity studies:

The dependence of σ_b on the degree of melting and on particle size for a specific temperature of $T = 5°\mathrm{C}$ is studied in detail in Subsection 8.17 on Page 106.

5.3.8 SUBROUTINE MIE_WATERSPH_WETGR (x_g,a_geo,b_geo,fmelt,m_w,m_i,lambda,C_back, mixingrulestring, matrixstring, inclusionstring)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
DOUBLE PRECISION, INTENT(in)      :: x_g, lambda, a_geo, b_geo, fmelt
COMPLEX(kind=kinddp), INTENT(in) :: m_w, m_i
CHARACTER(len=*), INTENT(in)      :: mixingrulestring
CHARACTER(len=*), INTENT(in)      :: matrixstring
CHARACTER(len=*), INTENT(in)      :: inclusionstring
DOUBLE PRECISION, INTENT(out)     :: C_back
```

Description:

Backscattering cross section σ_b (Mie-scattering, two-layered sphere) of a melting graupel particle, assumed as a **two-layered sphere composed of a homogeneous ice-air mixture core and a spherical water shell**. The bulk density (ice mass per particle volume) of the original unmelted particle is derived from the inverse mass-size-relation (40) with coefficients a_{geo} and b_{geo} assuming spherical shape. `fmelt` denotes the melted mass fraction or the degree of melting, f_{melt}, resp. It is assumed that the particle melts entirely at the outside of the ice-air core and that the meltwater is accumulated in a spherical shell. `mixingrulestring`, `matrixstring` and `inclusionstring` determine the effective medium approximation used to calculate the effective refractive index of the particle ice-air core, which is done by function `get_m_mix` (Subsection 5.2). Such a melting model should be applicable to relatively high-density graupel and/ or at later melting stages (`fmelt` > approx. 0.5).

For the calculation of the two-sphere backscattering cross section, the formulae of Kerker (1969) are applied (subroutine `COATEDSPHERE_SCATTER()`), see Subsection 4.4.

To speed up computation (but with some loss of stability), the **subroutine** `MIE_WATERSPH_WETGR_BH()` can be used instead with exactly the same input- and output parameters. This routine utilizes the formulae of Bohren and Huffman (1983) (subroutine `COATEDSPHERE_SCATTER_BH()`) instead of Kerker (1969), see Subsection 4.4.

Input parameters:

`kinddp`	kind parameter for double precision
`x_g`	Mass of particle in kg (without air fraction)
`a_geo`	Coefficient a_{geo} of the inverse mass-size-relation (40)
`b_geo`	Coefficient b_{geo} of the inverse mass-size-relation (40)
`fmelt`	Degree of melting, $f_{melt} = x_w/x_g$ (x_w = mass of water contained in the particle)
`m_w`	Complex refractive index of water
`m_i`	Complex refractive index of ice
`lambda`	Radar wavelength in m

`mixingrulestring`	A string constant to choose the mixing rule for the ice-air core:
	`'oguchi'` — `m_complex_oguchi()`, spherical inclusions
	`'maxwellgarnett'` — `m_complex_maxwellgarnett()`
	`'bruggemann'` — `m_complex_bruggemann()`

`matrixstring`	In case of `mixingrulestring = 'maxwellgarnett'`, choice of the matrix material for the ice-air core: `'air'` — air `'ice'` — ice `'water'` — water (does not make sense here)
`inclusionstring`	A string constant to choose if spherical or spheroidal inclusions should be assumed for the ice-air core: `'spherical'` — spherical inclusions `'spheroidal'` — spheroidal inclusions

Output parameters:

`C_back`	Backscattering cross section σ_b in m^2

Example:

```
CALL MIE_WATERSPH_WETGR(2.3e-3, a_geo, b_geo, &
          0.45, m_w, m_i, 0.055, C_back, &
          'maxwellgarnett', 'ice', 'spheroidal')
```

Example sensitivity studies:

The dependence of σ_b on the degree of melting and on particle size for a specific temperature of $T = 5°C$ is studied in detail in subsequent sections for the 4 different inverse mass-size-relations given in Subsection 7.1. These are:

- for inverse mass-size-relation (36) in Subsection 8.9 on Page 92,
- for inverse mass-size-relation (37) in Subsection 8.10 on Page 95,
- for inverse mass-size-relation (38) in Subsection 8.11 on Page 98,
- for inverse mass-size-relation (39) in Subsection 8.12 on Page 100.

5.3.9 SUBROUTINE MIE_SOAK_TWOSPH_WETGR (x_g,a_geo,b_geo,fmelt,m_w,m_i,lambda,C_back, mixingrulestring_iceair, matrixstring_iceair, inclusionstring_iceair, mixingrulestring_icewater, matrixstring_icewater, inclusionstring_icewater)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
DOUBLE PRECISION, INTENT(in)      :: x_g, lambda, a_geo, b_geo, fmelt
COMPLEX(kind=kinddp), INTENT(in) :: m_w, m_i
CHARACTER(len=*), INTENT(in)      :: mixingrulestring
CHARACTER(len=*), INTENT(in)      :: matrixstring
CHARACTER(len=*), INTENT(in)      :: inclusionstring
DOUBLE PRECISION, INTENT(out)     :: C_back
```

Description:

Backscattering cross section σ_b (Mie-scattering, two-layered sphere) of a melting graupel/snow particle, assumed as a **two-layered sphere composed of a homogeneous ice-air mixture core and a spherical ice-water mixture shell**. The bulk density (ice mass per particle volume) of the original unmelted particle is derived from the inverse mass-size-relation (40) with coefficients a_{geo} and b_{geo} assuming spherical shape. `fmelt` denotes the melted mass fraction or the degree of melting, f_{melt}, resp. It is assumed that the particle melts entirely on its outside and that the meltwater is soaked into the particle, displacing the air inclusions entirely from the outside. In this way, a spherical ice-water mixture shell forms around the ice-air core, growing to the inside with growing melt fraction, up to the melt fraction where the particle is completely soaked and the core has vanished. For a larger melt fraction, the particle is assumed as a sphere of homogeneous ice-water mixture.

Such a melting model should be applicable to graupel with intermediate density at all melting stages or to high-density graupel during an early melting stage (`fmelt` < approx. 0.5).

`mixingrulestring_iceair`/ `mixingrulestring_icewater`, `matrixstring_iceair`/ `matrixstring_icewater` and `inclusionstring_iceair`/ `inclusionstring_icewater` determine the effective medium approximation used to calculate the effective refractive index of the particle ice-air core/ ice-water shell. Both calculations are performed using the function `get_m_mix` (Subsection 5.2).

For the calculation of the two-sphere backscattering cross section, the formulae of Kerker (1969) are applied (subroutine `COATEDSPHERE_SCATTER()`), see Subsection 4.4.

To speed up computation (but with some loss of stability), the **subroutine** `MIE_SOAK_TWOSPH_WETGR_BH()` can be used instead with exactly the same input- and output parameters. This routine utilizes the formulae of Bohren and Huffman (1983) (subroutine `COATEDSPHERE_SCATTER_BH()`) instead of Kerker (1969), see Subsection 4.4.

Input parameters:

`kinddp`	kind parameter for double precision
`x_g`	Mass of particle in kg (without air fraction)
`a_geo`	Coefficient a_{geo} of the inverse mass-size-relation (40)
`b_geo`	Coefficient b_{geo} of the inverse mass-size-relation (40)

`fmelt`	Degree of melting, $f_{melt} = x_w/x_g$ (x_w = mass of water contained in the particle)
`m_w`	Complex refractive index of water
`m_i`	Complex refractive index of ice
`lambda`	Radar wavelength in m

`mixingrulestring_iceair`/ `mixingrulestring_icewater`	String constants to choose the mixing rule for the ice-air core/ ice-water shell:
	`'oguchi'` — `m_complex_oguchi()`, spherical inclusions
	`'maxwellgarnett'` — `m_complex_maxwellgarnett()`
	`'bruggemann'` — `m_complex_bruggemann()`

`matrixstring_iceair`/ `matrixstring_icewater`	In case of `mixingrulestring = 'maxwellgarnett'`, choice of the matrix material for the ice-air core/ ice-water shell: `'air'` — air (not for `matrixstring_icewater`) `'ice'` — ice `'water'` — water (not for `matrixstring_iceair`)
`inclusionstring_iceair`/ `inclusionstring_icewater`	String constants to choose if spherical or spheroidal inclusions should be assumed for the ice-air core/ ice-water shell: `'spherical'` — spherical inclusions `'spheroidal'` — spheroidal inclusions

Output parameters:

`C_back`	Backscattering cross section σ_b in m^2

Example:

```
CALL MIE_SOAK_TWOSPH_WETGR(2.3e-3, a_geo, b_geo, &
          0.45, m_w, m_i, 0.055, C_back, &
          'maxwellgarnett', 'ice', 'spheroidal', &
          'maxwellgarnett', 'water', 'spheroidal')
```

Example sensitivity studies:

The dependence of σ_b on the degree of melting and on particle size for a specific temperature of $T = 5°C$ is studied in detail in subsequent sections for the 4 different inverse mass-size-relations given in Subsection 7.1. These are:

- for inverse mass-size-relation (36) in Subsection 8.5 on Page 84,
- for inverse mass-size-relation (37) in Subsection 8.6 on Page 86,
- for inverse mass-size-relation (38) in Subsection 8.7 on Page 88,
- for inverse mass-size-relation (39) in Subsection 8.8 on Page 90.

5.3.10 SUBROUTINE MIE_MEAN_WETGR (x_g,a_geo,b_geo,fmelt,m_w,m_i,lambda,C_back, mixingrulestring_iceair, matrixstring_iceair, inclusionstring_iceair, mixingrulestring_icewater, matrixstring_icewater, inclusionstring_icewater)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
DOUBLE PRECISION, INTENT(in)      :: x_g, lambda, a_geo, b_geo, fmelt
COMPLEX(kind=kinddp), INTENT(in) :: m_w, m_i
CHARACTER(len=*), INTENT(in)      :: mixingrulestring_iceair
CHARACTER(len=*), INTENT(in)      :: matrixstring_iceair
CHARACTER(len=*), INTENT(in)      :: inclusionstring_iceair
CHARACTER(len=*), INTENT(in)      :: mixingrulestring_icewater
CHARACTER(len=*), INTENT(in)      :: matrixstring_icewater
CHARACTER(len=*), INTENT(in)      :: inclusionstring_icewater
DOUBLE PRECISION, INTENT(out)     :: C_back
```

Description:

Backscattering cross section σ_b of a melting graupel particle (Mie-scattering, two-layered sphere model), assumed as melt fraction weighted mean of the backscattering coefficients calculated with the subroutines `MIE_WATERSPH_WETGR()` (subsubsection 5.3.8) and `MIE_SOAK_TWOSPH_WETGR()` (subsubsection 5.3.9):

$$C_{back} \;=\; f_{melt}\, C_{watersphere} \;+\; (1.0 \;-\; f_{melt})\, C_{soak_twosphere} \quad .$$

In this way, the melting particle is assumed to soak the meltwater during the early stage of melting and to accumulate more and more meltwater on the outside at later melting stages.

`mixingrulestring_iceair`, `matrixstring_iceair` and `inclusionstring_iceair` determine the choice of the effective medium approximation for the two-component ice-air core in subroutine `MIE_WATERSPH_WETGR()` as well as in subroutine `MIE_SOAK_TWOSPH_WETGR()`. `mixingrulestring_icewater`, `matrixstring_icewater` and `inclusionstring_icewater` do the same for the ice-water shell in `MIE_SOAK_TWOSPH_WETGR()`.

Input- and output parameters are virtually the same as in subsubsection 5.3.9 on Page 45!

Example:

```
CALL MIE_MEAN_WETGR(2.3e-3, a_geo, b_geo, &
          0.45, m_w, m_i, 0.055, C_back, &
          'maxwellgarnett', 'ice', 'spheroidal', &
          'maxwellgarnett', 'water', 'spheroidal')
```

Example sensitivity studies:

Not shown in the present document.

5.3.11 SUBROUTINE MIE_SOAK_WETGR (x_g,a_geo,b_geo,fmelt,meltratio_outside,m_w,m_i,lambda,C_back, mixingrulestring, matrixstring, inclusionstring, hoststring, hostmatrixstring, hostinclusionstring)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)
DOUBLE PRECISION, INTENT(in)      :: x_g, lambda, a_geo, b_geo, fmelt
DOUBLE PRECISION, INTENT(in)      :: meltratio_outside
COMPLEX(kind=kinddp), INTENT(in) :: m_w, m_i
CHARACTER(len=*), INTENT(in)      :: mixingrulestring
CHARACTER(len=*), INTENT(in)      :: matrixstring
CHARACTER(len=*), INTENT(in)      :: inclusionstring
CHARACTER(len=*), INTENT(in)      :: hoststring
CHARACTER(len=*), INTENT(in)      :: hostmatrixstring
CHARACTER(len=*), INTENT(in)      :: hostinclusionstring
DOUBLE PRECISION, INTENT(out)     :: C_back
```

Description:

Backscatter cross section σ_b (Mie-scattering) of a melting graupel/snow particle, assumed as a **sphere composed of a homogeneous ice-water-air mixture material**. The bulk density (ice mass per particle volume) of the original unmelted particle is derived from the inverse mass-size-relation (40) with coefficients a_{geo} and b_{geo} assuming spherical shape. `fmelt` denotes the melted mass fraction or the degree of melting, f_{melt}, resp.

It is assumed that the particle melts partly on the outside and on the inside, within the ice structure, and that the meltwater is completely soaked and distributed homogeneously within the particle, displacing the air inclusions. The fraction of meltwater coming from the outside has to be preselected as input parameter `meltratio_outside` (between 0 and 1), which is the ratio when melting starts ($f_{melt} = 0$). Choosing `meltratio_outside` < 1 leads to larger particles compared to `meltratio_outside` $= 1$.

If f_{melt} is large enough (depending on bulk density and the actual `meltratio_outside`, see below), the meltwater completely fills the ice structure. Now the ice core melts homogeneously and the particle is assumed to be a homogeneous mixture of ice and water.

However, if `meltratio_outside` is sufficiently small, it could happen that the entire ice skeleton would be melted before all the air inclusions are filled with meltwater. Such particle would be unstable and splash into pieces sooner or later. To avoid this unrealistic asymptotic behaviour, the actual value of `meltratio_outside` increases linearily with growing f_{melt} from its value at $f_{melt} = 0$ (input parameter) to a value of 1 for $f_{melt} = 1$. In this way, the particle in any case converges to a water drop for $f_{melt} \to 1$.

Once the volume fractions of ice, water and air are derived based on the above assumptions, the effective refractive index of the particle is calculated by the function `get_m_mix_nested`, subsubsection 5.2.5. By proper choice of the input parameters `mixingrulestring`, `matrixstring`, `inclusionstring`, `hoststring`, `hostmatrixstring` and `hostinclusionstring`, the application of many different EMAs is possible, see subsubsection 5.2.5 on Page 28. Mie scattering is finally applied to calculate the backscattering cross section.

For small particles, the Rayleigh approximation can be applied instead to speed up the computation, by using subroutine `RAYLEIGH_SOAK_WETGR()` instead (subsubsection 5.3.12).

Input parameters:

`kinddp`	kind parameter for double precision
`x_g`	Mass of particle in kg (without air fraction)
`a_geo`	Coefficient a_{geo} of the inverse mass-size-relation (40)
`b_geo`	Coefficient b_{geo} of the inverse mass-size-relation (40)
`fmelt`	Degree of melting, $f_{melt} = x_w/x_g$ (x_w = mass of water contained in the particle)
`meltratio_outside`	Subpart ratio of the meltwater mass x_w which melts on the outside of the particle when melting starts ($f_{melt} = 0$). Value between 0 and 1. The complementary subpart of x_w is assumed to melt within the ice structure. The actual value depends on f_{melt} and increases linearily to 1 for $f_{melt} = 1$.
`m_w`	Complex refractive index of water
`m_i`	Complex refractive index of ice
`lambda`	Radar wavelength in m
`mixingrulestring`, `matrixstring`, `inclusionstring`, `hoststring`, `hostmatrixstring`, `hostinclusionstring`	see subroutine `get_m_mix_nested()`, subsubsection 5.2.5.

Output parameters:

`C_back`	Backscattering cross section σ_b in m^2

Example:

```
CALL MIE_SOAK_WETGR(2.3e-3, a_geo, b_geo, &
          0.45, 0.7, m_w, m_i, 0.055, C_back, &
          'maxwellgarnett', 'water', 'spheroidal', &
          'air', 'icewater', 'spheroidal')
```

Example sensitivity studies:

The dependence of σ_b on the degree of melting and on particle size for a specific temperature of $T = 5°C$ is studied in detail in subsequent sections for the 4 different inverse mass-size-relations given in Subsection 7.1. These are:

- for inverse mass-size-relation (36) in Subsection 8.13 on Page 102,
- for inverse mass-size-relation (37) in Subsection 8.14 on Page 103,
- for inverse mass-size-relation (38) in Subsection 8.15 on Page 104,
- for inverse mass-size-relation (39) in Subsection 8.16 on Page 105.

5.3.12 SUBROUTINE RAYLEIGH_SOAK_WETGR (x_g,a_geo,b_geo,fmelt,meltratio_outside,m_w,m_i,lambda,C_back, mixingrulestring, matrixstring, inclusionstring, hoststring, hostmatrixstring, hostinclusionstring)

```
INTEGER, PARAMETER                :: kinddp = KIND(1.0d0)

```

Description:

Backscatter cross section σ_b according to Rayleigh approximation of a melting graupel/snow particle, assumed as a **sphere composed of a homogeneous ice-water-air mixture material**. This subroutine uses the same principles to determine the effective refractive index of the melting particle as `MIE_SOAK_WETGR()` except that the backscattering cross section is calculated applying Rayleigh approximation instead of Mie-scattering. See subroutine `MIE_SOAK_WETGR()` in subsubsection 5.3.11 for further details.

Input- and output parameters the same as in subsubsection 5.3.11 on Page 48!

Example:

```
CALL MIE_SOAK_WETGR(2.3e-3, a_geo, b_geo, &
          0.45, 0.7, m_w, m_i, 0.055, C_back, &
          'maxwellgarnett', 'water', 'spheroidal', &
          'air', 'icewater', 'spheroidal')
```

Example sensitivity studies:

The dependence of σ_b on the degree of melting and on particle size for a specific temperature of $T = 5°C$ is studied in detail in subsequent sections for the 4 different inverse mass-size-relations given in Subsection 7.1. These are:

Description:

Backscatter cross section σ_b (Mie-scattering, two-layered sphere) of a melting soaked graupel/snow particle, assumed as a **spherical core of a homogeneous ice-water-air mixture material and a shell of a similar ice-water-air mixture material but with lower bulk density**.

This subroutine uses the same principles to determine the effective refractive index of the melting particle as `MIE_SOAK_WETGR()`, applied to core and shell. A further input parameter is the ratio between the outer and inner sphere radii, `radienverh`. The initial masses of the unmelted core and shell are derived from the inverse mass-size-relation (40) with coefficients a_{geo} and b_{geo} assuming spherical shape, in a similar way as in subroutine `MIE_DRYSNOW_TWOSPH()`, subsubsection 5.3.5. See subroutine `MIE_SOAK_WETGR()` in subsubsection 5.3.11 for further details. Note that the input parameter `meltratio_outside` from `MIE_SOAK_WETGR()` is termed `meltingratio_outside` here.

To calculate the backscattering coefficient of the two-layered spherical particle, the formulae of Bohren and Huffman (1983) are applied (subroutine `COATEDSPHERE_SCATTER_BH()`), see Subsection 4.4.

Input parameters:

`kinddp`	kind parameter for double precision
`x_s`	Mass of particle in kg (without air fraction)
`a_geo`	Coefficient a_{geo} of the inverse mass-size-relation (40)

`b_geo`	Coefficient b_{geo} of the inverse mass-size-relation (40)
`fmelt`	Degree of melting, $f_{melt} = x_w/x_s$ (x_w = mass of water contained in the particle). Same value for core and shell.
`meltingratio_outside`	Subpart ratio of the meltwater mass x_w which melts on the outside of the particle when melting starts ($f_{melt} = 0$). Value between 0 and 1. The complementary subpart of x_w is assumed to melt within the ice structure. The actual value depends on f_{melt} and increases linearily to 1 for $f_{melt} = 1$. Same value for core and shell.
`radienverh`	Ratio of the inner to the outer sphere radius
`m_w`	Complex refractive index of water
`m_i`	Complex refractive index of ice
`lambda`	Radar wavelength in m
`mixingrulestring_shell`, `matrixstring_shell`, `inclusionstring_shell`, `hoststring_shell`, `hostmatrixstring_shell`, `hostinclusionstring_shell`	Parameters determining the effective refractive index of the shell ice-water-air mixture material, see subroutine `get_m_mix_nested()`, subsubsection 5.2.5.
`mixingrulestring_core`, `matrixstring_core`, `inclusionstring_core`, `hoststring_core`, `hostmatrixstring_core`, `hostinclusionstring_core`	Parameters determining the effective refractive index of the core ice-water-air mixture material, see subroutine `get_m_mix_nested()`, subsubsection 5.2.5.

Output parameters:

`C_back`	Backscattering cross section σ_b in m^2

Example:

```
CALL MIE_WETSNOW_TWOSPH(2.3e-3, a_geo, b_geo, &
          0.45, 0.7, m_w, m_i, 0.055, 0.5, C_back, &
          'maxwellgarnett', 'water', 'spheroidal', &
          'maxwellgarnett', 'ice', 'spheroidal', &
          'air', 'icewater', 'spheroidal', &
          'water', 'water', 'spheroidal')
```

Example sensitivity studies:

The dependence of σ_b on the degree of melting and on particle size for a specific temperature of $T = 5°C$ is studied in detail in subsequent sections for the 2 different inverse mass-size-relations for snow given in Subsection 7.1. These are:

- for inverse mass-size-relation (38) in Subsection 8.19 on Page 108,
- for inverse mass-size-relation (39) in Subsection 8.20 on Page 138.

6 radar_mie_lm: Interface functions for the LM

As previously mentioned, the library radar_mie_lm provides interface routines for the LM to calculate Z_e as a sum of Integrals of the form equation (1) (Page 7) over the different hydrometeor types which are implemented into the LM microphysical schemes (cloud droplets, rain, cloud ice, snow, graupel and, depending on the scheme, hail). These interface functions call the subroutines for the basic particle properties m_{eff} and σ_b, which are provided by radar_mielib and were previously described in Section 5. For the particle size distributions, generalized gamma distributions are assumed for all hydrometeor types, which is consistent with the assumption in the bulk microphysical schemes of the LM. The parameters of these size distributions are derived from model variables (mass density, and in case of two-moment scheme, number density) consistent to the assumptions drawn for the applied microphysical scheme. Note that the exponential and gamma size distribution are a special case of the generatilzed gamma distribution.

For Mie-scattering as well as for Rayleigh approximation with general EMA approximation, the integration of Z_e is done over a finite size interval $[D_{min}; D_{max}]$ beeing prescribed in a reasonable way within the interface routines and beeing generally different for each hydrometeor category. There are also two much more efficient approaches implemented in radar_mielib utilizing Rayleigh approximation together with Oguchis EMA approximation, which enables analytical solutions of the reflectivity integral (see Subsection 6.2).

The degree of melting f_{melt} (melted mass fraction) of the single particles is estimated as a function of size and ambient temperature by a parameterization which will be presented in Subsection 6.1. Two important parameters of this parameterization, T_{min} and $f_{meltbegin}$ (see Subsection 6.1), are also specified in the interface routines in a reasonable way, but can certainly be changed by the user. Note that the estimated degree of melting can only be regarded as a very simplified and uncertain approximation since important information is not available for a more thorough description, e.g., the temperature and riming rate along the particle backward trajectories (the "melting history"). See Subsection 6.1 for a more detailed description.

The user can choose by appropriate settings of certain namelist parameters (described in Subsection 6.3), if full Mie-scattering or Rayleigh approximation with one of 3 different levels of simplification for m_{eff} of snow, graupel and hail is applied (see also Subsection 6.5 for an example of the relevant namelist parameters added to namelist GRIBOUT). These different levels of simplification can lead to largely different results for Z_e in case of melting hydrometeors, whereas in case of dry ice particles no significant differences are observed. The physical reason for this behaviour is that ice is only a weak dielectric whereas water is a strong dielectric (permanently polar molecules) so that the choice of a certain EMA-formulation becomes important primarily in the presence of water within a mixture particle.

6.1 An approximation for the degree of melting applicable for bulk microphysical schemes

This section describes a simple parameterization of the degree of melting f_{melt} (melted mass fraction) of hydrometeors, which can be used with bulk microphysical models which in turn do not explicitly predict the degree of melting. First of all, let us recall the definition of f_{melt},

$$f_{melt} = \frac{x_w}{x_{i,0}} \quad , \tag{24}$$

where x_w is the mass of meltwater and $x_{i,0}$ is the unmelted mass of the particle, only counting the ice fraction, not the enclosed air. Values for f_{melt} are in the range of $[0, 1]$. 0 means unmelted and 1 means fully melted.

Generally, f_{melt} depends on the time a certain particle has spent in a certain environment (T, riming rate, rate of turbulent heat transfer towards the particle, determined by, e.g., Reynolds number and particle surface roughness, etc.). This means that for an accurate calculation, the exact trajectory of each single particle has to be known together with a detailed solution of the equation of heat exchange of particles with the environment, considering also the feedback on the environmental temperature. In a numerical weather prediction model, this can hardly be done.

Therefore, to construct a parameterization f_{melt}, some assumptions have to be made to simplify the problem. We draw the following assumptions:

- In the environment, T decreases with height and no intense vertical motions are present, so that particles found at a specific time and place originate from regions above, not below.
- Every hydrometeor category can be assigned its own parameterization of f_{melt}, following the same master function (see below), but with different parameters.
- Within each hydrometeor class, the rate of heat exchange with the environment is a function of particle size only.
- It follows from the previous assumptions, that the particles all begin to melt at a certain temperature level T_{min}, e.g., 0°C or slightly below,
- that f_{melt} only depends on the environmental temperature T and particle diameter D,
- in particular that at a given temperature, f_{melt} is larger for smaller particles — we assume a simple dependence $f_{melt} \sim D^{-a}$ with $a > 0$.
- It is further assumed that below the height of a certain temperature level T_{max}, all particles are fully melted.

From these assumptions it follows that for a given environmental temperature there is a certain particle size D_{fm} at which the particles are just melted. Larger particles obey $f_{melt} < 1$. D_{fm} has to be 0 for $T = T_{min}$ and $D_{fm} \Rightarrow \infty$ for $T \Rightarrow T_{max}$. A simple *ansatz* for D_{fm} fulfilling these constraints is, for example, an inverse exponential formula with respect to temperature,

$$D_{fm}^a \;=\; D_{ref}^a \;\ln\left(\frac{T_{max} \;-\; T_{min}}{T_{max} \;-\; T}\right) \quad , \tag{25}$$

with $T_{min} \leq T < T_{max}$. The exponent a has been introduced here for later convenience. D_{ref} is a scaling parameter and has to be specified properly. D_{ref} represents the value of D_{fm} at a temperature $T = T_{1/e}$, where

$$T_{1/e} \;=\; T_{max} - \frac{1}{e}\,(T_{max} \;-\; T_{min}) \quad , \tag{26}$$

the e-folding value of T within the interval $[T_{min}, T_{max}]$.

Now, requiring that $f_{melt}(D_{fm}) = 1$ and $f_{melt} \sim D^{-a}$ immediately leads to

$$f_{melt} \;=\; \left(\frac{D_{fm}}{D}\right)^a \;=\; \left(\frac{D_{ref}}{D}\right)^a \ln\left(\frac{T_{max} \;-\; T_{min}}{T_{max} \;-\; T}\right) \;=\; \mathrm{fct}(D,T) \tag{27}$$

again for $T_{min} \leq T < T_{max}$. This function has to be limited to the codomain $f_{melt} \in [0,1]$ and extended to arbitrary temperatures by the constraints $f_{melt}(D_{fm}) = 0$ for $T < T_{min}$ and $f_{melt}(D_{fm}) = 0$ for $T < T_{max}$, which finally leads to the formulation

$$f^*_{melt} = \begin{cases} 0 & , \; T < T_{min} \\ \left(\frac{D_{ref}}{D}\right)^a \ln\left(\frac{T_{max} - T_{min}}{T_{max} - T}\right) & , \; T_{min} \leq T < T_{max} \\ 1 & , T \geq T_{max} \end{cases}$$

$$f_{melt} = \min[\, \max[\, f^*_{melt}\,, 0\,]\,, 1\,] \quad . \tag{28}$$

This formulation is intended to describe f_{melt} in a temperature regime in which the sensible heat flux from the environment to the particle is an important mechanism in enhancing the temperature of the particle. The parameter T_{min} denotes the temperature where this melting process starts. In that regime, the abovementioned assumptions leading to formula (27) may be more or less reasonable.

However, it may be desireable to also include the effects of melting at lower temperatures $T < T_{min}$ caused by high riming rates and too small a transfer of latent heat of freezing away from the particle, as it is sometimes observed for, e.g., high density graupel particles. This effect may be active for large particles in the temperature range of $-10 < T < 0°\mathrm{C}$. To this end, a simple extension to formula (27) is proposed, based on the (maybe contradictory) assumption that the effect on f_{melt} does not depend on particle size. Without a more sound theoretical basis, we would not dare to go any further than a linear dependence on size or a stepfunction, and we limit ourselves to the even simpler constance assumption above. Concerning the temperature dependence at fixed size, a linear *ansatz* is used.

Introducing the two new parameters T_{mb} and f_{tmin} (T_{mb} = Temperature, at which riming induced melting starts, f_{tmin} = degree of melting reached at T_{min}), the following extended formula

$$f^*_{melt} = \begin{cases} 0 & , \; T < T_{mb} \\ \frac{f_{tmin}}{T_{min} - T_{mb}}\,(T - T_{mb}) & , \; T_{mb} \leq T < T_{min} \\ (1 - f_{tmin})\left(\frac{D_{ref}}{D}\right)^a \ln\left(\frac{T_{max} - T_{min}}{T_{max} - T}\right) + f_{tmin} & , \; T_{min} \leq T < T_{max} \\ 1 & , T \geq T_{max} \end{cases}$$

$$f_{melt} = \min[\, \max[\, f^*_{melt}\,, 0\,]\,, 1\,] \tag{29}$$

is implemented into `radar_mie_lm`.

Formula (29) is used if $T_{mb} < T_{min}$ whereas the extension is switched off choosing $T_{mb} \geq T_{min}$, which leads to application of formula (28).

Figure 9 shows f_{melt} as function of T and D after formula (29) for an exemplaric parameter set of T_{mb}, T_{min}, T_{max}, f_{tmin} and D_{ref}, suitable for high density graupel or hail particles. It can be seen that a distinct transition between the riming- and environmental temperature-induced melting processes can be modeled by appropriate parameter settings of the parameterization (29).

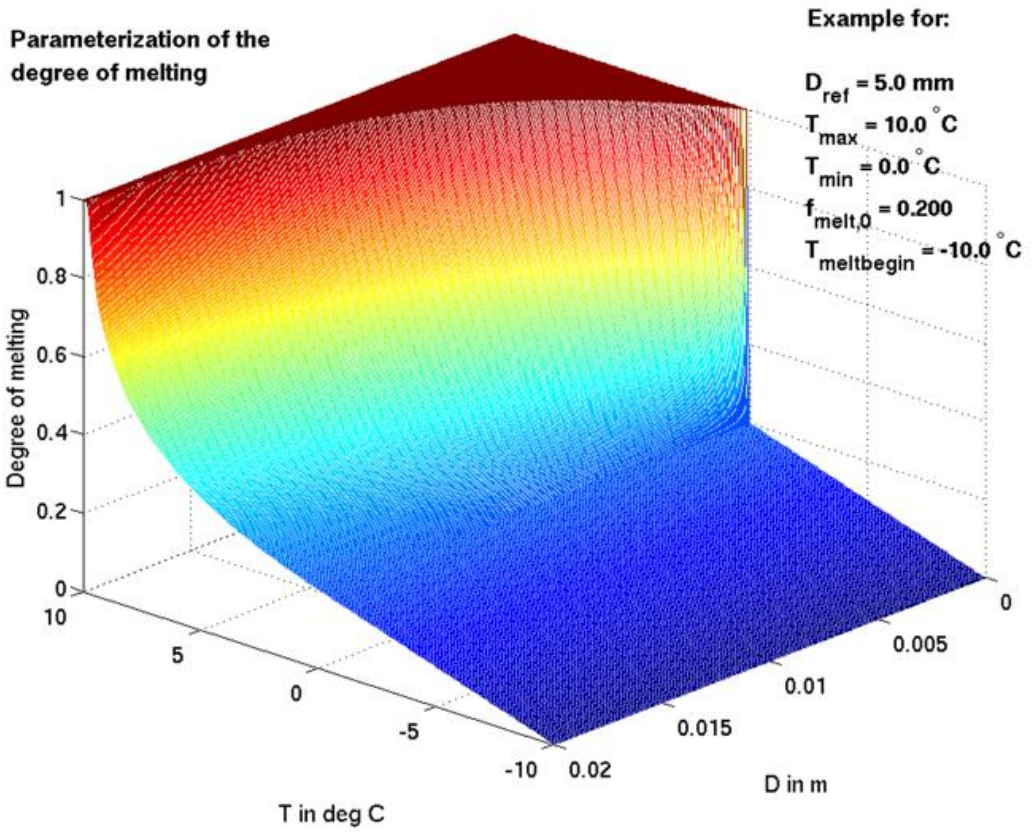

Figure 9: Parameterization function for the degree of melting f_{melt} as function of temperature in °C and particle diameter in mm for an exemplaric parameter set of formula (29), applicable to graupel or hail particles, see annotations. The exponent parameter a is 1.0.

The implementation into `radar_mie_lm` is as follows: for graupel- and hail particles, the parameters T_{mb} and f_{tmin} are set equal to the values annotated in Figure 9 by default. T_{min} is set to 0°C for all species. D_{ref} is chosen as min[6 mm, $\overline{D}(\overline{x})$], with $\overline{D}(\overline{x})$ beeing the mean mass spherical equivalent diameter of the particle spectrum. For snow- and cloud ice particles, the riming-induced melting is switched off by choosing $T_{mb} > T_{min}$ by default, and D_{ref} is the same as for graupel and hail. Based on explicit simulations of melting particles carried out with a spectral bin microphysical model (Hebrew University Cloud Model HUCM), the exponent a is chosen as 0.5 for snow and cloud ice, 0.6 for graupel and 0.8 for hail particles.

To give the user some more control over the riming-induced melting degree parameterization at $T < 0$°C, the parameters T_{mb} and f_{tmin} are available as namelist parameters for the snow-, graupel- and hail categories.

So far the parameter T_{max} remains to be discussed. This parameter denotes the temperature above which even the largest particles are assumed to be fully melted. From physical arguments it would seem reasonable to specify a fixed value (e.g., 10°C). However, there might be situations, e.g., strong convective downdrafts, in which the particles may "survive" longer. To account for this, a dynamic approach is chosen to make use of the information about the melting process and T_{max} which is provided by the melting parameterization of the cloud microphysical scheme itself: If there are particles of the specific type are present at locations with T exceeding the above fixed value, T_{max} is dynamically adjusted to the temperature of the lowest model height level where these melting hydrometeors are present. The fixed minimum value is presently chosen as 5°C for snow and cloud ice, 10°C for graupel and 20°C for hail. This is done every timestep at every horizontal gridpoint. This "precipitation-column"-approach should be reasonable in case of coarse numerical horizontal grid resolution and/or low windspeed. To prevent problems in case of high grid resolution and high windspeed, T_{max} is further set to its maximum value within a "search area" of 10 x 10 km^2 centered around each gridpoint, providing a certain degree of smoothing.

The following subroutines in `radar_mie_lm` are connected to the f_{melt}-parameterization:

- `degree_of_melting_fun()`:

  master function (29), input parameters are D, T_{mb}, T_{min}, T_{max}, f_{tmin} and D_{ref}. Output parameter is f_{melt}.

- `initialize_tmax()`:

  Determination of T_{max}, separately for every hydrometeor category.

- Subroutines which itself call `degree_of_melting_fun()` with suitable input parameter sets for each hydrometeor type:

  - `degree_of_melting_ice()`, `degree_of_melting_ice_sb()`
  - `degree_of_melting_snow()`, `degree_of_snow_hail_sb()`
  - `degree_of_melting_graupel()`, `degree_of_graupel_hail_sb()`
  - `degree_of_melting_hail()`, `degree_of_melting_hail_sb()`

The results of the reflectivity calculations using the presented parameterization for f_{melt} look qualitatively promising for stratiform precipitation (radar "bright band"), but there will almost certainly be problems in case of deep convective events. It has to be mentioned, too, that up to now no attempt to verify or calibrate the formula (29) and its parameters has been undertaken aside the abovementioned tests using the HUCM bin microphysical model. Therefore, the above parameterization remains speculative to some degree. However, since almost no suitable measurements of the degree of melting in clouds are existing, the verification/calibration would have to rely on further simulations with HUCM or on a suitable detailed Lagrangian melting model. But even such a Lagrangian model would require

certain assumptions on the vertical and horizontal structure of precipitation and horizontal and vertical windspeed and therefore it is unclear whether the results of such a verification/calibration approach would be applicable in general.

6.2 An efficient Rayleigh-Approximation for melting hydrometeors with Oguchis refractive index formulation

There is a nice closed analytical solution for Z_e in Rayleigh approximation if a generalized gamma distribution is assumed for the particle mass distribution and Oguchis EMA formula for m_{eff} with shape factor $u = 2$ (equation (16) on Page 15) is applied. A further precondition is that the same degree of melting is assumed for all particles, regardless of their size. However, this EMA approximation is not valid in case of a mixture of strong and/or strongly differing dielectric materials, as is the case with melting hydrometeors.

Nevertheless, this approach is implemented into `radar_mie_lm` because of its computational efficiency. It has to be remembered that it can be safely applied for rain and for dry ice particles but may lead to much too small reflectivity values for melting hydrometeors.

Now, recalling that the dielectric factor K in the Rayleigh approximation equals $(\epsilon-1)/(\epsilon+2)$, Oguchis formula (16) with $u = 2$ for the effective refractive index of an ice-water-air mixture reads

$$\begin{aligned} \frac{\epsilon_{eff}-1}{\epsilon_{eff}+2} &= \frac{\epsilon_i-1}{\epsilon_i+2}\,p_i + \frac{\epsilon_w-1}{\epsilon_w+2}\,p_w + \frac{\epsilon_a-1}{\epsilon_a+2}\,p_a \\ K_{eff} &= K_i\,p_i + K_w\,p_w + K_a\,p_a \quad , \end{aligned} \tag{30}$$

where indices i, w, a and s denote ice, air, water and the mixture particle, and p_i, p_w, p_a are the respective volume fractions. Since

$$p_x = \frac{V_x}{V} = \frac{m_x}{\rho_x V} \qquad x \in i,w,a \quad , \tag{31}$$

where V_X is partial volume of material x, V is total particle volume, m_x is partial mass of material x and ρ_x is the material's density, equation (30) can be rewritten to

$$K_{eff} = \frac{1}{V}\left(K_i\,\frac{m_i}{\rho_i} + K_w\,\frac{m_w}{\rho_w} + K_a\,\frac{m_a}{\rho_a}\right) \quad . \tag{32}$$

To a very good approximation, $K_a = 0$, and using the definition of partial densities $\rho_{p,s} = m_i/V$ and $\rho_{p,w} = m_w/V$,

$$K_{eff} = K_i\,\frac{\rho_{p,s}}{\rho_i} + K_w\,\frac{\rho_{p,w}}{\rho_w} \quad . \tag{33}$$

K_x are complex numbers, $K_x = K_{x,r} + i\,K_{x,i}$, so the square of the modulus of K_{eff} is

$$|K_{eff}|^2 = |K_i|^2\left(\frac{\rho_{p,s}}{\rho_i}\right)^2 + |K_w|^2\left(\frac{\rho_{p,w}}{\rho_w}\right)^2 + 2\,\frac{\rho_{p,s}\rho_{p,w}}{\rho_i\rho_w}\left(K_{i,r}K_{w,r} + K_{i,i}K_{w,i}\right) \quad . \tag{34}$$

Defining $x = m_i + m_w$ as mass of a melting particle without its air contribution and f_{melt} as its degree of melting, so that $m_i = (1 - f_{melt})x$ and $m_w = f_{melt}x$, the Rayleigh reflectivity (equation (5)) for a population of melting particles is

$$
\begin{aligned}
Z_e &= \frac{1}{|K_{w,0}|^2} \int_0^\infty |K_{eff}|^2 \, D^6 \, N(D) \, dD \\
&= \frac{1}{|K_{w,0}|^2} \int_0^\infty |K_{eff}|^2 \, D(x)^6 \, N(x) \, dx \\
&= \frac{1}{|K_{w,0}|^2} \left[\frac{|K_i|^2}{\rho_i^2} \int_0^\infty \left(\frac{6V}{\pi}\right)^2 \frac{m_i^2}{V^2} \, N(x) \, dx + \right. \\
&\quad \left. \frac{|K_w|^2}{\rho_w^2} \int_0^\infty \left(\frac{6V}{\pi}\right)^2 \frac{m_w^2}{V^2} \, N(x) \, dx + 2 \, \frac{K_{i,r}K_{w,r} + K_{i,i}K_{w,i}}{\rho_i \rho_w} \int_0^\infty \left(\frac{6V}{\pi}\right)^2 \frac{m_i m_w}{V^2} \, N(x) \, dx \right] \\
&= \frac{6^2}{\pi^2 \, |K_{w,0}|^2} \left[\frac{|K_i|^2}{\rho_i^2} \int_0^\infty (1 - f_{melt})^2 \, x^2 \, N(x) \, dx + \right. \\
&\quad \left. \frac{|K_w|^2}{\rho_w^2} \int_0^\infty f_{melt}^2 \, x^2 \, N(x) \, dx + 2 \, \frac{K_{i,r}K_{w,r} + K_{i,i}K_{w,i}}{\rho_i \rho_w} \int_0^\infty f_{melt} \, (1 - f_{melt}) \, x^2 \, N(x) \, dx \right] \\
&= \frac{6^2}{\pi^2 \, |K_{w,0}|^2} \left[\frac{|K_i|^2}{\rho_i^2} \, (1 - f_{melt})^2 + \frac{|K_w|^2}{\rho_w^2} \, f_{melt}^2 + 2 \, \frac{K_{i,r}K_{w,r} + K_{i,i}K_{w,i}}{\rho_i \rho_w} \, f_{melt} \, (1 - f_{melt}) \right] M_2 \quad ,
\end{aligned}
\tag{35}
$$

where M_2 denotes the second moment of the particle mass distribution function. The last equality in equation (35) is only valid if all particles obey the same degree of melting, independent of their size. equation (35) is especially attractive since it only envolves the calculation of the second moment with respect to mass, which in most cases is far more efficient since, for certain types of distribution functions $N(x)$ (e.g., generalized gamma distribution), M_2 can be written in closed analytical form.

Note, however, that a systematical underestimation of Z_e might possibly occur, since it is assumed here (as in all other routines of `radar_mie_lm`) that the mass of meltwater is contained in the particle mass x and the second moment M_2, which contrasts the treatment of melting in most microphysical schemes, where the meltwater is (partially or completely) shedded to rainwater.

6.3 Controlling reflectivity calculations in LM — relevant namelist parameters and their setting

To enable output of radar reflectivity in LM, the user simply has to specify the output variable `'dBZ'` within the list of output variables in the `GRIBOUT`-namelist. `'dBZ'` is implemented for model level output as well as for pressure-level- or height-level interpolation. In case of interpolated output, the reflectivity is calculated first on model levels and subsequently interpolated to output pressure/height levels. In standard LM, the interpolation is done by cubic tension splines. However, reflectivity is a positive definite quantity and can vary over several orders of magnitude between adjacent grid points. In this case, cubic splines can lead to serious undershoots producing negative values. We therefore changed the interpolation in

our LM version to simple linear interpolation, but unfortunately this is not available in the operational LM version.

Once reflectivity output is chosen, the basic namelist parameter to control the kind of reflectivity calculation is

- `dbz%itype_refl`, namelist `GRIBOUT` (`INTEGER`: 1, 2, 3, or 4).

The radarwavelength can be specified by

- `dbz%lambda_radar`, namelist `GRIBOUT` (`REAL`).

To choose the parameters of the parameterization for the degree of melting in Subsection 6.1, which influence the riming-induced melting for $T < 0°C$ (namelist `GRIBOUT`, `REAL`):

- `dbz%Tmeltbegin_s` (T_{mb} for snow)
- `dbz%meltdegTmin_s` (f_{tmin} for snow)
- `dbz%Tmeltbegin_g` (T_{mb} for graupel)
- `dbz%meltdegTmin_g` (f_{tmin} for graupel)
- `dbz%Tmeltbegin_h` (T_{mb} for hail; only for `itype_gscp` $\geq$ 2000)
- `dbz%meltdegTmin_h` (f_{tmin} for hail; only for `itype_gscp` $\geq$ 2000)

To further choose different EMA approximations of m_{eff} for different hydrometeor types, the following namelist parameters apply (namelist `GRIBOUT`, `CHARACTER(len=12)`):

- `dbz%ctype_drysnow_mie`
- `dbz%ctype_wetsnow_mie`
- `dbz%ctype_drygraupel_mie`
- `dbz%ctype_wetgraupel_mie`
- `dbz%ctype_dryhail_mie` (only for `itype_gscp` $\geq$ 2000)
- `dbz%ctype_wethail_mie` (only for `itype_gscp` $\geq$ 2000)
- `dbz%ctype_drysnow_ray`
- `dbz%ctype_wetsnow_ray`
- `dbz%ctype_drygraupel_ray`
- `dbz%ctype_wetgraupel_ray`
- `dbz%ctype_dryhail_ray` (only for `itype_gscp` $\geq$ 2000)
- `dbz%ctype_wethail_ray` (only for `itype_gscp` $\geq$ 2000)

Their setting depends in turn on `dbz%itype_refl`. The listing below and the subsequently linked tables show the different possible combinations of these parameters and the corresponding `radar_mielib` functions which are used to calculate radar reflecitvity.

Further, in case of graupel particles and application of Mie-scattering (`dbz%itype_refl=1`), the namelist parameter `dbz%igraupel_type` (=1, 2, or 3) provides three possibilities for the melting model of graupel, see the listing below.

In case of melting hydrometeors, the degree of melting is derived from the parameterization described in Subsection 6.1 before calculating reflectivity according to the following listing.

The followin listing shows combinations of the namelist parameter `dbz%itype_refl` with the other namelist parameters mentioned previously in this section. The links in the right column lead to the description of the corresponding `radar_mielib` subroutine and to subsequent tables which describe in detail the possible settings of the corresponding namelist parameter for the EMA approximation:

- `dbz%itype_refl` = **1:**

  Mie scattering, general EMA approximation

  - **Cloud drops:**
    Rayleigh approximation, analytical solution of (5)
  - **Cloud ice:**
    dry / melting: Rayleigh approximation (35) with EMA after Oguchi
  - **Rain:**
    Mie scattering, numerical solution using (3): `SPHERE_SCATTER_BH()`
  - **Snow:**
    dry ($T \leq 0°C$):
    `MIE_DRYSNOW_TWOSPH()` — `dbz%ctype_drysnow`: 6-character code, composed of two 3-character codes after Table 38 for core and shell, resp.

    melting ($T > 0°C$):
    `MIE_WETSNOW_TWOSPH()` — `dbz%ctype_wetsnow`: 12-character code, composed of two 6-character codes after Table 40 for core and shell, resp.
    `meltingratio_outside` = 0.7
    `radienverh` = 0.5

  - **Graupel:**
    dry ($T \leq$ -10°C):
    `MIE_DRY_GRAUPEL()` — `dbz%ctype_drygraupel`

    melting ($T >$ -10°C):
    depends on namelist parameter `dbz%igraupel_type`:
    - `dbz%igraupel_type` = 1:
      `MIE_SOAK_WETGR()` — `dbz%ctype_wetgraupel`
      `meltratio_outside` = 0.7
    - `dbz%igraupel_type` = 2:
      `MIE_SOAK_TWOSPH_WETGR()` — `dbz%ctype_wetgraupel`
    - `dbz%igraupel_type` = 3:
      `MIE_WATERSPH_WETGR()` — `dbz%ctype_wetgraupel`

  - **Hail:**
    dry ($T > 0°C$): `MIE_DRY_GRAUPEL()` — `dbz%ctype_dryhail`
    melting ($T \leq 0°C$): `MIE_SPONGY_WETHAIL()` — `dbz%ctype_wethail_ray`
    `fwater` = 0.5

- `dbz%itype_refl` = **2:**

  Rayleigh approximation with general EMA approximation

  - **Cloud drops:**
    Rayleigh approximation, analytical solution of (5)

- **Cloud ice:**
  dry / melting:Rayleigh approximation with EMA after Oguchi
- **Rain:**
  Rayleigh approximation, analytical solution of (5)

- **Snow:**
  dry ($T > 0°C$):
  `RAYLEIGH_DRY_GRAUPEL()` — `dbz%ctype_drysnow_ray`

  melting ($T \leq 0°C$):
  `RAYLEIGH_SOAK_WETGR()` — `dbz%ctype_wetsnow_ray`

- **Graupel:**
  dry ($T \leq$ -10°C):
  `RAYLEIGH_DRY_GRAUPEL()` — `dbz%ctype_drygraupel_ray`

  melting ($T >$ -10°C):
  `RAYLEIGH_SOAK_WETGR()` — `dbz%ctype_wetgraupel_ray`

- **Hail:**
  dry ($T \leq 0°C$):
  `RAYLEIGH_DRY_GRAUPEL()` — `dbz%ctype_dryhail_ray`

  melting ($T > 0°C$):
  `RAYLEIGH_SOAK_WETGR()` — `dbz%ctype_wethail_ray`

- `dbz%itype_refl` = **3:**

  Rayleigh approximation with EMA after Oguchi for cloud ice, snow, graupel and hail (analytical formula from Subsection 6.2), Rayleigh approximation (5) for cloud droplets and rain drops.

- `dbz%itype_refl` = **4:**

  Very simple and efficient Rayleigh approximation from `pp_utilities.f90` for all particles, crude description of melting particles

6.4 Tables of namelist parameter settings for the EMA choice

Table 38: 3-character Coding of the namelist-parameters `dbz%ctype_XXX` for two-component ice-air mixture materials and different EMA approximations, controlling the keywords of function `get_m_mix()`. Question marks denote wildcards for arbitrary characters.

mixingrulestring (1. character)	matrixstring (2. character)	inclusionstring (3. character)	ctype-Code
'bruggemann' -- 'b'	N/A	N/A	'b??'

```

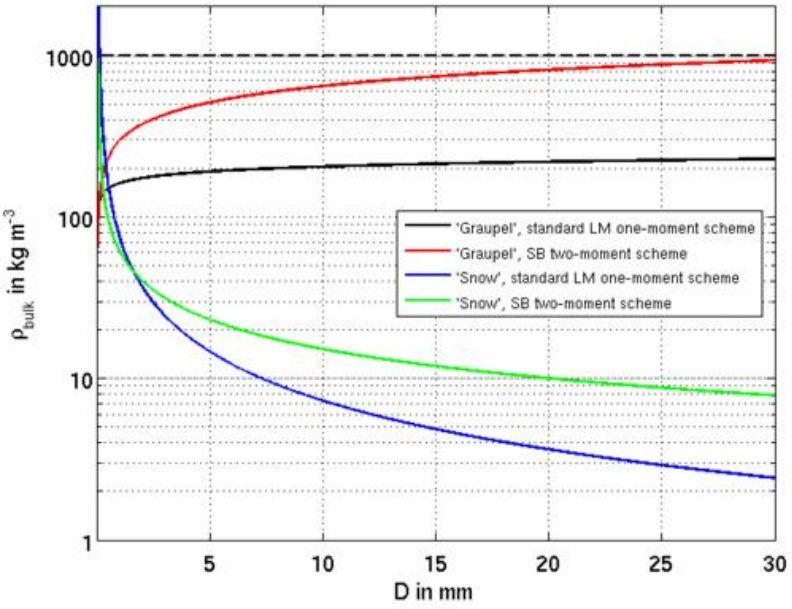

Figure 10: Bulk density of snow/graupel particles in $\mathrm{kg\,m^{-3}}$ as funktion of sphere equivalent diameter in mm, deduced from the 4 different inverse mass-size-relations presented in equations (36), (37), (38) and (39).

7 Backscattering cross sections of dry ice particles

We now turn to a more detailed investigation on the backscattering properties of single precipitation particles. In this section, the focus is on results for dry ice particles. In later sections, similar investigations will also be presented for melting ice particles.

For dry ice particles, basically two different particle models are available in `radar_mielib` if Mie-scattering is assumed. These are the one-layered ordinary sphere (suitable, e.g., for graupel and hail particles) and the two-layered sphere (e.g., for snow flakes). With Rayleigh scattering, only one-layered spheres are accounted for, since the Rayleigh approximation is an approximation to the Mie scattering functions for ordinary spheres.

In the following, the two different particle models are briefly described, together with a short examination of the differences in Z_e which they produce for the **C-Band radar wavelength $\lambda_0 = 5.5$ cm.**

7.1 One-layered sphere

In this section, the differences in Z_e caused by the application of different EMAs in case of different particle bulk densities is examined at $\boldsymbol{\lambda_0 = 5.5}$ **cm (C-Band)** to provide a qualitative guideline what to expect from what combination of these settings. The focus here is on dry ice particles which are assumed to be one-layered spheres of a homogeneous two-compontent mixture of ice and air. This particle model should be applicable to graupel and hail particles and in case of Rayleigh approximation, it has to be applied to all kinds of ice particles.

To this end, backscatter cross sections of graupel particles were calculated as a function of particle diameter by the `radar_mielib` subroutine `MIE_DRY_GRAUPEL()` (subsubsection 5.3.1) or, in case of Rayleigh approximation, by subroutine `RAYLEIGH_DRY_GRAUPEL()` (subsubsection 5.3.2). This was done for two different temperatures (T = -10°C, T = -20°C) and for

the mixing rules presented in subsubsection 4.5.4, applied to a two-component mixture. To show the dependence on particle bulk density (important to deduce the volume fractions of ice and air for the EMAs), this parameter is derived alternatively from the four inverse mass-size-relations

$$\frac{D}{D_0} = 0.19091 \left(\frac{x}{x_0}\right)^{0.32258} \quad \text{("Graupel", standard LM one-moment scheme)} \tag{36}$$

$$\frac{D}{D_0} = 0.11 \left(\frac{x}{x_0}\right)^{0.3} \quad \text{("Graupel", SB two-moment scheme)} \tag{37}$$

$$\frac{D}{D_0} = 5.12989 \left(\frac{x}{x_0}\right)^{0.5} \quad \text{("Snow", standard LM one-moment scheme)} \tag{38}$$

$$\frac{D}{D_0} = 1.33398 \left(\frac{x}{x_0}\right)^{0.41667} \quad \text{("Snow", SB two-moment scheme)} \quad , \tag{39}$$

assuming equivalent spherical particles. x is the particle mass (without the mass of the enclosed air), D its diameter and x_0 and D_0 are constant scaling parameters of 1 kg and 1 m, resp. The general form of the inverse mass-size-relation used throughout this document is

$$\frac{D}{D_0} = a_{geo} \left(\frac{x}{x_0}\right)^{b_{geo}} \quad , \tag{40}$$

with a_{geo} and b_{geo} beeing dimensionless constants.

equation (36) and (38) are taken from the operational one-moment bulk microphysical scheme of the LM, and equation (37) and (39) from the two-moment bulk microphysical scheme of Seifert and Beheng (2006). Figure 10 presents the resulting particle bulk densities as function of size and shows that, with these 4 different relations, nearly the whole range of possible bulk densities occuring in nature is covered.

For the refractive index of ice, the model of Mätzler (1998) (cf. Figure 6 on Page 13) is used in the following.

The results (Figure 11) show that there is no substantial difference at the two assumed temperatures. In addition, all applied mixing rules lead to nearly the same backscattering cross section for a given particle (the variation range of σ_b for different EMAs is less than 3 dB — a factor of two — which is not much). Considerable differences occur for larger particles when Rayleigh scattering is assumed instead of Mie scattering. Most important, the backscattering cross section shows a strong increase with particle bulk density, as shown by the four different used mass-size-relations.

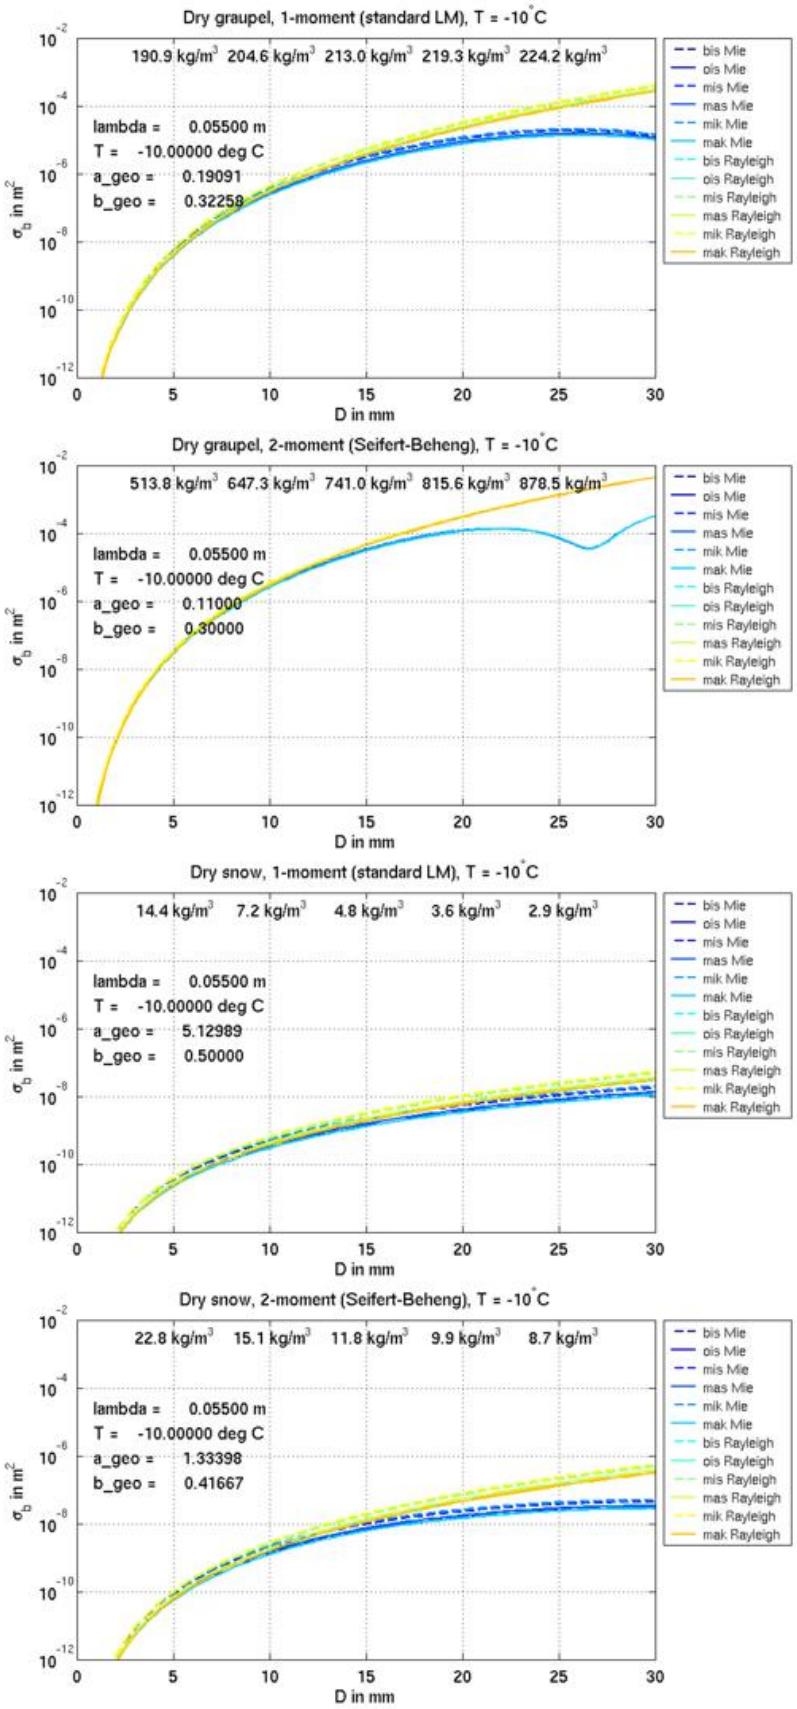

Figure 11: Backscattering cross section σ_b in m^2 as a function of particle diameter, EMA (see legend and explanation in Table 38 in combination with section 5.2.4) for T = -10°C. **Panels from top to bottom:** Graupel with mass-size-relation (36) from the LM standard microphysics scheme, graupel from Seifert and Beheng two-moment scheme (equation (37)), snow from the LM standard scheme (equation (38)), snow from the two-moment scheme (equation (39)).

7.2 Two-layered sphere

Backscattering cross sections for a two-layered sphere (cf. Figure 1 on Page 10) were calculated by using the `radar_mielib` subroutine `MIE_DRYSNOW_TWOSPH()` (subsubsection 5.3.5). Here, an additional important parameter is the ratio between the inner sphere and outer sphere radii. This ratio has to be preset and is a fixed input parameter for subroutine `MIE_DRYSNOW_TWOSPH()`. Without loss of generality, a value of 0.5 is used throughout `radar_mie_lm`, but this can be changed by the user. As mentioned before, this model is applicable to snow particles, as shown by, e.g., Fabry and Szyrmer (1999).

A similar comparison as presented in the last Subsection 7.1 is repeated here for snow particles of two different mass-size-relations as a function of particle diameter, temperature and mixing rule. The inverse mass-size-relations were given earlier in equation (38) and (39) in Subsection 7.1.

For the refractive index of ice, again the model of Mätzler (1998) (cf. Figure 6 on Page 13) is used in the following.

A comment is necessary on the derivation of the particle bulk densities in the inner and outer spherical shells. Note that for snow flakes, it is observed that the bulk density usually decreases with size, reflected by the mass-size-relations found in literature. To explain this behaviour, Fabry and Szyrmer (1999) present an interesting *Gedankenexperiment*: Snow flakes preferably form by aggregation of smaller ice and snow particles. Thats why they are called "aggregates" in technical terms. Consider now without loss of generality a population of equally sized snow flakes having equal bulk density. Through collision and sticking, larger flakes are formed. In the extreme case of flakes aggregating around a single "embryonal flake" in dense sphere packing, the resulting flake would be double in diameter with a nearly equal but slightly lower bulk density. In reality, this dense packing will almost never be fully realised and there will always be some voids causing the overall bulk density to be even lower. Generalization to an initial population of differently sized snow flakes, the outcome will always be a decreasing mean bulk density with snow flake diameter.

To model this, the bulk densities of the inner and outer shell of the two-layered spherical particles are calculated in the following way: Given a fixed mass-size-relation representing a decreasing bulk density with diameter, a certain snowflake diameter and an assumed ratio of inner to outer shell diameter (e.g., 0.5), at first the inner core is assigned the density found by applying the inner sphere diameter within the mass-size-relation. Then, given the total mass by applying the outer sphere diameter within the mass-size-relation, the mass of the outer spherical shell is just the difference of total mass minus mass of inner sphere. From this and the preset and fixed ratio of inner to outer sphere radius, the bulk density of the outer shell can be calculated.

From the bulk densities of core and shell, the corresponding volume fractions of ice and air are calculated further. To get m_{eff} of core and shell, the volume fractions are plugged into the different formulas for the EMA approximations presented earlier in this document. Table 38 gives the 6 possible different settings for an ice-air mixture material (cf. subsubsection 5.2.4). With this, backscattering coefficients are calculated as function of size and all implemented combinations of EMA approximations for core and shell ($6 \times 6 = 36$) . This was done for both inverse mass-size relations mentioned earlier in this section. In all cases, the temperature was set to -10°C.

Figure 12 shows the results for both mass-size relations in a simplified way (upper panel: relation (38), lower panel: relation (39)). In each figure, the blue "strip" marks the envelope (variation range) of σ_b as function of size and EMA for the two-layered Mie calculation. For

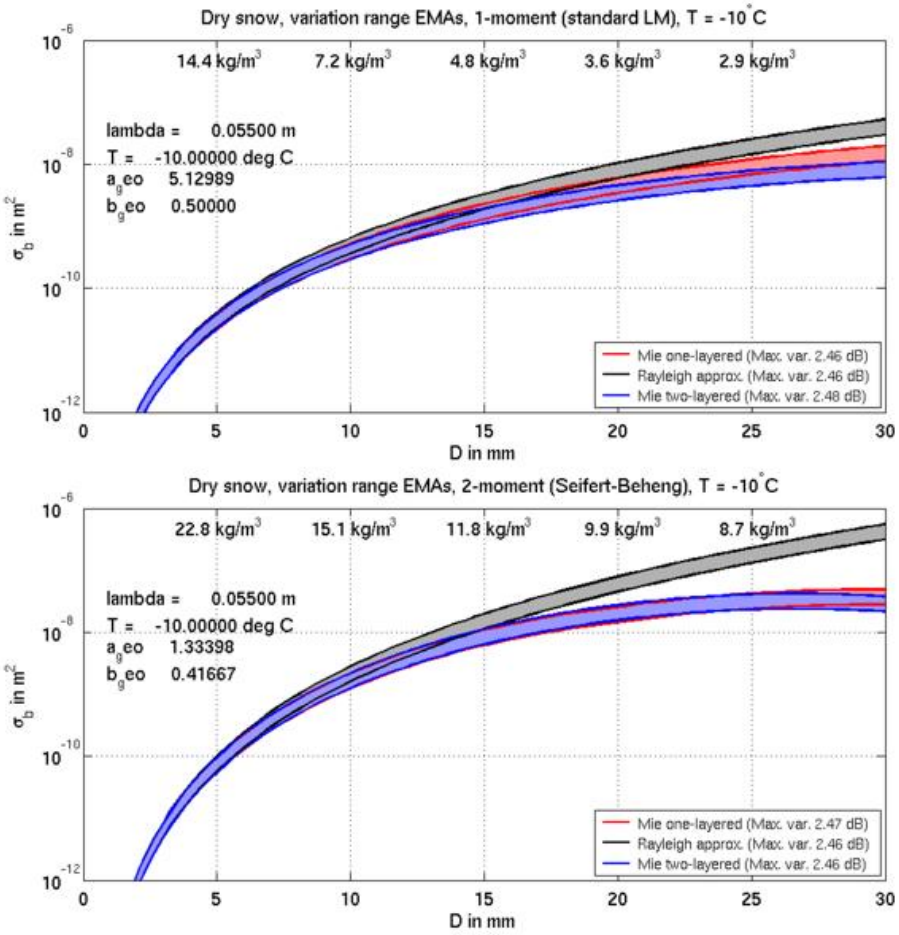

Figure 12: Variation range of Backscattering cross section σ_b for snow in m^2 as a function of particle diameter considering all possible combinations of the implemented EMAs for a two-layered sphere at T = -10°C. See text for explanation. **Upper panel:** Snow with mass-size-relation (38) from the LM standard microphysics scheme, **lower panel:** snow from Seifert and Beheng two-moment scheme (equation (39)).

comparison, the red "strip" gives the corresponding results considering Mie scattering by simple spheres only (6 different EMA approximations), and further applying Rayleigh approximation leads to the grey "strip". It is found that imposing different EMA-approximations leads to only moderate variations of σ_b for a given size. This can be explained by the fact that ice is weak dielectric only and nearly every different choice of an EMA approximation leads to the nearly the same m_{eff}. Moreover, in case of $\lambda_0 = 5.5$ cm as considered here, for particles with $D < 15$ mm it does not make a large difference if choosing a two-sphere particle model or simple spheres, or if choosing an even simpler Rayleigh approximation. For larger particles, the two-sphere model produces slightly smaller backscattering cross sections than the simple sphere model (larger difference for less dense particles) and the Rayleigh approximation becomes unrealistic.

As a result, considering the large numerical effort, application of Mie scattering for dry snowflakes makes sense in case for large snowflakes whereas a further complication by using the two-layered sphere model seems to be unnecessary in this case.

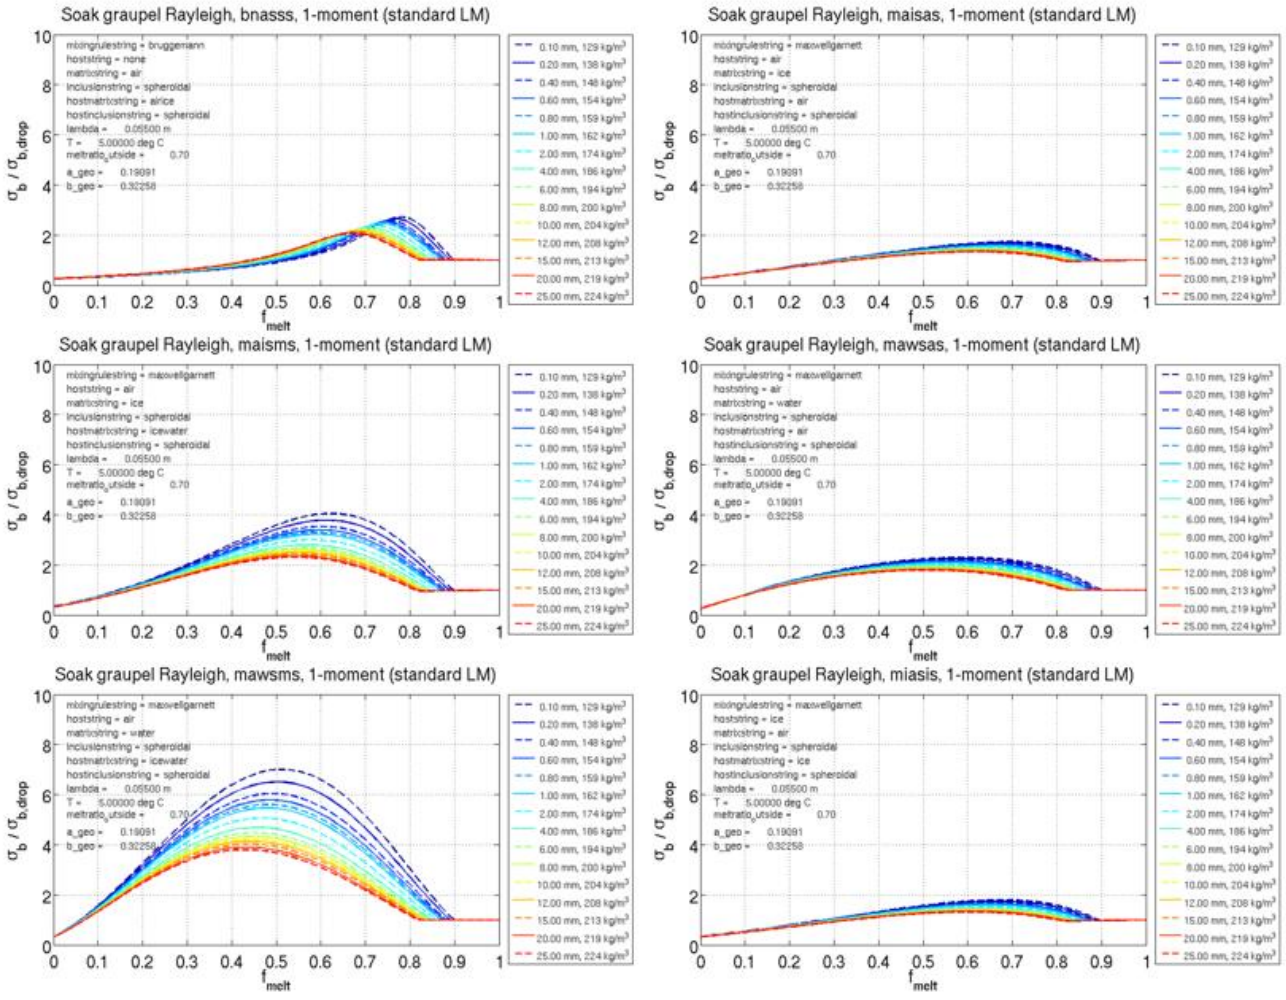
However, it will be shown in the next section that in case of melting snowflakes, the two-layered sphere model leeds to significantly different results compared to simple spheres.

8 Backscattering cross sections for melting ice particles relative to the mass-equivalent water drop

For melting ice particles, the presence of water (a strong dielectric) within the ice structure of melting particles poses a particular problem when it comes to the proper choice of an effective medium approximation. In fact, is there a proper choice at all? The answer to this question stronly depends on the mixture topology of the ice-water-air mixture. Whereas for nearly solid hail it seems quite easy, the structure of melting intermediate- or low-density graupel or snowflakes is more difficult to treat.

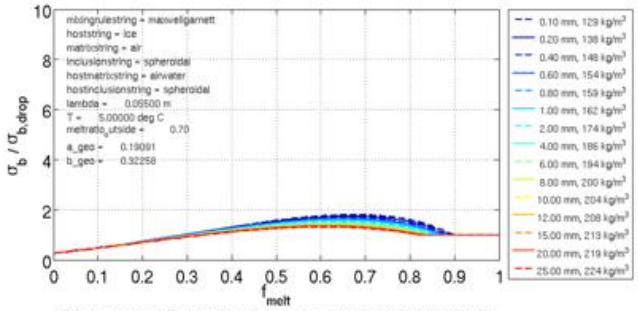
Therefore, `radar_mielib` and `radar_mie_lm` provide no definite answer (the one and only solution) but permit the user to choose between many different possibilities to get a feeling for the range of uncertainty of the resulting reflectivity value. However, there are theoretical and experimental results presented in literature providing guidelines which EMA formulation and particle model should work better for certain hydrometeor types. Some basic discussion was presented earlier in the sections describing different EMA approximations For more detailed informations, the reader is kindly referred to the corresponding literature. A starting point could be, e.g., the book of Bohren and Huffman (1983) and a number of subsequent articles by C. Bohren and coauthors. The literature is so numerous that we omit further citing here.

For LM users, the "hints" and guidelines from literature are reflected by reasonable default parameter values for the corresponding subroutines in `radar_mie_lm`, which can, of course, be changed. And to provide some guideline about what happens to Z_e if the default parameter settings are changed, the following sections provide a detailed sensitivity investigation of the backscattering cross sections of melting hydrometeors considering all possible parameter settings for the most basic particle models implemented into `radar_mielib`.



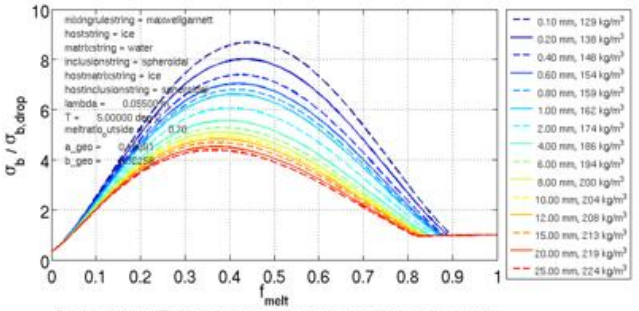
To this end, the same 4 different inverse mass-size relations as in Subsection 7.1 are applied to deduce the mass of the initally unmelted particle which is varied from small to large values. Subsequent variation of the degree of melting f_{melt} and the particle model together with the EMA approximation leads to a very large compilation of results which is presented in the following subsections.

The results apply to a **C-Band radar wavelength of $\lambda_0 = 5.5$ cm and to a temperature of 5°C.**



8.1 Rayleigh: soaked wet graupel, LM-scheme

Results are shown for calculations of the backscattering cross section σ_b with subroutine `RAYLEIGH_SOAK_WETGRAUPEL()` (Rayleigh approximation), see subsubsection 5.3.12 on Page 50. The following figures show the ratio of σ_b to the backscattering cross section $\sigma_{b,drop}$ of the resulting water drop, if the particle would be completely melted, as function of f_{melt} and the unmelted particle diameter for different EMA-formulations of the particles effective refractive index m_{eff}. The particle bulk density as function of size is determined by equation (36) on Page 69. A depiciton of the resulting bulk density as function of particle size can be found in Figure 10 (black solid line).



Every figure represents one particular EMA-formulation for m_{eff}, which is obtained by using function `get_m_mix_nested()` (subsubsection 5.2.5 on Page 28). The input parameter set for `get_m_mix_nested()` can be found in the text annotation within each graph. For users of the LM, the corresponding setting of the namelist-parameter `ctype_wetgraupel_ray` can be found as 6-character code in the figures title. For explanation of this code, see Table 40. The results of this section apply to the LM for graupel and snow particles in case of application of the standard one-moment bulk microphysical scheme (namelist-parameter `itype_gscp` $<$ 100) together with `itype_refl` $= 2$.

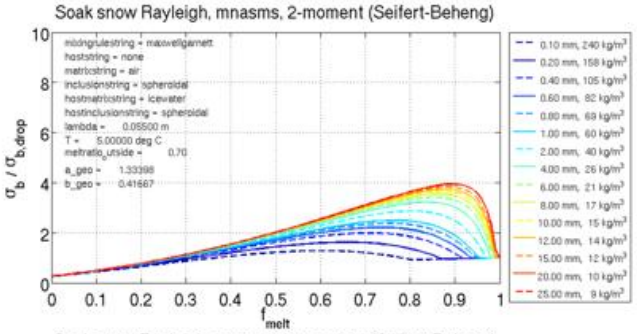
8.4 Rayleigh: soaked wet snow, Seifert/Beheng-scheme

Similar to Subsection 8.1, results are shown for calculations of the backscattering cross section σ_b with subroutine `RAYLEIGH_SOAK_WETGRAUPEL()` (Rayleigh approximation), see subsubsection 5.3.12 on Page 50, but this time the particle bulk density as function of size is determined by equation (39) on Page 69. A depiciton of the resulting bulk density as function of particle size can be found in Figure 10 (green solid line). The following figures show the ratio of $\sigma_b/\sigma_{b,drop}$ as function of f_{melt} and the unmelted particle diameter for different EMA-formulations of the particles effective refractive index m_{eff}.



Again, every figure represents one particular EMA-formulation for m_{eff}, which is obtained by using function `get_m_mix_nested()` (subsubsection 5.2.5 on Page 28). The input parameter set for `get_m_mix_nested()` can be found in the text annotation within each graph. Although not beeing implemented into the LM interface functions for snow, the corresponding setting of the namelist-parameter `ctype_wetsnow_ray` (in analogy to `ctype_wetgraupel_ray`) can be found as 6-character code in the figures title. For explanation of this code, see Table 40.

8.5 Mie: soaked twosphere wet graupel, LM-scheme

Similar to Subsection 8.1, results are shown for calculations of the backscattering cross section σ_b with subroutine `MIE_SOAK_TWOSPHERE_WETGRAUPEL()` (Mie scattering, two-layered sphere), see subsubsection 5.3.9 on Page 45. The following figures show the ratio of $\sigma_b/\sigma_{b,drop}$ as function of f_{melt} and the unmelted particle diameter for different EMA-formulations of the particles effective refractive indices m_{eff} of core and shell. The particle bulk density as function of size is determined by equation (36) on Page 69. A depiciton of the resulting bulk density as function of particle size can be found in Figure 10 (black solid line).

Again, every figure represents one particular EMA-formulation combination for m_{eff} of core and shell, which both are obtained by using function `get_m_mix()`, applied for two-component mixture materials (subsubsection 5.2.4 on Page 26). The input parameter sets for `get_m_mix()` can be found in the text annotation within each graph, discriminating ice-air core and ice-water shell. For users of the LM, the corresponding setting of the namelist-parameter `ctype_wetgraupel` can be found in the figures title as a combination of two 3-character codes. For explanation of this code, see Table 41. The results of this section apply to the LM for graupel particles in case of application of the standard one-moment bulk microphysical scheme (namelist-parameter `itype_gscp` < 100) together with namelist-parameters `itype_refl` $= 1$ and `igraupel_type` $= 2$.

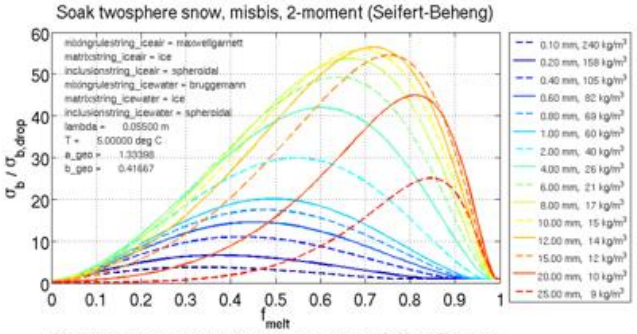
8.8 Mie: soaked twosphere wet snow, Seifert/Beheng-scheme

Similar to Subsection 8.5, results are shown for calculations of the backscattering cross section σ_b with subroutine `MIE_SOAK_TWOSPHERE_WETGRAUPEL()` (Mie scattering, two-layered sphere), see subsubsection 5.3.9 on Page 45. But this time, the particle bulk density as function of size is determined by equation (39) on Page 69. A depiciton of the resulting bulk density as function of particle size can be found in Figure 10 (green solid line). The following figures show the ratio of $\sigma_b/\sigma_{b,drop}$ as function of f_{melt} and the unmelted particle diameter for different EMA-formulations of the particles effective refractive indices m_{eff} of core and shell.



Again, every figure represents one particular EMA-formulation combination for m_{eff} of core and shell, which both are obtained by using function `get_m_mix()`, applied for two-component mixture materials (subsubsection 5.2.4 on Page 26). The input parameter sets for `get_m_mix()` can be found in the text annotation within each graph, discriminating ice-air core and ice-water shell. Although not beeing implemented into the LM interface functions for snow, the corresponding setting of the (nonexisting) namelist-parameter `ctype_wetsnow` (in analogy to `ctype_wetgraupel`) can be found in the figures title as a combination of two 3-character codes. For explanation of this code, see Table 41.

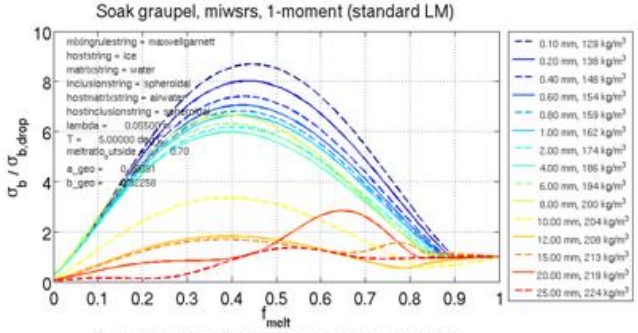
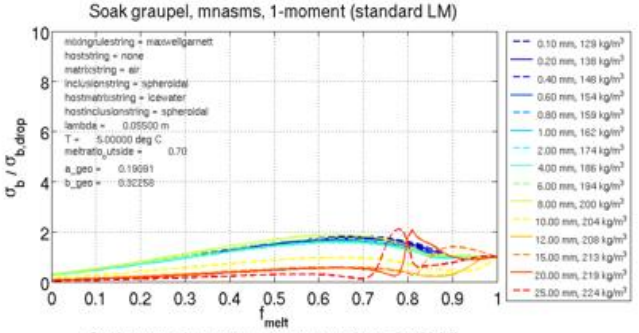
8.9 Mie: soaked wet graupel, LM-scheme



Similar to Subsection 8.1, results are shown for calculations of the backscattering cross section σ_b with subroutine `MIE_SOAK_WETGRAUPEL()` (Mie scattering), see subsubsection 5.3.11 on Page 48. The following figures show the ratio of $\sigma_b/\sigma_{b,drop}$ as function of f_{melt} and the unmelted particle diameter for different EMA-formulations of the particles effective refractive index m_{eff}. The particle bulk density as function of size is determined by equation (36) on Page 69. A depiciton of the resulting bulk density as function of particle size can be found in Figure 10 (black solid line).



Again, every figure represents one particular EMA-formulation for m_{eff}, which is obtained by using function `get_m_mix_nested()` (subsubsection 5.2.5 on Page 28). The input parameter set for `get_m_mix_nested()` can be found in the text annotation within each graph. For users of the LM, the corresponding setting of the namelist-parameter `ctype_wetgraupel` can be found as 6-character code in the figures title. For explanation of this code, see Table 40. The results of this section apply to the LM for graupel particles in case of application of the standard LM one-moment bulk microphysical schemes (namelist-parameter `itype_gscp` $<$ 100) together with `itype_refl` $= 1$ and `igraupel_type` $= 1$.

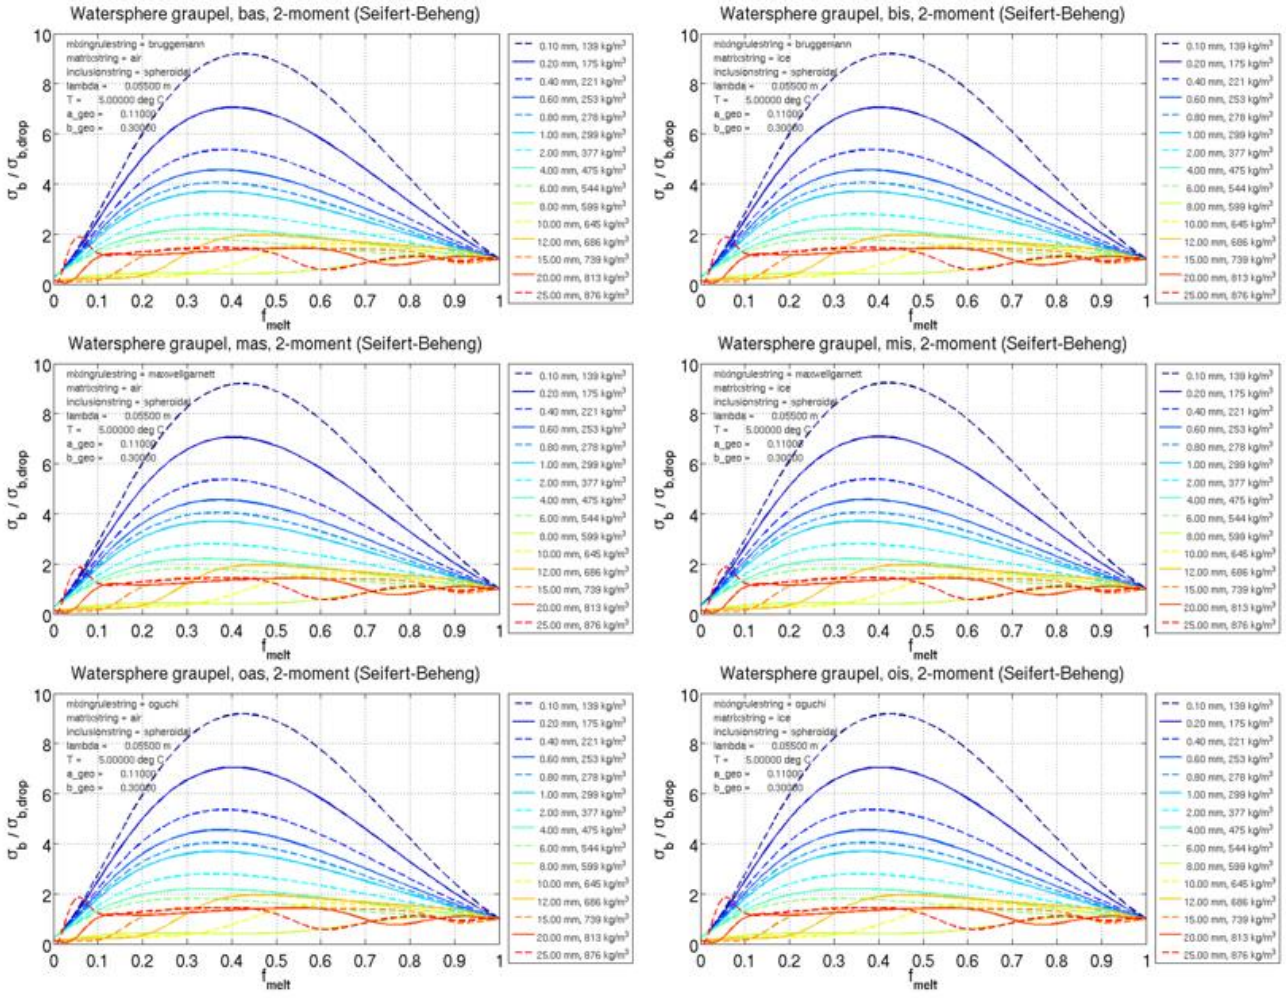
8.13 Mie: watersphere wet graupel, LM-scheme

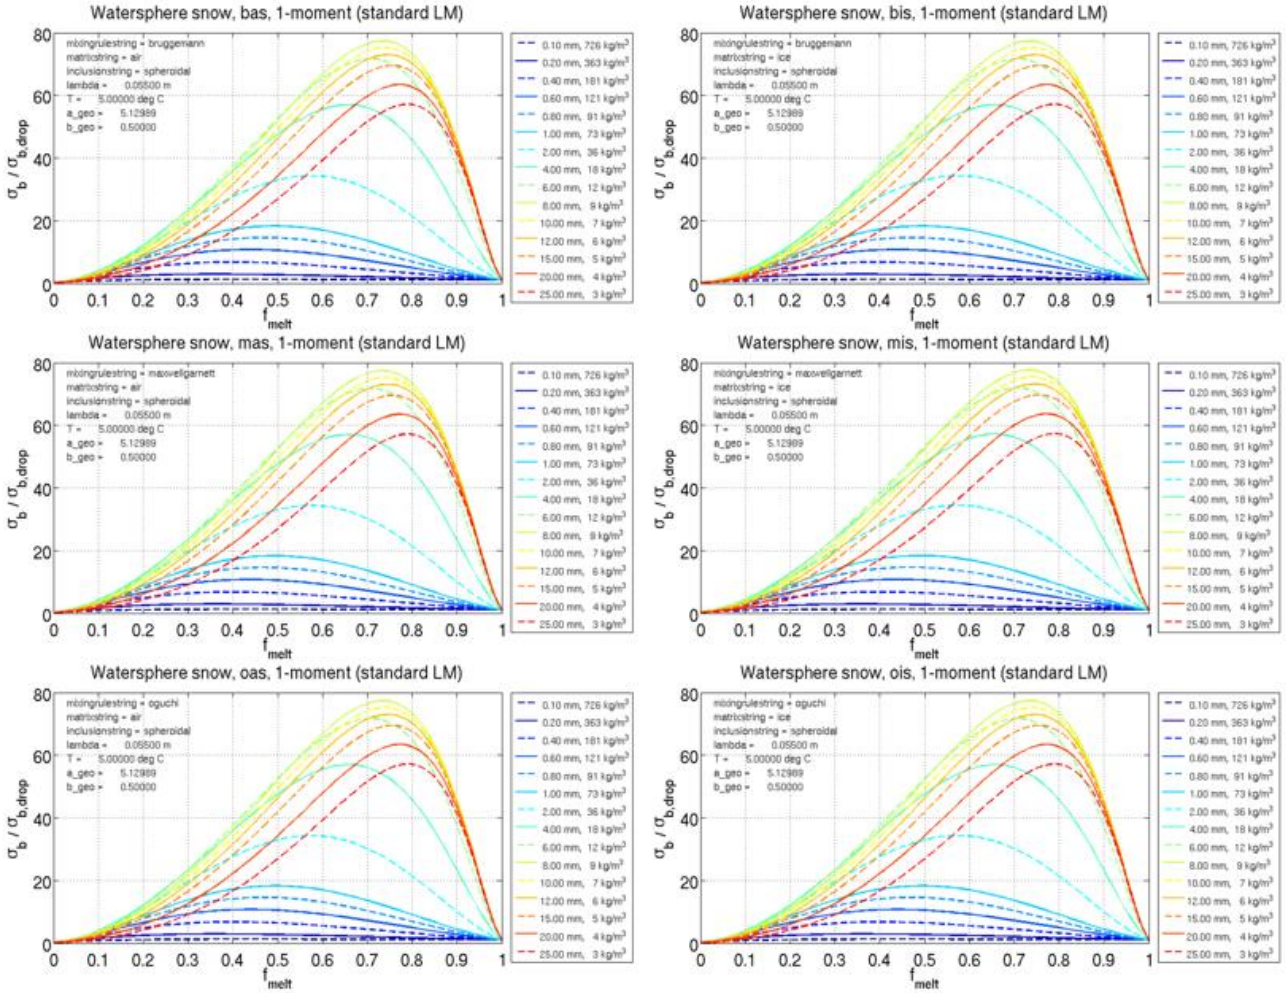
Similar to Subsection 8.1, results are shown for calculations of the backscattering cross section σ_b with subroutine `MIE_WATERSPHERE_WETGRAUPEL()` (Mie scattering, two-layered sphere), see subsubsection 5.3.8 on Page 43. The following figures show the ratio of $\sigma_b/\sigma_{b,drop}$ as function of f_{melt} and the unmelted particle diameter for different EMA-formulations of the particles core effective refractive index m_{eff}. The particle bulk density as function of size is determined by equation (36) on Page 69. A depiciton of the resulting bulk density as function of particle size can be found in Figure 10 (black solid line).



Again, every figure represents one particular EMA-formulation for m_{eff} of the particles ice-air core (the shell is composed of pure water), which is obtained by using function `get_m_mix()` (subsubsection 5.2.4 on Page 26). The input parameter set for `get_m_mix()` can be found in the text annotation within each graph. For users of the LM, the corresponding setting of the namelist-parameter `ctype_wetgraupel` can be found as 3-character code in the figures title. For explanation of this code, see Table 38. The results of this section apply to the LM for graupel particles in case of application of the standard LM one-moment bulk microphysical schemes (namelist-parameter `itype_gscp` < 100) together with `itype_refl` $= 1$ and `igraupel_type` $= 3$.

8.14 Mie: watersphere wet graupel, Seifert/Beheng-scheme

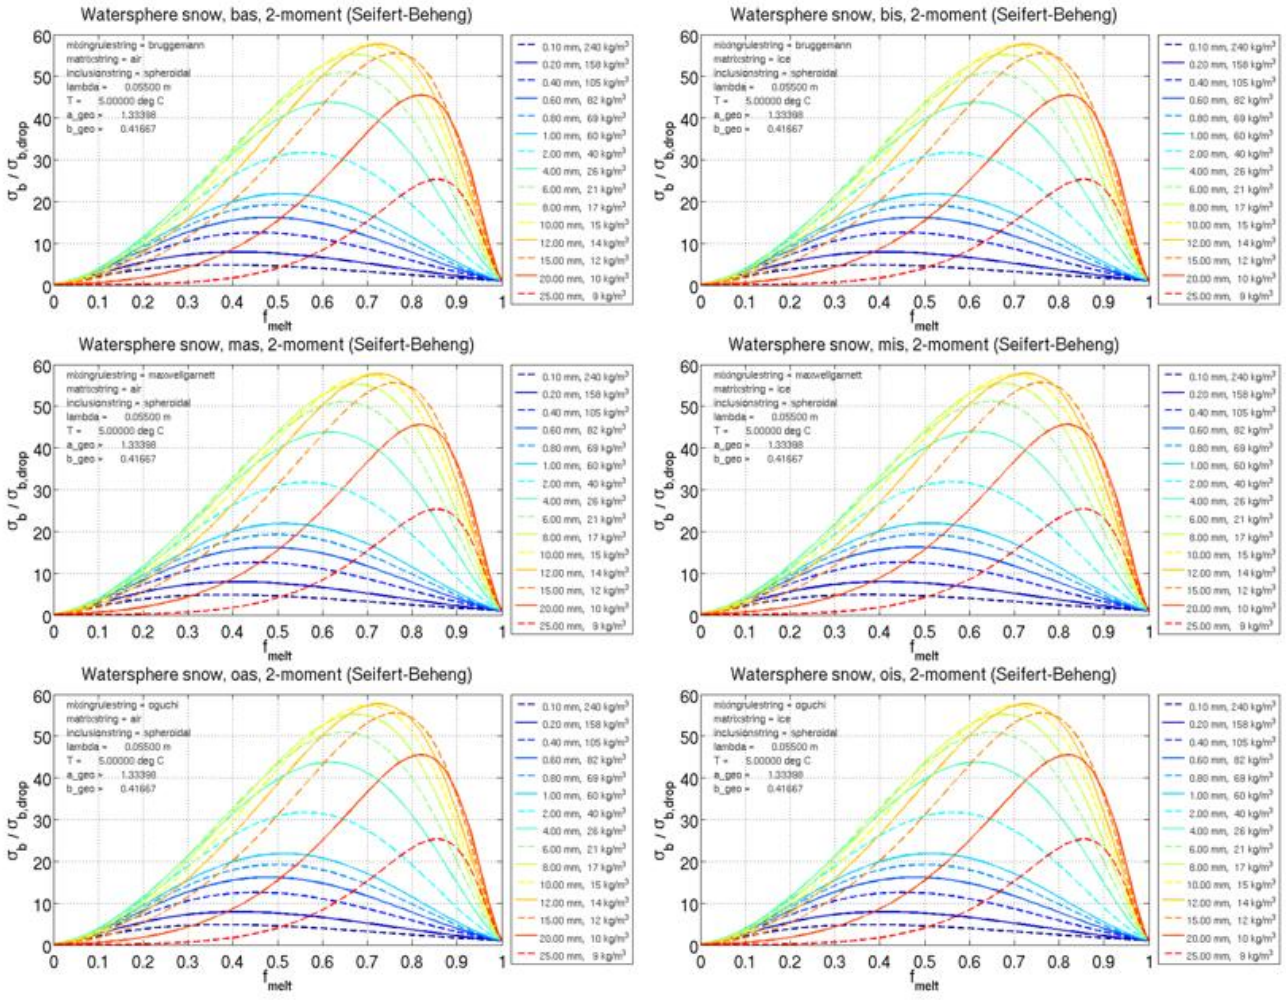
Similar to Subsection 8.13, results are shown for calculations of the backscattering cross section σ_b with subroutine `MIE_SOAK_WETGRAUPEL()` (Mie scattering, two-layered sphere), see subsubsection 5.3.8 on Page 43. But this time, the particle bulk density as function of size is determined by equation (37) on Page 69. A depiciton of the resulting bulk density as function of particle size can be found in Figure 10 (red solid line). The following figures show the ratio of $\sigma_b/\sigma_{b,drop}$ as function of f_{melt} and the unmelted particle diameter for different EMA-formulations of the particles core effective refractive index m_{eff}.



Again, every figure represents one particular EMA-formulation for m_{eff} of the particles ice-air core (the shell is composed of pure water), which is obtained by using function `get_m_mix()` (subsubsection 5.2.4 on Page 26). The input parameter set for `get_m_mix()` can be found in the text annotation within each graph. For users of the LM, the corresponding setting of the namelist-parameter `ctype_wetgraupel` can be found as 3-character code in the figures title. For explanation of this code, see Table 38. The results of this section apply to the LM for graupel particles in case of application of the Seifert and Beheng (2006) two-moment bulk microphysical scheme (namelist-parameter `itype_gscp` ≥ 100) together with `itype_refl` $= 1$ and `igraupel_type` $= 3$.

8.15 Mie: watersphere wet snow, LM-scheme

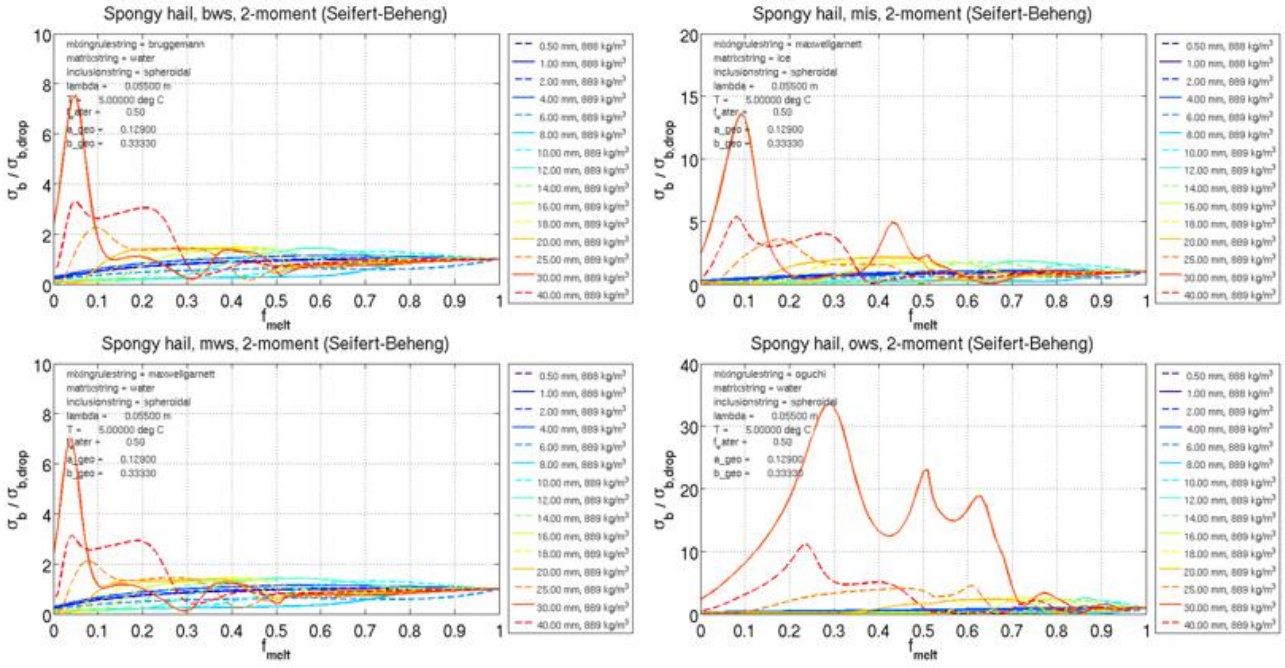
Similar to Subsection 8.13, results are shown for calculations of the backscattering cross section σ_b with subroutine `MIE_SOAK_WETGRAUPEL()` (Mie scattering, two-layered sphere), see subsubsection 5.3.8 on Page 43. But this time, the particle bulk density as function of size is determined by equation (38) on Page 69. A depiciton of the resulting bulk density as function of particle size can be found in Figure 10 (blue solid line). The following figures show the ratio of $\sigma_b/\sigma_{b,drop}$ as function of f_{melt} and the unmelted particle diameter for different EMA-formulations of the particles core effective refractive index m_{eff}.



Again, every figure represents one particular EMA-formulation for m_{eff} of the particles ice-air core (the shell is composed of pure water), which is obtained by using function `get_m_mix()` (subsubsection 5.2.4 on Page 26). The input parameter set for `get_m_mix()` can be found in the text annotation within each graph. Although not beeing implemented into the LM interface functions for snow, the corresponding setting of the (provisional) namelist-parameter `ctype_wetsnow` (in analogy to `ctype_wetgraupel`) can be found as 3-character code in the figures title. For explanation of this code, see Table 38.

8.16 Mie: watersphere wet snow, Seifert/Beheng-scheme

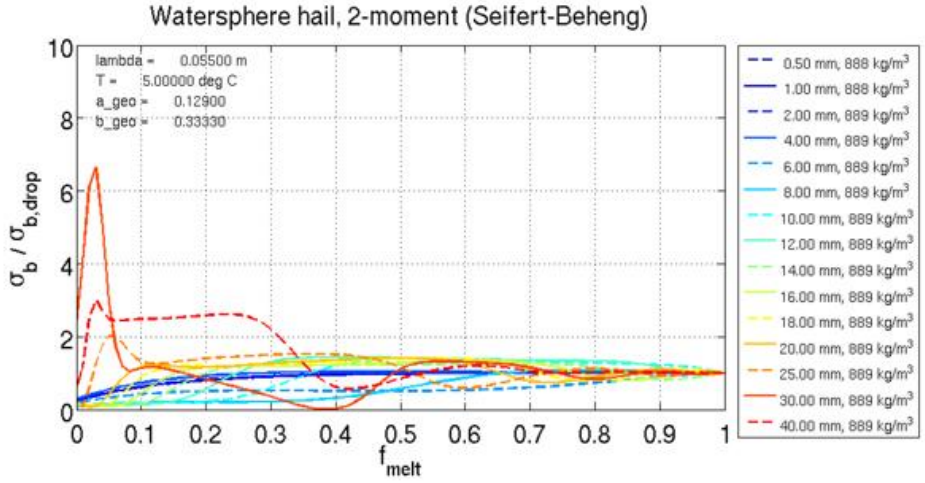
Similar to Subsection 8.13, results are shown for calculations of the backscattering cross section σ_b with subroutine `MIE_SOAK_WETGRAUPEL()` (Mie scattering, two-layered sphere), see subsubsection 5.3.8 on Page 43. But this time, the particle bulk density as function of size is determined by equation (39) on Page 69. A depiciton of the resulting bulk density as function of particle size can be found in Figure 10 (green solid line). The following figures show the ratio of $\sigma_b/\sigma_{b,drop}$ as function of f_{melt} and the unmelted particle diameter for different EMA-formulations of the particles core effective refractive index m_{eff}.



Again, every figure represents one particular EMA-formulation for m_{eff} of the particles ice-air core (the shell is composed of pure water), which is obtained by using function `get_m_mix()` (subsubsection 5.2.4 on Page 26). The input parameter set for `get_m_mix()` can be found in the text annotation within each graph. Although not beeing implemented into the LM interface functions for snow, the corresponding setting of the (provisional) namelist-parameter `ctype_wetsnow` (in analogy to `ctype_wetgraupel`) can be found as 3-character code in the figures title. For explanation of this code, see Table 38.

8.17 Mie: spongy wet hail, Seifert/Beheng-scheme

Similar to Subsection 8.1, results are shown for calculations of the backscattering cross section σ_b with subroutine `MIE_SPONGY_WETHAIL()` (Mie scattering, two-layered sphere), see subsubsection 5.3.7 on Page 41. The following figures show the ratio of $\sigma_b/\sigma_{b,drop}$ as function of f_{melt} and the unmelted particle diameter for different EMA-formulations of the particles ice-water shell effective refractive index m_{eff}. The unmelted particle bulk density does not depend on size here and is that of pure ice. The input parameter `f_water` (melt fraction within the ice-water shell) was set to 0.5, independent of size and f_{melt}.

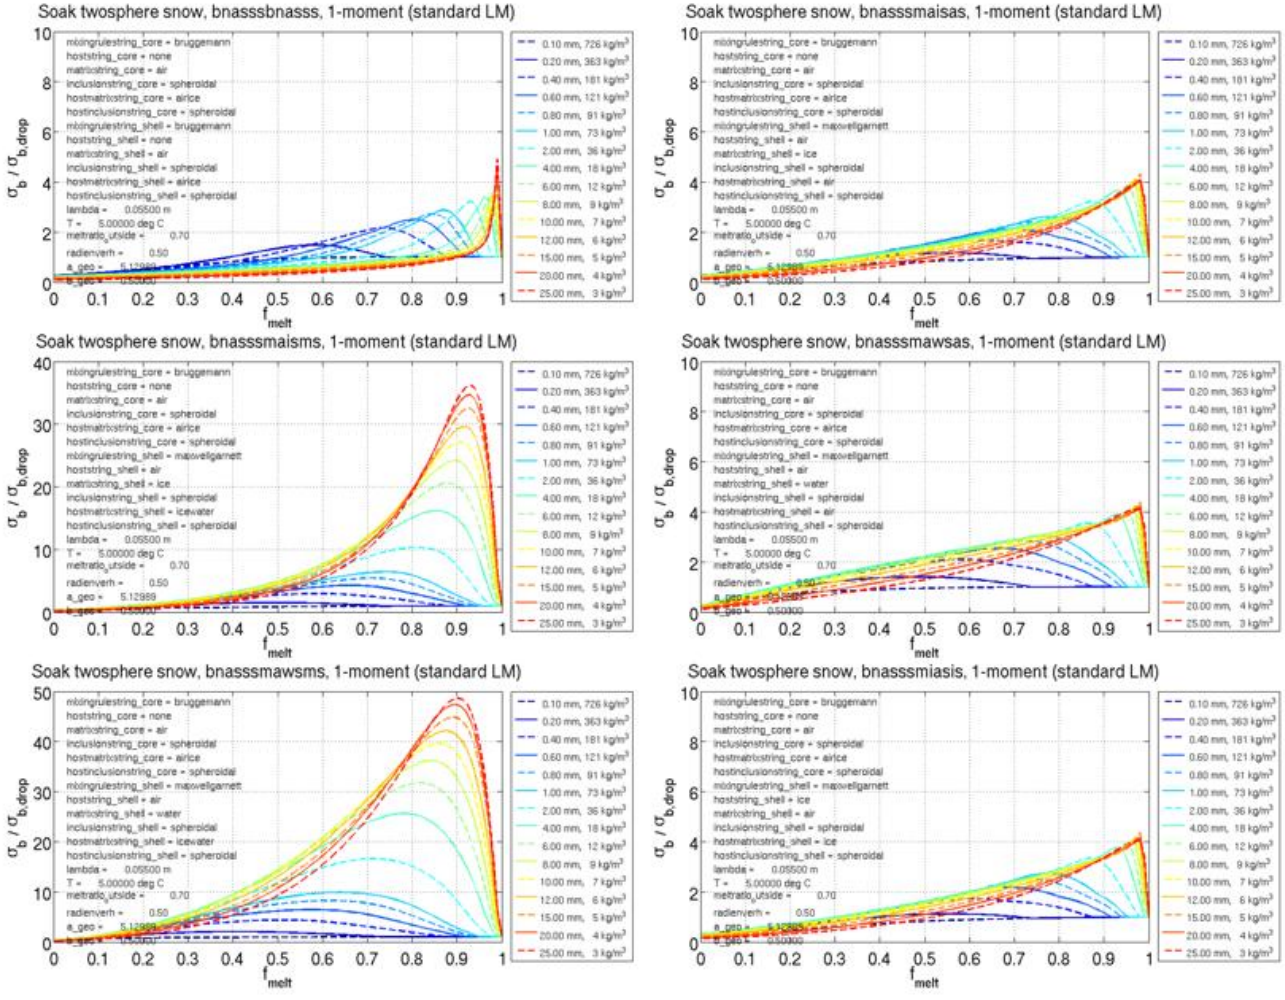


Again, every figure represents one particular EMA-formulation for m_{eff} of the particles ice-water shell (the core is composed of solid ice), which is obtained by using function `get_m_mix()` (subsubsection 5.2.4 on Page 26). The input parameter set for `get_m_mix()` can be found in the text annotation within each graph. For users of the LM, the corresponding setting of the namelist-parameter `ctype_wethail` can be found as 3-character code in the figures title. For explanation of this code, see Table 39. The results of this section apply to the LM for hail particles in case of application of the Seifert and Beheng (2006) two-moment bulk microphysical scheme (namelist-parameter `itype_gscp` ≥ 100) together with `itype_refl` $= 1$.

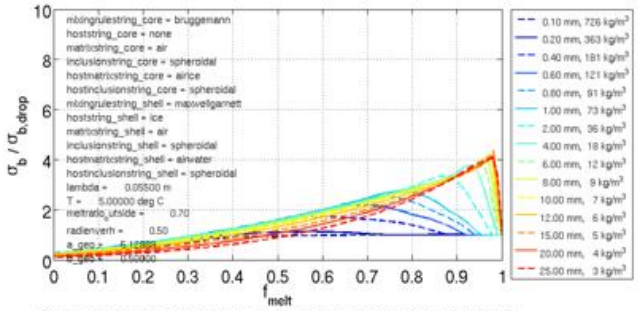
8.18 Mie: watersphere wet hail, Seifert/Beheng-scheme

Similar to Subsection 8.17, results are shown for calculations of the backscattering cross section σ_b with subroutine `MIE_WATERSPHERE_WETHAIL()` (Mie scattering, two-layered sphere), see subsubsection 5.3.6 on Page 40. The following figure shows the ratio of $\sigma_b/\sigma_{b,drop}$ as function of f_{melt} and the unmelted particle diameter. Since the core is composed of pure ice and the shell is assumed to be water, no effective medium approximation for m_{eff} of mixture materials is needed here. Therefore, only one figure is sufficient in the following.

`MIE_WATERSPHERE_WETHAIL()` is not implemented into the interface subroutines for the LM, but would be a possible choice in case of application of the Seifert and Beheng (2006) two-moment bulk microphysical scheme (namelist-parameter `itype_gscp` ≥ 100), together with `itype_refl` $= 1$.

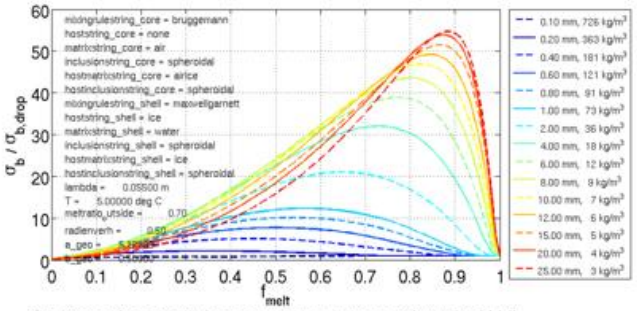


8.19 Mie: twosphere soaked wet snow, LM-scheme



Similar to Subsection 8.1, results are shown for calculations of the backscattering cross section σ_b with subroutine `MIE_WETSNOW_TWOSPHERE()` (Mie scattering, two-layered sphere), see subsubsection 5.3.13 on Page 51. The following figures show the ratio of $\sigma_b/\sigma_{b,drop}$ as function of f_{melt} and the unmelted particle diameter for different EMA-formulations of the particles core and shell effective refractive indices m_{eff}. The particle bulk density as function of size is determined by equation (38) on Page 69. A depiciton of the resulting bulk density as function of particle size can be found in Figure 10 (blue solid line).

The input parameter `meltingratio_outside` (see subsubsection 5.3.13 on Page 51) is set to 0.7, and `radienverh` (inner to outer sphere radius) is set to 0.5, independent of size and f_{melt}.



Again, every figure represents one particular EMA-formulation for m_{eff} of the particles ice-water-air core and ice-water-air shell, which both are obtained by using function `get_m_mix_nested()` (subsubsection 5.2.5 on Page 28). The input parameter sets of `get_m_mix_nested()` for core and shell can be found in the text annotation within each graph. For users of the LM, the corresponding setting of the namelist-parameter `ctype_wetsnow` can be found as 12-character code in the figures title. For explanation of the two 6-character parts of this code, see Table 40. The first 6-character sequence corresponds to the core material, the second 6-character sequence to the shell material. The results of this section apply to the LM for snow particles in case of application of the standard LM one-moment bulk microphysical schemes (namelist-parameter `itype_gscp` < 100) together with `itype_refl` $= 1$.

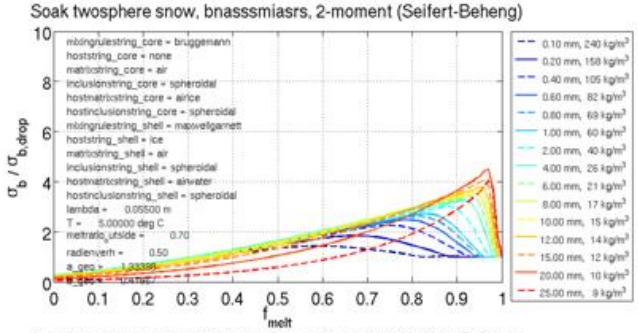
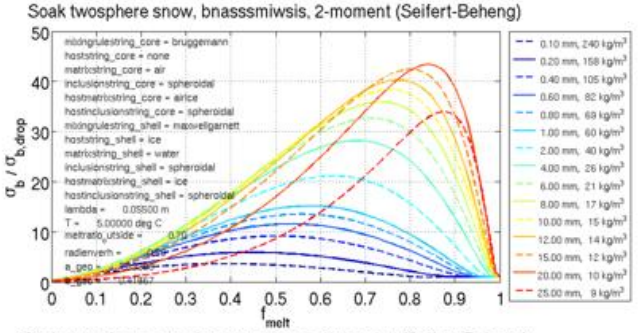
8.20 Mie: twosphere soaked wet snow, Seifert/Beheng-scheme



Similar to Subsection 8.19, results are shown for calculations of the backscattering cross section σ_b with subroutine `MIE_WETSNOW_TWOSPHERE()` (Mie scattering, two-layered sphere), see subsubsection 5.3.13 on Page 51. But this time, the particle bulk density as function of size is determined by equation (39) on Page 69. A depiciton of the resulting bulk density as function of particle size can be found in Figure 10 (green solid line). The following figures show the ratio of $\sigma_b/\sigma_{b,drop}$ as function of f_{melt} and the unmelted particle diameter for different EMA-formulations of the particles core and shell effective refractive indices m_{eff}.

The input parameter `meltingratio_outside` (see subsubsection 5.3.13 on Page 51) is set to 0.7, and `radienverh` (inner to outer sphere radius) is set to 0.5, independent of size and f_{melt}.



Again, every figure represents one particular EMA-formulation for m_{eff} of the particles ice-water-air core and ice-water-air shell, which both are obtained by using function `get_m_mix_nested()` (subsubsection 5.2.5 on Page 28). The input parameter sets of `get_m_mix_nested()` for core and shell can be found in the text annotation within each graph. For users of the LM, the corresponding setting of the namelist-parameter `ctype_wetsnow` can be found as 12-character code in the figures title. For explanation of the two 6-character parts of this code, see Table 40. The first 6-character sequence corresponds to the core material, the second 6-character sequence to the shell material. The results of this section apply to the LM for snow particles in case of application of the Seifert and Beheng (2006) two-moment bulk microphysical scheme (namelist-parameter `itype_gscp` ≥ 100) together with `itype_refl` $= 1$.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Abstract

In this work, the main characteristics of COSMO–LEPS, the Limited–area Ensemble Prediction System developed in the framework of the COnsortium for Small-scale MOdelling, are presented. The present status of the system is shown with the description of the methodology and of the main upgrades which took place during its years of activity. The performance of COSMO–LEPS for the probabilistic prediction of precipitation is assessed in terms of both time–series and seasonal scores over a 7–year period. A fixed number of stations is selected and observations are compared to short and early–medium–range forecasts. Different verification indices are used to assess the skill of COSMO–LEPS and to identify the impact of system modifications on forecast skill. The different system upgrades are found to impact positively on COSMO–LEPS performance, with a gain of two days of predictability in the last four years of operational forecasts. This holds when the skill of the system is assessed both for single events (e.g. precipitation surpassing a fixed threshold) and for multi–event situations. Scores for fixed forecast ranges but varying thresholds confirm increasingly better performance of the system. Finally, the main stream of development for COSMO–LEPS system are discussed with future possible upgrades and methodology modifications.

2 Introduction

One of the main challenges for numerical weather prediction (NWP) is still recognised as quantitative precipitation forecasting. Computer power resources have greatly increased in the last years, thus allowing the generation of more and more sophisticated NWP model with accurate parametrisation of physical processes supported by high horizontal and vertical resolution. Nevertheless, the accurate forecast of high–impact weather still remains difficult beyond day 2 and sometimes, also for shorter ranges (Mullen and Buizza, 2001; Tibaldi et al., 2006). Several factors contribute to forecast failures and can be usually related to shortcomings in the definition of the initial conditions of the integrations, to model errors of different types and, last but not least, to the intrinsic low predictability of the physical phenomena under investigation. The use of the probabilistic approach via the ensemble forecasting has now become commonplace to tackle the chaotic behaviour of the atmosphere and to support forecasters in the management of alert procedures for events with little deterministic predictability. Several national and international weather centres, like the European Centre for Medium–Range Weather Forecasts (ECMWF), the Canadian Meteorological Centre (CMC), the National Centers for Environmental Prediction (NCEP) and the UK Meteorological Office, provide valuable operational ensemble prediction at a global scale (Tracton and Kalnay, 1993; Houtekamer et al., 1996; Molteni et al., 1996; Buizza et al., 2007; Bowler et al., 2008). In addition to them, many limited–area ensemble prediction systems have been recently developed, either in research or in operational mode, so as to address the need of detailing high–impact weather forecasts at higher and higher resolution and to support the reliability of the deterministic forecast beyond the very short range.

As far as operational implementations are concerned, the Consortium for Small–Scale MOdelling Limited–area Ensemble Prediction System (COSMO–LEPS) was the first mesoscale ensemble application running on a daily basis in Europe[1]. This system, initially developed and implemented by the HydroMeteoClimate Regional Service of Emilia-Romagna, in Bologna, Italy (ARPA–SIMC), has been running at ECMWF since November 2002 (Montani et al., 2003a) thanks to the ECMWF computer resources provided by the COSMO

[1]Information about the activities of the COSMO consortium can be found at http://www.cosmo-model.org.

countries which are ECMWF Member states. Nowadays, COSMO–LEPS is based on 16 integrations of the non–hydrostatic mesoscale model COSMO, formerly known as the Lokal Modell (Steppeler et al., 2003). The methodology (described more thoroughly in the next section) aims at combining the advantages of the probabilistic approach by global ensemble systems with the high–resolution details gained in the mesoscale integrations. In the construction of COSMO–LEPS, an algorithm selects a number of members (referred to as Representative Members, RMs) by a global ensemble system (Marsigli et al., 2001; Molteni et al., 2001). This intermediate step, referred to as "ensemble–size reduction", is required to keep the computational load operationally affordable, since it is not presently feasible to nest the limited-area model on each individual member of a highly–populated global ensemble. After the "ensemble–size reduction", the selected RMs are used to provide both initial and boundary conditions to the integrations with the COSMO model, which is run once for each RM. Therefore, COSMO–LEPS performs a sort of dynamical downscaling of a global–model probabilistic system, limiting to a certain extent the computation investment (Tibaldi et al., 2006).

In this work, the progresses in the development of COSMO–LEPS are reviewed, focusing on past and recent system upgrades and on the impact on its forecast skill. It is aimed to quantify the improvements of COSMO–LEPS in terms of probabilistic prediction of light and heavy precipitation events in the short and early–medium range. This will enable to indicate both strengths and weaknesses of the system, to highlight the open challenges and to suggest the main streams of future developments.
The rest of the paper is organised as follows: section 3 describes the main characteristics of the COSMO–LEPS system, while, in section 4, the features of the verification procedure are reported. Results in terms of both time–series and seasonal scores are presented in sections 5 and 6, respectively. Finally, conclusions are drawn in section 7.

3 Description of COSMO-LEPS operational system

As previously mentioned, the "core" of COSMO–LEPS methodology lies in the idea of reducing the number of global–ensemble elements driving the limited–area runs, still retaining a large fraction of the driving–ensemble information. In its first experimental–operational implementation which dates November 2002, the set–up of COSMO–LEPS can be described as follows (Montani et al., 2003b):

1. three successive runs of ECMWF Ensemble Prediction System (EPS), starting at 12UTC at day *d-1*, at 00UTC and 12UTC of day *d* are joined together, thus generating a 153–member lagged–ensemble, since each EPS is made up of one control run plus 50 perturbed members (Buizza, 2005);

2. EPS members are grouped into 5 clusters, the discriminating variable being a combination of four variables at three pressure levels and at 2 forecast steps: the two horizontal wind components, the geopotential height and the specific humidity at 500, 700, 850 hPa and at the ranges of 96 and 120 hours (the ranges are relative to the "youngest" ensemble, run at 12UTC of day *d*);

3. for each variable at each forecast step, the mean over the clustering area is calculated and, then, subtracted from any grid-point value. Hence, the result is divided by the standard deviation, thus obtaining a non–dimensional field;

4. the quadratic distances among the EPS members are computed for all variables at all levels at all steps and, then, space–averaged;

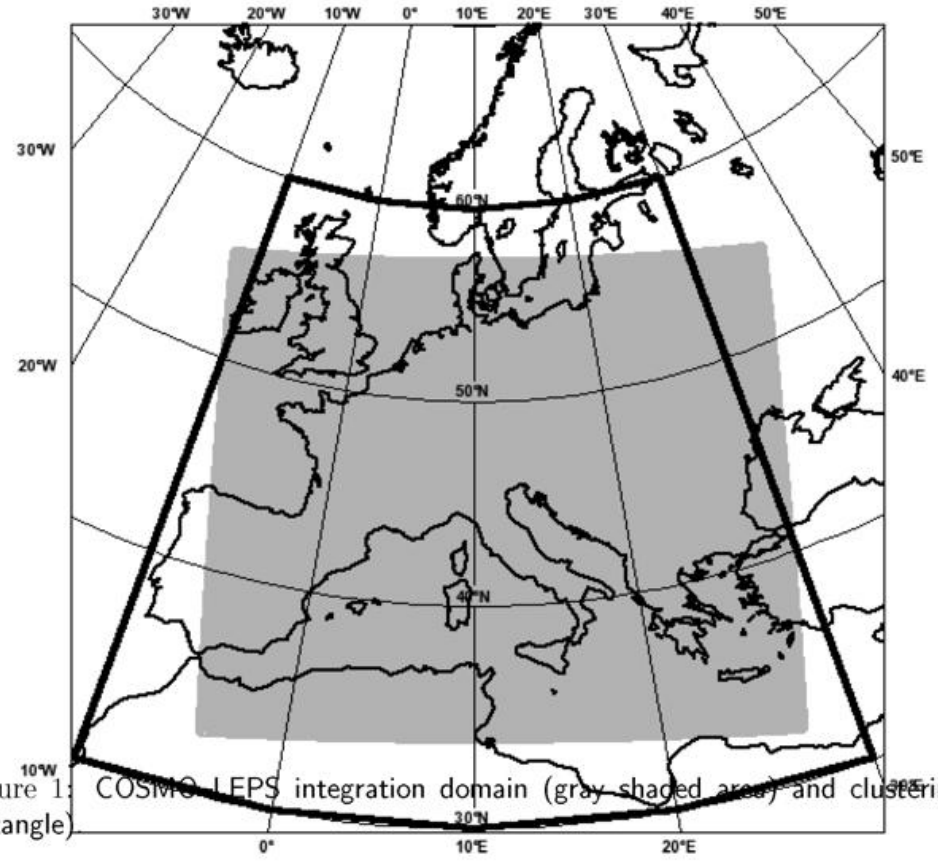

Figure 1: COSMO–LEPS integration domain (gray shaded area) and clustering area (black rectangle)

5. the cluster analysis is performed over the following area: 40N–60N, 10W–30E (denoted by the black rectangle of Fig. 1); the clusters are constructed using the complete–linkage algorithm (Wilks, 1995);

6. within each cluster (with different populations), one RM is selected, using the same discriminating variables as before; the RM is that cluster element which minimises the ratio between its distance from the other members of its own cluster and its distance from the members of the other clusters;

7. the so–selected RMs provide both initial and boundary conditions for the integrations with the COSMO model, which is run once for each RM over a domain covering Central and Southern Europe (shaded area in Fig. 1);

8. the 5 COSMO integrations which generate the COSMO–LEPS system, start at 12UTC of day d, with a horizontal resolution of 10 km, 32 vertical levels and a forecast length of 120 hours;

9. post–processed products (e.g. the probability of exceeding a threshold) are generated, assuming a relationship between cluster population and the probability of occurrence of its associated RM; hence each COSMO integration is given a weight proportional to the population of the cluster from which the RM (providing initial and boundary conditions) was selected.

In the course of its operational activity, the COSMO–LEPS system has undergone many changes. Without accounting for the model upgrades with bug fixes and more sophisti-

cated and precise parametrisation, the main milestones of COSMO–LEPS history can be summarised as follows:

- 4 November 2002: beginning of COSMO–LEPS activity in the above–described configuration;
- 1 June 2004 ([**A**]): ensemble population increased to 10 members; the RMs are selected out of 102 EPS members (only 2 successive EPS runs starting at 00UTC and 12UTC of day d are used); random procedure for the choice of either Kain-Fritsch or Tiedtke convection scheme with each COSMO–LEPS run;
- 1 July 2005: the forecast range of COSMO–LEPS integrations is increased from 120 to 132 hours;
- December 2005; COSMO–LEPS application becomes an "*ECMWF Member State time–critical application*" managed by ARPA–SIMC and monitored by ECMWF operators;
- 2 February 2006 ([**B**]); ensemble size increased from 10 to 16 members; vertical resolution increased from 32 to 40 model levels;
- 1 December 2007 ([**C**]); change of the numerical scheme in COSMO–LEPS integrations; introduction of new perturbations in the model parametrisations.

In this list, a number of changes are labelled with letters **[A], [B], [C]**: they represent those system upgrades with direct consequences on the performance of the COSMO–LEPS forecast skill, as will be shown later on.
It is worth pointing out that, both in the first years of activity as well as more recently, Marsigli et al. (2005a, 2005b and 2008), Montani et al. (2008a and 2008b) and Walser (2006) showed that COSMO–LEPS provided high–quality probabilistic quantitative prediction of heavy precipitation events. Over a number of case studies as well as over continuous verification periods, COSMO–LEPS was shown to perform usually better than ECMWF EPS in terms of geographical localisations of the regions most likely to be affected by the events as well as in terms of more realistic rainfall patterns. The above works used different verification techniques and different observational datasets; hence, they cannot provide exhaustive information on the evolution of the skill of the system. In order to shed light on the progresses of COSMO–LEPS, a comprehensive verification over the full history of the system is undertaken with the features described in the next section.

4 Methodology of verification

The performance of COSMO–LEPS system is analysed considering the probabilistic prediction of 12–hour accumulated precipitation exceeding a number of thresholds for several forecast ranges. Instead of the "more traditional" 24–hour accumulation period, it was decided to focus the attention on 12–hour precipitation (accumulated from 18 to 6 UTC and from 6 to 18 UTC) in order to investigate the performance of the system for both day–time and night–time precipitation forecasts. This should allow the possibility to isolate possible biases and/or systematic errors in the diurnal cycle of COSMO-LEPS model integrations, which would be otherwise masked if verification were performed over a 24–hour window.

As for observations, it is clear that a high–resolution network would be very desirable in order to assess the predictive skill of a mesoscale ensemble system. Since precipitation has a high-spatial variability, this network would provide better estimates of precipitation at

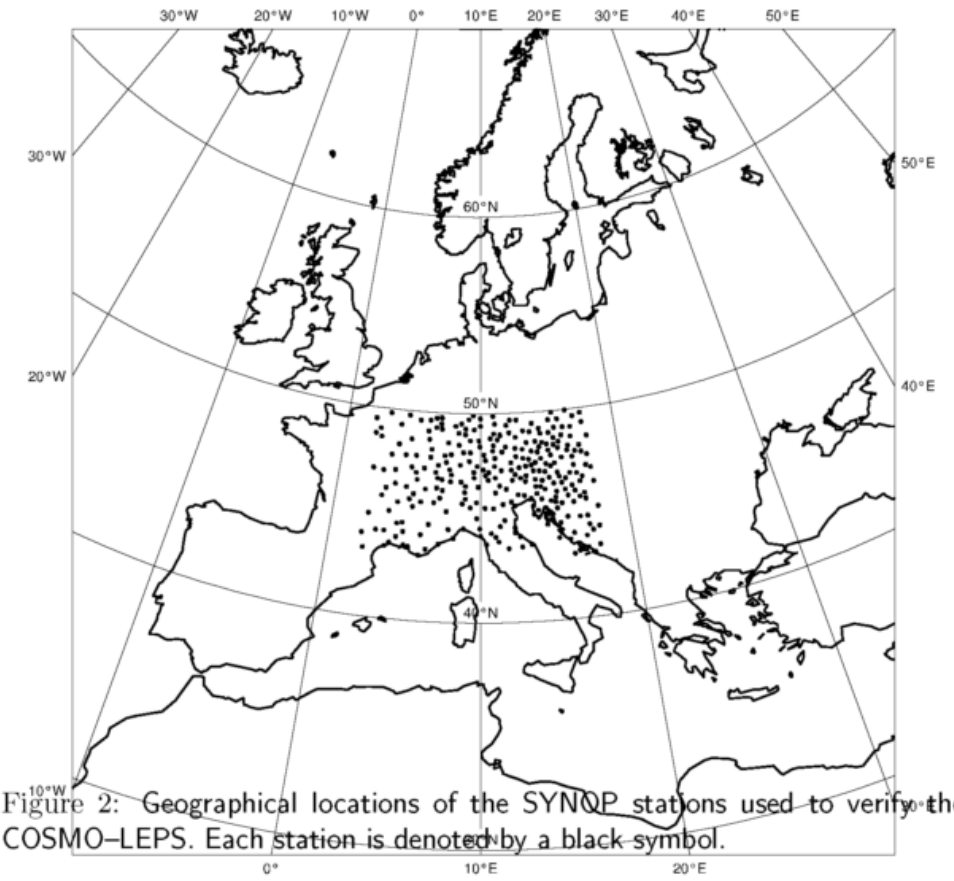

Figure 2: Geographical locations of the SYNOP stations used to verify the performance of COSMO–LEPS. Each station is denoted by a black symbol.

high resolution. Unfortunately, this type of network, like the high–density network adopted by Marsigli et al. (2008), is not available with continuity in the period 2002–2009, as it presents several "gaps", this making impossible a detailed evaluation of how the performance of COSMO–LEPS evolved in the years. For this reason, it has been decided to use the data obtained from the SYNOP reports available on the Global Telecommunication System (GTS), since this is recognised to be a homogeneous and stable dataset throughout the years 2002–2009.

In order to assess the skill of the system over complex topography, verification is performed in the domain ranging from 43N to 50N and from 2N to 18E. This domain, sometimes referred to as MAP D-PHASE area (Mesoscale Alpine Programme, Demonstration of Probabilistic Hydrological and Atmospheric Simulation of flood Events in the alpine region), is the common terrain of investigation for the Forecast Demonstration Project which took place during the Operation Period of D-PHASE (Zappa et al., 2008; Rotach et al., 2009). Within this domain, a fixed list of 412 SYNOP stations is considered and the relative reports in terms of total precipitation are used to evaluate the COSMO–LEPS skill.

Fig. 2 reports the locations of the stations used for the verification. The SYNOP reports have undergone a simple quality control firstly based on the "surpassing" of a confidence level (provided in the data retrieved by ECMWF archive) for the full report. In addition to this, for cases of very high precipitation records, the values are compared, whenever possible, to those taken from nearby non–GTS stations. In case of discrepancy between non–GTS and SYNOP reports, the latter is discarded and the relative data not used in the computation of the scores.

As for the comparison of model forecasts against SYNOP reports, we select the grid point

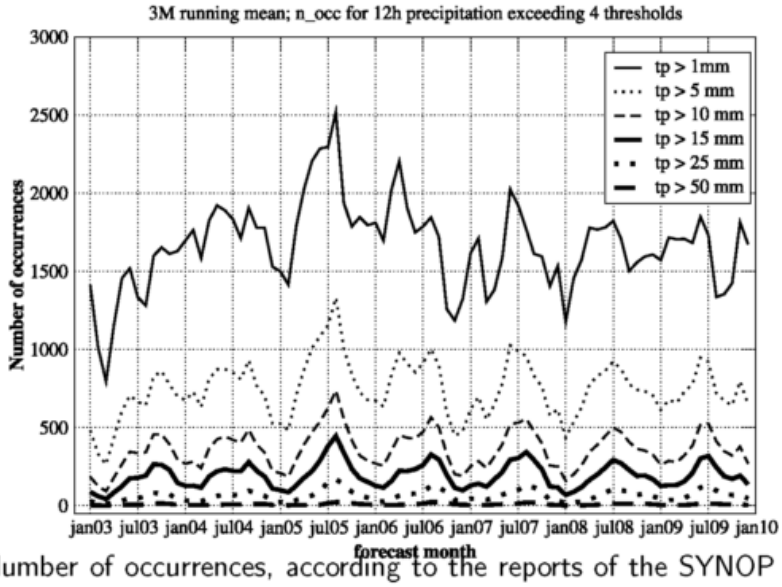

Figure 3: Number of occurrences, according to the reports of the SYNOP stations of Fig. 2, for 12–hour observed precipitation exceeding 4 different thresholds: 1mm/12h (thin–solid line), 5mm/12h (dotted), 10mm/12h (dashed), 15mm/12h (thick–solid), 25mm/12h (thick–dotted) and 50 mm/12h (thick–dashed). A 3–month running mean is applied to improve the readability of the plots.

closest to the observation. Little sensitivity to the results is found when, instead of the nearest grid point, a bi-linear interpolation using the 4 nearest points to the station location, is used to generate the model forecasts. Therefore, the results shown hereafter will be relative only to the nearest grid-point method.
The performance of COSMO–LEPS is examined for 6 different thresholds: 1, 5, 10, 15, 25 and 50 mm/12h.

Fig. 3 shows the overall number of occurrences for each threshold and for each month, from December 2002 to November 2009, according to the reports of the stations of Fig. 2. As the occurrences have a strong marked month–to–month variability (and for ease of comparison with the future plots), a 3–month running mean was applied to improve the readability of the figure. The high values for precipitation observed in July–August 2005 stand out, with about 500 events of rainfall exceeding 15 mm in 12 hours. In addition to that, other shifts between dry and wet periods are also evident. It is immediately worth pointing out that, when considering the two highest thresholds (thick–dotted and thick–dashed lines, relative to the 25 and 50 mm/12h values, respectively), a low number of occurrences, often below 10, is found for several seasons (especially in winters). This may cast some doubts on the statistical solidity of the results for these types of events over a long verification period. Good (poor) performance over specific seasons could be due to the fact that COSMO–LEPS predictions captured (did not capture) those few heavy precipitation events, this not allowing any solid conclusions on the effective performance of the system for the highest thresholds. On the other hand, large numbers of occurrences are often found for the other thresholds, including the event “15 mm of precipitation over 12 hours” (thick–solid line in Fig. 3), which is already a quite substantial amount. Therefore, the results relative to the two highest thresholds (25 and 50 mm/12h) will not be shown and more emphasis will be given to the remaining thresholds (1, 5, 10, 15 mm/12h).
As already mentioned, verification was performed over a 7-year period, from December 2002 to November 2009. For each month as well as for each season, the following probabilistic

Table 1: Main features of the verification configuration.

variable:	12–hour accumulated precipitation (18–06, 06–18 UTC);
period:	from Dec 2002 to Nov 2009;
region:	43–50N, 2–18E (D–PHASE area);
method:	nearest grid–point;
observations:	SYNOP reports;
forecast ranges (h):	6-18, 18-30, 30-42, 42-54, 54-66, 66-78, 78-90, 90-102, 102-114, 114-126;
thresholds:	1, 5, 10, 15, 25, 50 mm/12h;
scores:	ROC area, BSS, RPSS, OUTL;

scores are computed: the Brier Skill Score (BSS), the Ranked Probability Skill Score (RPSS), the Relative Operating Characteristic Curve (ROC) area and the Percentage of Outliers (OUTL). For a description of these scores, the reader is referred to Wilks (1995) and to Marsigli et al. (2008). The main features of the verification exercise are summarised in Table 1.

5 Time–series results

In the following subsections, the results relative to the performance of COSMO–LEPS for particular types of weather events are presented in terms of time–series scores for the above–mentioned probabilistic indices.

5.1 ROC Area

The ROC area (Mason and Graham, 1999) ranges from 0 to 1, the higher the better, and the value of 0.5 is the limit from skill and no–skill. For a forecast system to be useful, the ROC area should exceed the value of 0.7 (Buizza et al., 1999).

Fig. 4 shows the performance of COSMO-LEPS in terms of time-series values of the ROC area for the 30–42h forecast range (that is, the precipitation accumulated over the 12–hour period ending at 42–hour forecast step). The score exhibits a marked month–to–month variability and a 3–month running mean was applied to improve the readability of the plots. The skill of COSMO–LEPS is shown for the first 4 thresholds of Table 1: it can be noticed that, in any case, the performance of the system has increased throughout the years of COSMO–LEPS activity. This is especially true for the 10mm/12h and 15mm/12h thresholds (dashed and thick–solid lines, respectively), since the scores increased from about 0.6, in the first months of 2003, to more than 0.8, since mid–2007. The letters [A], [B] and [C] in the lower part of the plot denote the major system upgrades among those described in the previous section. It can be noticed that the [A] upgrade, relative to the increase of COSMO–LEPS ensemble size had a positive impact on the performance of the system. As for the [B] upgrade, it has to be noticed that, in February 2006, not only did COSMO–LEPS increase both ensemble size and vertical resolution, but also ECMWF EPS decreased its horizontal grid size from 80 to about 50 km in the horizontal (Buizza et al., 2007), thus improving the quality of both initial and boundary conditions provided to the limited–area runs. Despite these system upgrades, the performance of COSMO–LEPS was not as good as could be expected in the following months (Spring to Summer 2006), with scores below 0.8 for the 10 and 15 mm thresholds. On the other hand, some recovery in the performance of the system

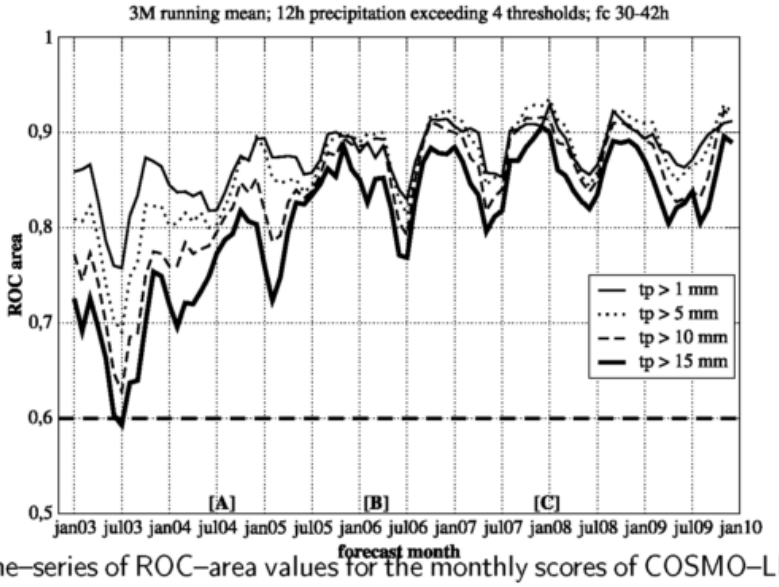

Figure 4: Time–series of ROC–area values for the monthly scores of COSMO–LEPS for 4 different thresholds: 1mm/12h (thin–solid line), 5mm/12h (dotted), 10mm/12h (dashed) and 15mm/12h (thick–solid). The forecast range is 30–42h. A 3–month running mean is applied to improve the readability of the plots. For the meaning of letters [A], [B], [C], refer to the text.

can be noticed in the following seasons. Hence, the drop in skill seems circumscribed to just a few months and cannot be ascribed to wrong implementations and/or faulty system upgrades. As for the [C] upgrade, the impact seems initially neutral with ROC area scores peaking up again in late 2009; a more detailed analysis (in next sections) will show some positive impact on the skill of the system also for 2008.
If the attention is focused on a longer forecast range, most of the above–mentioned results are confirmed.

Fig. 5 shows the ROC area values for the 78–90h range: it is clear that the absolute values of the scores are lower than before, since the prediction range has increased. In the first two years of activity of COSMO-LEPS (up to about February 2005), the scores relative to the 10 and 15 mm/12h thresholds fell below 0.7, which is generally considered the lower boundary for a prediction system to be useful. In the following months (and years), the improvement of performance is well detectable for all thresholds. The limited skill of the system after the [B] upgrade is confirmed for all thresholds, as well as the recovery of COSMO–LEPS in the subsequent months. Particularly high is the skill of the system during autumn and winter 2007, with ROC area value close, or slightly above, 0.9. It can be noticed that, for these seasons, the skill of the system is very similar for both the 30–42h and the 78–90h forecast range, this indicating a slow degrade of the prediction skill with the forecast range.
In addition to these comments, some dependence of the scores on the season can also be noticed. Both Figs. 4 and 5 indicate that ROC area values tend to be higher (lower) in autumns (summers). This may be related to the different types of atmospheric forcing for the precipitation events. In summer, precipitation is more related to convective–type of events, while in autumn large–scale forcing usually prevails. The former type of forcing tends to be less predictable by global–model ensemble systems (Buizza et al., 1999), which may provide less accurate initial and boundary conditions to COSMO–LEPS runs. In addition to this, convection is explicitly resolved by neither global nor limited–area integrations and this adds limitations to the system capability of simulating properly convective–type events. On the other hand, large–scale forcing is usually well captured by global–model systems,

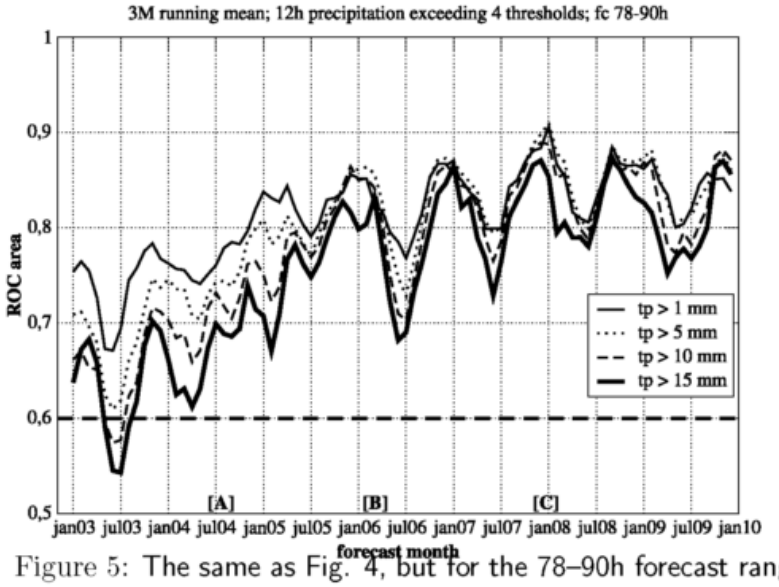

Figure 5: The same as Fig. 4, but for the 78–90h forecast range.

which provide higher quality boundaries for the dynamical downscaling by limited–area ensemble systems. On their turn, the added value of higher resolution and the more accurate description of mesoscale features, like the interaction of flow with orography, contributes to the better performance of COSMO–LEPS during the autumn season.

5.2 Brier Skill Score

Now, the attention is focused on the performance of COSMO–LEPS in terms of BSS (Wilks, 1995). This score ranges from minus infinity to 1 and, for a forecast system to be more useful than climatology (in this case, the reference climatology is given by the sample climate), has to be positive. Fig. 6 shows the time–series evolution of COSMO–LEPS performance for the 30–42h forecast range: despite a 3–month running mean is applied to the score values so as to increase the readability of the plot, the month–to–month variability is larger than in the case of the ROC area and the increase in forecast skill throughout the years of COSMO–LEPS activity is less evident. It is difficult to detect a clear benefit by any of the above–mentioned upgrades and, depending on the threshold, periods of relative high (low) skill alternate. Nevertheless, it can be noticed that the BSS has been positive for all thresholds since April 2009, possibly a consequence of the most recent forecast improvements.

In order to detect trends in the score, it was decided to apply a 12–month running mean[2] to the monthly BSS scores, as in Fig. 7. In this figure, the shapes of the profiles are much smoother than before, but longer–term trends can be identified. Depending on the threshold, the following considerations can be presented:

- the quality of the forecast progressed quite slowly for the 1mm/12h and 5mm/12h events (thin–solid and dotted lines, respectively); BSS is nearly always positive indicating a performance of the system better than climatology; the system upgrades do not seem to have had a large impact on the performance of COSMO–LEPS for the

[2]The BSS value for a particular month is given by the average of the score for the preceding 6 months and for the following 6 month values. Hence, BSS values cannot be computed for the first 6 months and for the last 6 month of the time–series.

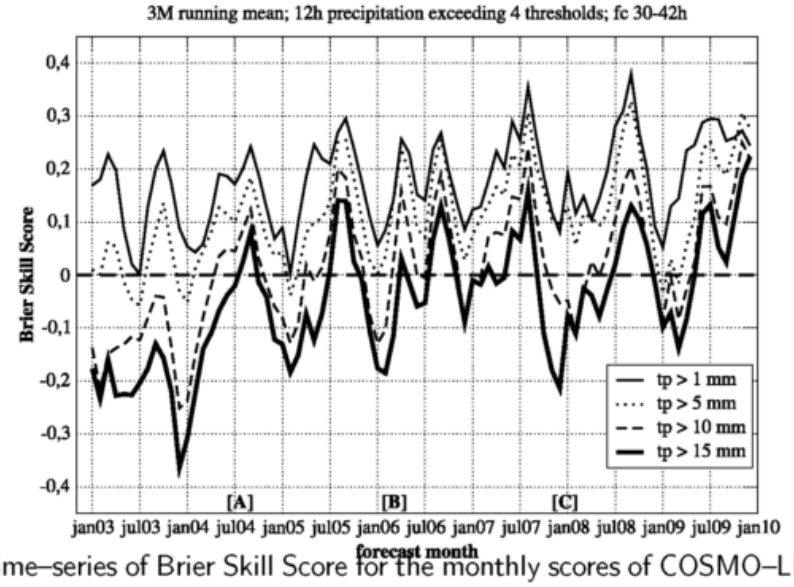

Figure 6: Time–series of Brier Skill Score for the monthly scores of COSMO–LEPS for 4 different thresholds: 1mm/12h (thin–solid line), 5mm/12h (dotted), 10mm/12h (dashed) and 15mm/12h (thick–solid). The forecast range is 30–42h. A 3–month running mean is applied to improve the readability of the plots. For the meaning of letters [A], [B], [C], refer to the text.

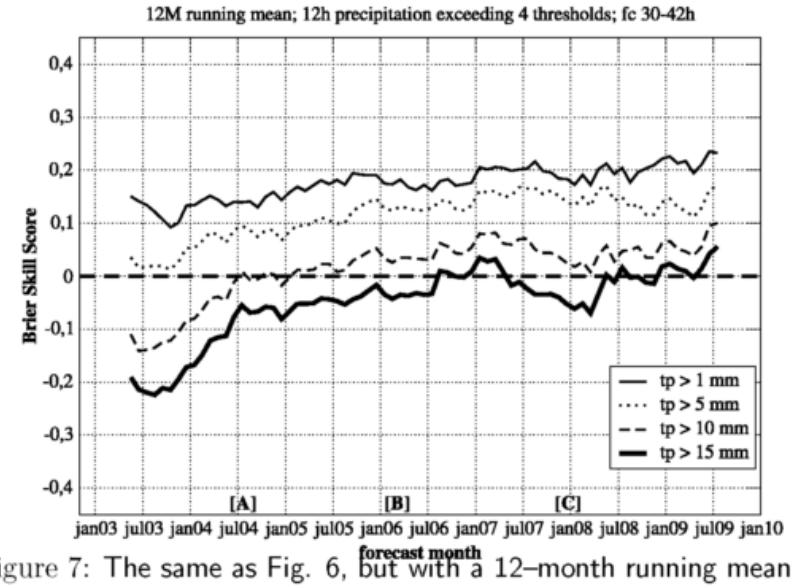

Figure 7: The same as Fig. 6, but with a 12–month running mean applied.

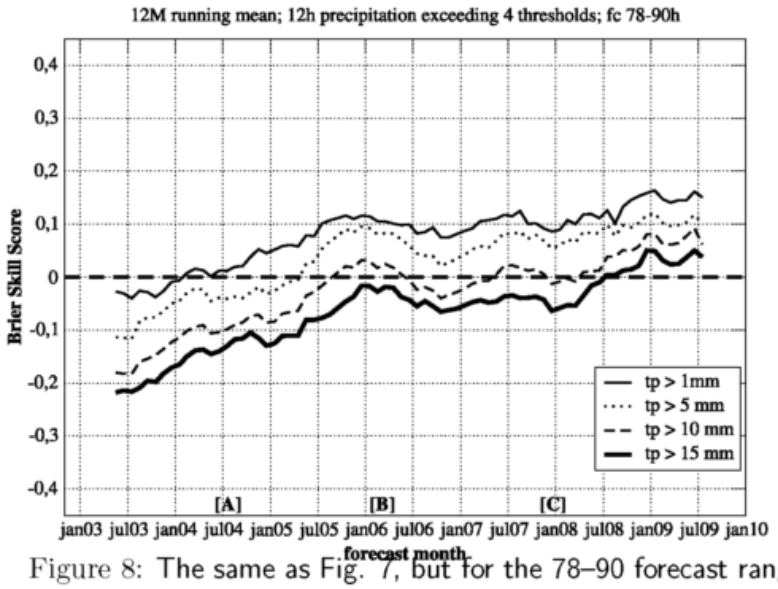

Figure 8: The same as Fig. 7, but for the 78–90 forecast range.

prediction of this type of events;

- the improvement is more evident for the two highest thresholds (dashed and thick–solid lines, respectively) throughout the years; BSS is systematically negative in the first years of activity, while it has been above zero for the 10mm/12h threshold since July 2005; as for the 15 mm/12h threshold, a good trend is evident up to January 2006, then the quality for the prediction of this type of events decreases up to mid–2008; since then, the skill of the system has started to increase again, although very close to the zero line. This is a very encouraging result, since it shows the improvement of the system performance for events of moderate–to–heavy precipitation in the early–medium range, the "hunting ground" of COSMO–LEPS;

- the dependence of the forecast skill on the threshold value has been reduced during the years of COSMO–LEPS activity. In 2003, the values of the BSS ranged roughly from -0.2 to 0.15 when passing from the highest to the lowest threshold; during 2009, BSS variations are approximately limited to the interval $[0.05, 0.25]$.

If the same type of running mean is applied to the BSS relative to the 78–90h forecast range, a common behaviour is evident for all thresholds. Fig. 8 shows an increase in the skill of the system for all types of events from the beginning of the activity up to January 2006. Then, the performance of the system stays stable for about 2 years and, finally, picks up again from July 2008 onwards. It can be seen that, for the 1mm (5mm) threshold, denoted with the solid (dotted) line of Fig. 8, the BSS has been positive since July 2004 (July 2005). As for the 10mm/12h and 15mm/12h thresholds (dashed and thick–solid lines, respectively), a positive trend on the forecast skill after the [C] upgrade can be noticed starting from July 2008. It is worth pointing out that we are assessing the possibility to predict 12–hourly accumulated precipitation after almost 4 days of integration (78–90 prediction range), which is a very "severe" test for any ensemble system. These results indicate the progresses of COSMO–LEPS forecasts in the early detection of severe and localised weather events. A quick comparison relative to the performance of the system for the highest thresholds (thick–solid lines of Figs. 7 and 8) indicates almost identical scores for both the shorter and the longer forecast range. This seems in apparent contradiction with the usual degrade of the

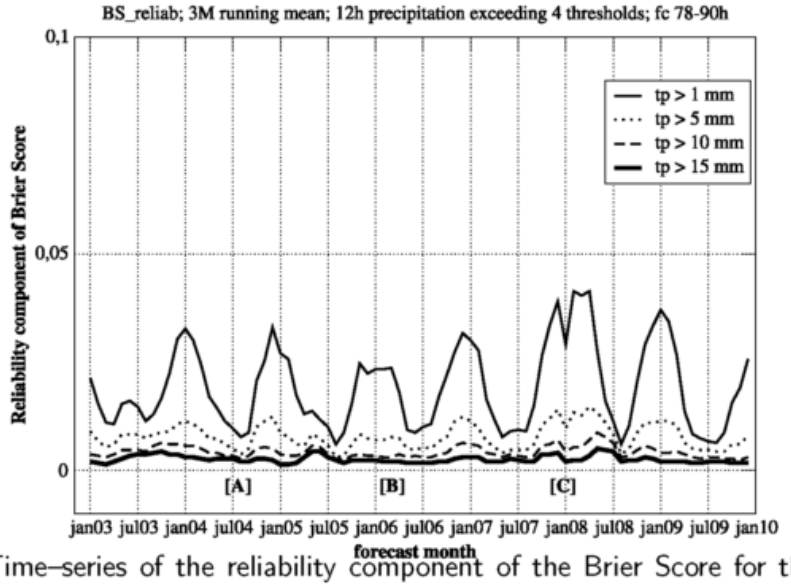

Figure 9: Time–series of the reliability component of the Brier Score for the monthly scores of COSMO–LEPS for 4 different thresholds: 1mm/12h (thin–solid line), 5mm/12h (dotted), 10mm/12h (dashed) and 15mm/12h (thick–solid). The forecast range is 78–90h. A 3–month running mean is applied to improve the readability of the plots. For the meaning of letters [A], [B], [C], refer to the text.

forecast skill with increasing forecast range, but is actually a feature of COSMO–LEPS system, which is mainly targeted for the early–medium range and is driven by those selected EPS members which should provide better guidance after the short range.

The reasons for the different results between the BSS and the ROC area can be found in the different type of information conveyed by the two indices (Marsigli et al., 2008). On the one hand, the BSS (and the RPSS) gives information about both the reliability and the resolution of the forecast system. The former one indicates how well the forecast probabilities by the ensemble system match the observed frequencies; the latter one highlights the extent to which the system can discriminate among events in different categories. A more thorough investigation on these two components, in their formulation used to compute the Brier Score (BS, not the BSS), shows the following:

- reliability component: the time–series of this quantity, which should be low (to contribute to a low BS and, hence, to a high BSS) is shown in Fig. 9 for the forecast range 78–90h, relative to the four thresholds in the previous figures. The time–series scores indicate little progress (if any) as for the reduction of the reliability component throughout the years of COSMO–LEPS activity. As for the 1mm/12h and 5mm/12h thresholds (thin–solid and dotted lines, respectively), a yearly cycle with almost constant amplitude is evident with higher values in winter; on the other hand, stable values can be noticed for the other thresholds. The reliability component could be modified by a change in the methodology used to construct the driving ensemble (ECWMF EPS) and/or COSMO–LEPS, which did not occur in these years;

- resolution component: this quantity should be high so as to provide a lower BS and a higher BSS. The time–series of this term (shown in Fig. 10 for the range 78–90h) indicates an increase of the values especially for the two lowest thresholds, indicating a greater capability of the system to distinguish among events in different categories.

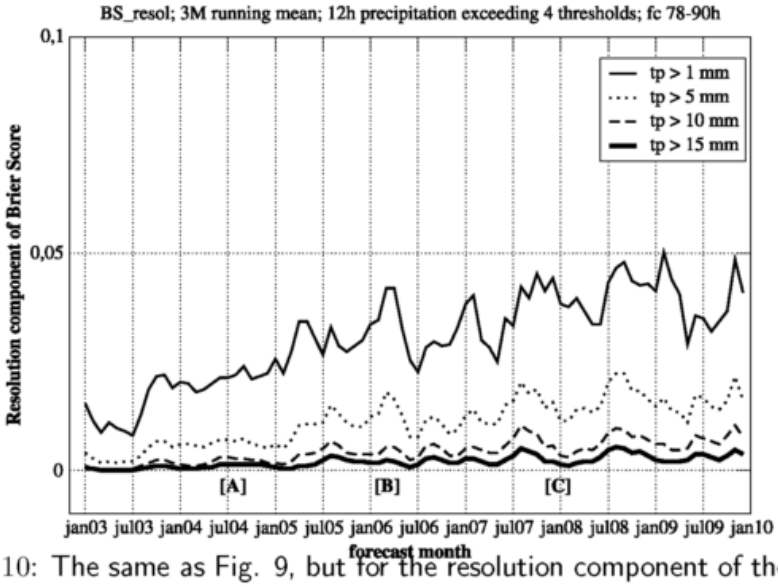

Figure 10: The same as Fig. 9, but for the resolution component of the Brier Score.

Therefore, the less marked improvement in terms of BSS is related to the behaviour of these two terms and on their relative weight in the generation of the score.
On the other hand, the ROC area provides information about the resolution component, which was shown to increase. For this reason, the improvement in terms of the ROC area is more evident, as was shown by Figs. 4 and 5.

5.3 Ranked Probability Skill Score

The RPSS (Epstein, 1969) is an extension of the BSS to a situation with many events, in this case those represented by the list of thresholds of Table 1. As before, the score ranges from minus infinity to 1 and a forecast system providing more useful information than the climatology (as before, given by the sample climate) would have a positive RPSS. If the RPSS is calculated for each month and for the different forecast ranges of Table 1, it turns out that the month–to–month variability of the score is extremely high (not shown). Therefore, in order to detect long–term behaviour for the value of this score, a 12–month running mean was again applied, like for the BSS. Fig. 11 shows the performance of the RPSS for different ranges, representative of COSMO–LEPS quality throughout the full integration period: 30–42h (solid), 54–66h (dotted), 78–90h (dashed) and 102–114 (thick–solid). The increase of the quality of COSMO–LEPS forecasts in the years is evident, although the pace of improvement is different depending on the forecast range. Periods of almost "monotonic growth" (e.g. the Jul05–Jan06 period for the 78–90h range) alternate with others of steady or slightly decaying performance. As an overall comment, the RPSS has been always positive for all forecast intervals, since the [B] upgrade, with particularly high scores in the last 12 months. The improvements concern all forecast ranges, the RPSS growing especially for the longest ones. In addition to that, those RPSS values reached around January 2004 in the early range (30–42h forecast, solid line in Fig. 11) are recently obtained for the 102–114 prediction range, with a gain of predictability of about 3 days in 5 years of system upgrades.

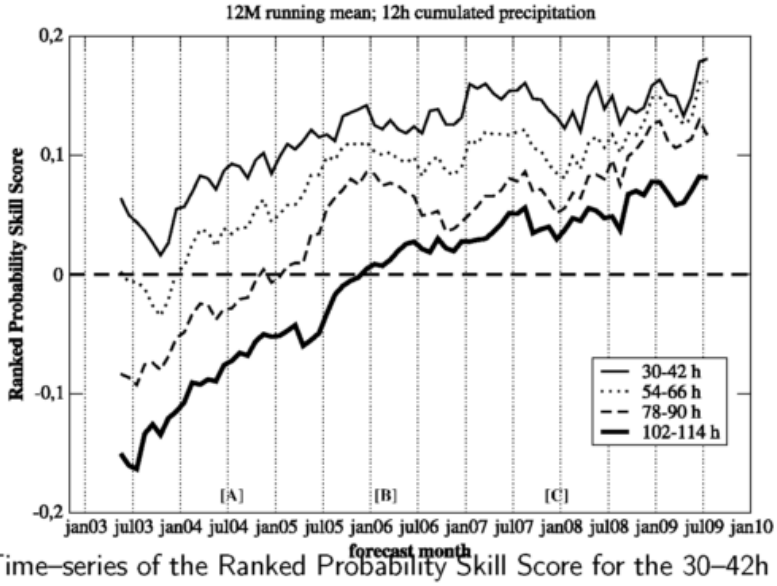

Figure 11: Time–series of the Ranked Probability Skill Score for the 30–42h (solid line), 54-66h (dotted line), 78–90h (dashed–line) and 102–114h (thick–solid line) forecast ranges. A 12–month running mean is applied to improve the readability of the plots. For the meaning of letters [A], [B], [C], refer to the text.

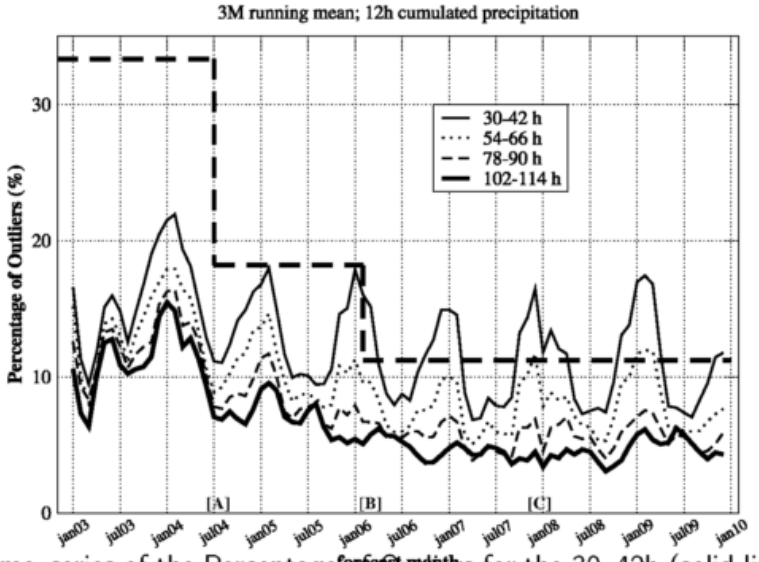

Figure 12: Time–series of the Percentage of Outliers for the 30–42h (solid line), 54-66h (dotted line), 78–90h (dashed–line) and 102–114h (thick–solid line) forecast ranges. A 3–month running mean is applied to improve the readability of the plots. The thick–dashed line indicates the theoretical values of the OUTL. For the meaning of letters [A], [B], [C], refer to the text.

5.4 Percentage of Outliers

The OUTL measures the percentage of times the observation stays outside the interval spanned by the values predicted by the ensemble members. For an ensemble of size N, its theoretical value is given by $2/(N+1)$ (Talagrand et al., 1999) and for a real ensemble system, it should be below this value. As for COSMO–LEPS, this value has changed during the years of the system activity: more precisely, it was 33.3% from November 2002 to July 2004 (up to the [A] upgrade); then, 18.2% for the 10–member ensemble (up to the [B] upgrade); finally, 11.2% for the 16–member size.
Fig. 12 shows the time–series evolution for OUTL at four different forecast ranges: 30–42h (solid), 54–66h (dotted), 78–90h (dashed) and 102–114 (thick–solid). For reference, the thick–dashed line indicates the theoretical value not to be exceeded. As for the previous scores, a 3–month running mean was applied to highlight the main results of the verification, which can be summarised as follows:

- a seasonal cycle of the score can be identified for all forecast ranges; OUTL tends to be higher in winters, especially for shorter forecast ranges, and lower in summers. This is due to an overestimation of little precipitation amounts during the cold season by the model runs; in fact, a partitioning of the OUTL into outl_max (observed value larger than all forecast ones) and outl_min (observed value smaller than all forecast ones) indicates that the latter contribution is well dominant for shorter ranges;

- for a fixed forecast range, it is shown an overall reduction of OUTL throughout the years of COSMO–LEPS activity from 2003 up to mid–2007, when, for any forecast range, OUTL was less than 10%, well below the theoretical value for a 16–member ensemble.

- from mid–2007 to early 2009, the OUTL has remained stable or has slightly grown for any range; in this period, the OUTL for shorter ranges exceeded the theoretical value;

- during 2009, a new reduction of OUTL takes place, with values of the same order (or below) those attained in 2007. For any forecast range but the first one, OUTL stays below the theoretical value. The excessive amount of OUTL for the shortest range is related to a lack of spread among COSMO–LEPS members in the early forecast intervals; this is possibly a consequence of the driving ensemble, which is specifically targeted to have sufficient spread in the medium range.

When the population of a small–size ensemble is increased, the reduction of OUTL is almost a natural consequence, since the probabilistic system can now access a wider fraction of the atmospheric phase space and account for a larger percentage of possible evolution weather scenario. Therefore, the OUTL reduction relative to upgrades [A] and [B] were not unexpected. On the other hand, the 2009–reduction is more likely due to the better performance of the individual COSMO–LEPS runs, related to model upgrades and refinements.

6 Seasonal scores

The results obtained in the previous section indicate that, on the basis of a number of probabilistic indices, the forecast skill of COSMO–LEPS has improved in many respects, in the past as well as recently. In this section, the performance of the system is studied in greater detail, investigating the COSMO–LEPS behaviour over specific periods and for particular types of weather events. More precisely, the attention is focused on the skill of

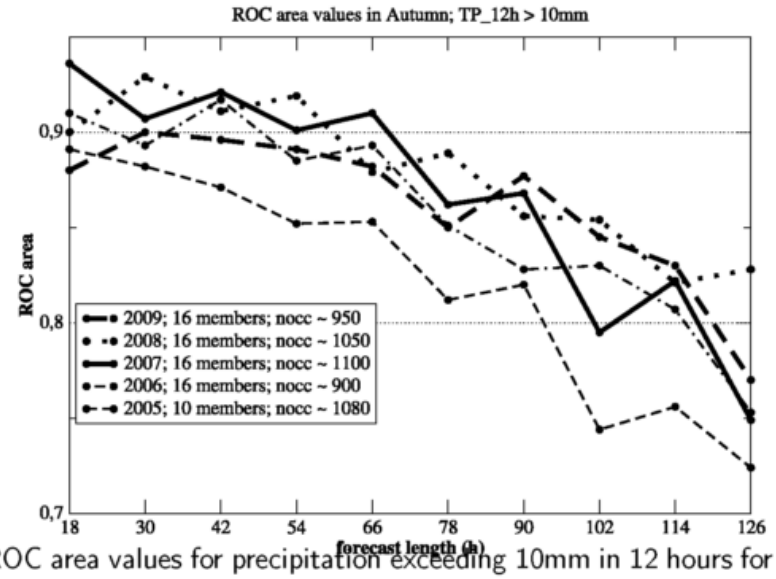

Figure 13: ROC area values for precipitation exceeding 10mm in 12 hours for the forecast ranges of Table 1 and for 5 successive autumns: 2005 (dashed), 2006 (dot–dashed), 2007 (thick–solid), 2008 (thick–dotted) and 2009 (thick–dashed).

the system during the two most rainy seasons in the Alpine area: autumn, defined as the 3–month period covering September, October and November (SON) and summer (June, July and August; JJA).
It has to be pointed out that, when comparing different seasons, the variations in the scores from one season to the other may depend on the fact that more occurrences took place during one season rather than during another one. In other words, if one autumn is more rainy than the previous one and also with a prevailing forcing better captured by the limited–area–model runs, then the ROC area values would be higher than for the other one. This may be probably due the different statistics of the two seasons under consideration and may not necessarily reflect an absolute improvement in forecast skill because of, e.g., model refinement or new ensemble strategies. Nevertheless, this type of verification, when applied to more and more seasons, enables to identify the improvements of the forecast system as well as of particular periods of good (or bad) performance.

6.1 Scores in autumn

For the autumn season, it is investigated the capability of the system to predict the event "precipitation exceeding 10mm over 12 hours". Fig. 13 shows the evolution of COSMO–LEPS performance in terms of ROC area for the forecast of this event. In order to limit the number of lines per plot, the scores of the system are reported only for the last 5 autumns (from 2005 to 2009). It can be noticed that the ROC area values relative to autumn 2005 (dashed line) are lower than those obtained in the following years for almost all forecast ranges. This may be related to the fact that in 2005 COSMO–LEPS still had a population of 10 members, the ensemble size being 16 in the other years. As for years 2006–2009, the performance of the system is quite stable: for shorter forecast ranges, COSMO-LEPS has slightly better performance in autumn 2007 (thick–solid line of Fig. 13), while higher ROC area values for longer ranges can be noticed in 2009 (thick–dashed line). For reference, the legend of Fig. 13 also reports, for each autumn, the number of occurrences, that is the number of times precipitation actually surpassed the 10mm threshold in 12 hours, according

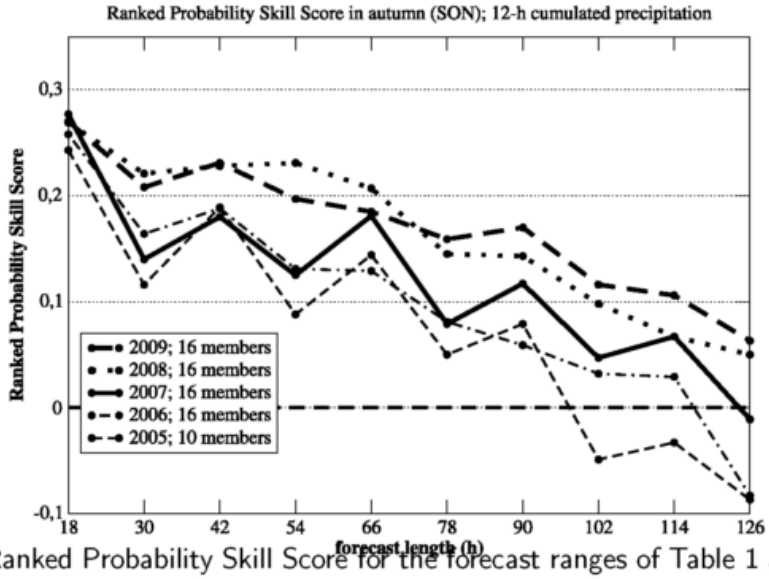

Figure 14: Ranked Probability Skill Score for the forecast ranges of Table 1 and for 5 successive autumns: 2005 (dashed), 2006 (dot–dashed), 2007 (thick–solid), 2008 (thick–dotted) and 2009 (thick–dashed).

to all reports of the SYNOP stations of Fig. 2.
As a further example of the behaviour of the probabilistic indices for the same season but in different years, the attention is focused on a score describing the COSMO–LEPS skill for multi–event situations. Fig. 14 shows the behaviour of the RPSS for the last 5 autumns as a function of the forecast step. The highest values are obtained in the last 2 years, the RPSS being positive for all forecast ranges (thick–dotted and thick–dashed lines for 2008 and 2009, respectively). In addition to that, Fig. 14 also indicates that, in the first years of activity, RPSS values had a marked semi–diurnal cycle. The system provides better guidance for "night–time" precipitation, that is for rainfall observed between 18UTC and 6UTC (and corresponding to the ranges 6–18h, 30–42h, 54–66h, 78–90h, 102–114h). As for "day–time" precipitation (observed from 6UTC to 18UTC), the model runs had a worse performance due to a systematic overestimation of rainfall (linked with a too rapid onset of convection). This is a general feature of the model, as pointed out by Oberto and Turco (2008) for runs of COSMO in "deterministic mode". This behaviour is evident throughout the full forecast range in 2005 and 2007 (dashed and thick–solid line, respectively). As for the last 2 years, the cycle in the score is still present, but its amplitude is reduced. It has to be pointed out that this type of model (mis)–behaviour shows up because of the decision to verify 12–hour accumulated precipitation. If the performance of COSMO–LEPS were evaluated over a 24–hour period, the problems relative to the semi–diurnal cycle would be masked and it would be more difficult to highlight the improvements in forecast performance under that aspect. Nevertheless, it can be noticed that, while the RPSS dropped definitely below 0.1 after about 72 hours of forecast in 2005, it does the same in 2009 but after 114 hours, with a gain of predictability of almost 2 days in 4 years.

Finally, it is presented the COSMO–LEPS performance at different forecast ranges in terms of Percentage of Outliers. The attention is focused, as before, on the last 5 autumns and Fig. 15 indicates that the best performance of the system is achieved in autumn 2009 (thick–dashed line), with OUTL below 10% after about 42 forecast hours. It has to be noticed that, during autumn 2007, the performance of the system was less satisfactory than in the other seasons up to day 4 (thick–solid line in the figure). This was due to a large

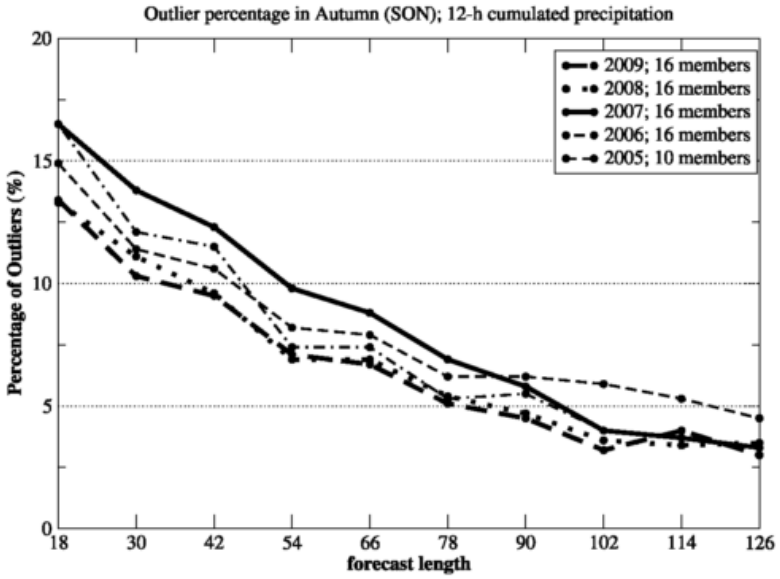

Figure 15: Percentage of Outliers for the forecast ranges of Table 1 and for 5 successive autumns: 2005 (dashed), 2006 (dot–dashed), 2007 (thick–solid), 2008 (thick–dotted) and 2009 (thick–dashed).

amount of outl_min, indicative of an overestimation of precipitation by COSMO–LEPS runs for several forecast ranges. As for 2005, the only season with a 10–member ensemble, a larger fraction of outliers is found for longer prediction ranges (dashed line), but the gap is not large. It is encouraging to notice that, as for the last autumns of activity, only in 5% of the cases is the observed precipitation outside the range spanned by the ensemble members from forecast–day 4 onwards.

6.2 Scores in summer

As for summer, the attention is limited to the COSMO–LEPS forecast skill in terms of RPSS for several prediction ranges. The 12–hourly cycle in the system performance, already shown for autumn by Fig. 14, is more evident during the warm season. Fig. 16 indicates that, for all summers under investigation (from 2005 to 2009), COSMO–LEPS has higher scores for "night–time" verification, while the skill is lower for precipitation observed between 6UTC to 18UTC and corresponding to the forecast ranges 18–30h, 42–54h, 66–78h, 90–102h and 114–126h [3]. As pointed out in the section 6.1, the sensitivity of the system performance to the time of verification is mainly due to an anticipation in the onset of convection by the model. This leads to precipitation occurring too early (morning or first hours of the afternoon) in the model runs. Obviously, this problem is amplified in summers, when the large–scale forcing is weaker than in autumns and the precipitation is mainly driven by convection processes. Due to the stronger role played by convection, the 12–hourly cycle in RPSS behaviour persists up to day 5 for all years but the last one. In fact, in 2009 (thick–dashed line), are not only the score values higher than in the past, but also the amplitude of the cycle is smaller for short forecast ranges and almost missing from day 3 onwards. This result seems to suggest that the model upgrades did bring benefit to the accuracy of COSMO–LEPS runs, which provide

[3]For a part of summer 2005, the forecast length was 120 hours, which means 12 hours shorter than in the other summers. Therefore, the score relative to this year (represented by the dashed line in Fig. 16) does not cover the last forecast range, but stops earlier.

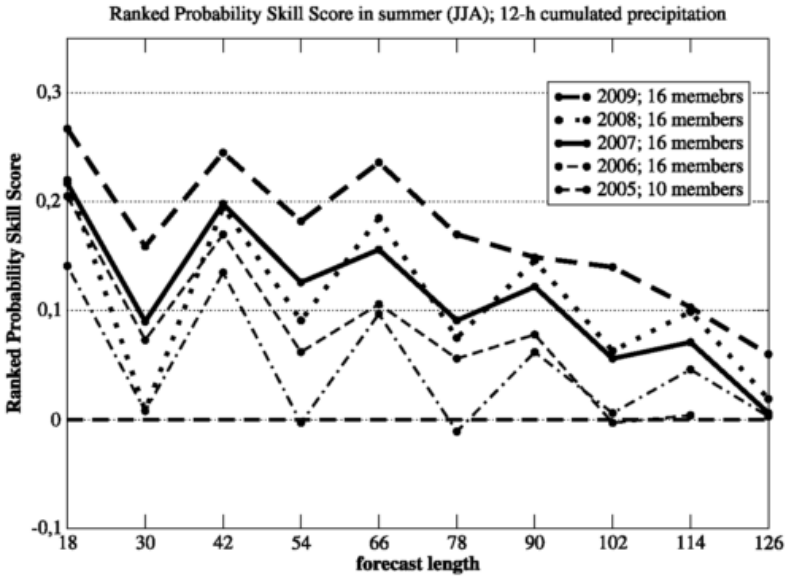

Figure 16: Ranked Probability Skill Score for the forecast ranges of Table 1 and for 5 successive summers: 2005 (dashed), 2006 (dot–dashed), 2007 (thick–solid), 2008 (thick–dotted) and 2009 (thick–dashed).

more and more valuable forecasts in the short and early–medium range. In fact, a quick comparison between the performances of 2005 and 2009 (dashed versus thick–dashed line in Fig. 16) shows that, with reference to the 0.1 value, the skill score obtained after 66 hours is now achieved after 114 hours, thus confirming the gain of about 2 days of predictability in 4 years of operational activity.

7 Conclusions

The main features of the mesoscale ensemble system COSMO–LEPS were presented. At the moment, the system is made up of 16 integrations of the non–hydrostatic COSMO model with a horizontal resolution of 10 km, 40 vertical levels and a forecast length of 132 hours, thus providing short and early–medium range ensemble forecast of high–impact weather with great spatial detail. COSMO–LEPS runs can be viewed as a dynamical downscaling of ECMWF EPS, where the number of global–ensemble members are reduced via an "ensemble–size reduction" technique.
The performance of COSMO–LEPS has been analysed in terms of probabilistic prediction of 12–hourly accumulated precipitation for a number of thresholds. The evolution of the skill of the system has been assessed over a 7–year period, namely from December 2002 up to November 2009. Observations of 12–hour accumulated precipitation were taken from the SYNOP reports over the Alpine area and compared to the nearest grid–point forecasts of the COSMO–LEPS members. A number of probabilistic indices has been used so as to evaluate both reliability and resolution of the system and to assess the extent to which the quality of COSMO–LEPS forecasts improved in recent times.
The main findings can be summarised as follows:

- time–series scores of the ROC area values for different thresholds indicate a clear improvement of COSMO–LEPS skill throughout the years, with an increase of this score up to 2006, then slower growth in the 2 following years and a resumption of

growth in the last part of 2009. This holds in the short as well as in the early–medium range;

- as for the BSS (and the RPSS), the month–to–month variability of the time–series scores is higher than for the ROC area and the positive impacts of system upgrades are more difficult to detect. If 12–month filters are applied to the scores, more insight is gained and forecast improvements with time become more detectable. As for an estimate of the improvement, RPSS values enables to quantify it as "2 days of predictability gained in the last 5 years";

- time–series of the OUTL indicate a decrease of Outliers up to early 2007 for various forecast ranges and a steady behaviour since then on. A new decrease is evident in 2009, with the OUTL below 10% from day 2;

- seasonal scores confirm to a large extent the previous results; they enable to highlight the progresses in the skill of the system over the same season but in different years. The improvements in skill are well noticeable in terms of RPSS during summer, where the gain in forecast skill can be estimated as about 2 days of predictability in the last 4 years of activity.

The reasons for the different results between the BSS and the ROC area were shown to be due to the different type of information conveyed by the two indices. On the one hand, the BSS (and the RPSS) gives information about both the reliability and the resolution of the forecast system (Marsigli et al., 2008). The former one indicates how well the forecast probabilities by the ensemble system match the observed frequencies. The latter one indicates the extent to which the system can discriminate among events in different categories. Reliability can be increased after a good calibration, which manages to match probabilities and frequencies; resolution cannot be improved by any statistical post-processing. On the other hand, the ROC area provides information only about the discrimination capability of the forecast system. As such, the ROC area scores show the COSMO–LEPS ability to detect between events and nonevents, despite the reliability, and represent the hypothetical skill of the system once it were properly calibrated. It was shown that the reliability component of COSMO–LEPS forecasts did not increase in the last years at the same pace as the resolution one, this explaining the better results obtained in terms of ROC area.

Work is in progress at both ARPA–SIMC and MeteoSwiss to provide calibrated COSMO–LEPS forecasts, thanks to the results obtained by the re–forecast exercise described in Fundel et al. (2009). This would improve the skill of COSMO–LEPS forecasts, making the system more reliable than it is now. As for the future, it is being tested the increase of the horizontal resolution of COSMO–LEPS runs so as to provide more detailed forecasts for the interaction of the flow with orography and to describe with a higher degree of accuracy mesoscale–related processes and local effects. This would have a positive impact on the prediction of a number of those surface fields still nowadays strongly influenced by local effects and not always properly represented in terms of their uncertainty by mesoscale ensemble systems.

8 Acknowledgments

The authors are indebted to the countries of the COSMO Consortium and to ECMWF for the possibility to run the COSMO–LEPS application. We are grateful to Manuel Fuentes, Umberto Modigliani and Paolo Patruno for technical assistance and continuous support. We also thank André Walser, Carlo Cacciamani and Stefano Tibaldi for useful discussions.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW) and Romania (NMA). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

Abstract

Data assimilation techniques based on the statistical least squares theory or the best linear unbiased estimate (BLUE), such as variational or ensemble Kalman filter methods rely on the assumption that the model first guess and the observations are bias free and its errors are normally distributed with known variances and covariances. Nonlinearities, resulting from strong dynamical instabilities can result in non-Gaussian error distributions and thus potentially cause problems in data assimilation.
In this study, error distributions of the non-hydrostatic COSMO model in a convection-permitting deterministic and ensemble configuration are investigated. Forecast departures and ensemble background anomalies of varying lead time and different variables are considered for this purpose.
The forecast departures of most of the investigated variables show a reasonable Gaussian behaviour around the median, but exhibit more larger departures (both negative and positive) than described by a normal distribution ("fat tails"). Near-surface variables tend to be closer to normality than upper-level variables. Humidity and rainfall show a rather exponential than Gaussian behaviour.
Ensemble background anomalies at short lead times can deviate significantly from normality. Especially low-level temperature has been found to have multiple modes in their distribution. At longer lead times the anomaly distributions are much closer to normality. Upper level distributions are close to Gaussian. The large deviations from normality at short lead times are largely due to the physical perturbations employed in the current COSMO ensemble system to introduce spread.
Overall, the results of this study suggest that, ensemble data assimilation systems relying on the BLUE theory may well be feasible for the use with the high-resolution COSMO model, given that appropriate (i.e. more random) physics parametrisation perturbations are applied.

1 Introduction

Ensemble Kalman filter based assimilation methods for numerical weather prediction models currently receive considerable attention in the scientific community. While first implementations for global models are already operationally employed, the development of such schemes for regional [mesh size O(10km)] and convection permitting scale [mesh size O(1km)] models is still in its infancy. The COSMO consortium (http://www.cosmo-model.org) is currently developing a new ensemble assimilation system for its convection permitting NWP model. The Local Ensemble Transform Kalman Filter (LETKF, Hunt et al., 2007) is an ensemble Kalman filter method based on the statistical least squares theory or the best linear unbiased estimate (BLUE). Assimilation methods based on this theory (e.g. variational methods, ensemble Kalman filter methods) allow an optimal combination of model and observations, given that the basic assumptions of the BLUE theory are met, namely that the model first guess and the observations are bias free and its errors are normally distributed with known variances and covariances. The violation of the Gaussian assumption has found to be of concern in non-mean-preserving deterministic square-root filters (Sakov and Oke, 2008), where the ensemble can show a tendency to develop markedly non-Gaussian error distributions (Lawson and Hansen, 2004; Leeuwenburgh et al., 2005; Mitchell and Houtekamer, 2009). In these studies, the stochastic ensemble Kalman filter with perturbed observations seemed largely immune to this problem, even in strongly nonlinear applications. On the other hand, Bonavita et al. (2010) demonstrated that the LETKF works reasonable in a regional NWP system with distributions that slightly deviate from Normality. Yang and Kalnay (2009) and Kalnay and Yang (2009) proposed ways to deal with strong non-linearities and non-Gaussianity using the LETKF in iterative ways.

In an ensemble Kalman filter approach, the optimal combination of model forecast and observations, called analysis, can formally be determined by finding the minimum of the cost function

$$J(\mathbf{x}) = \left(\mathbf{x} - \bar{\mathbf{x}}^{\mathbf{b}}\right)^T \left(\mathbf{P}^b\right)^{-1} \left(\mathbf{x} - \bar{\mathbf{x}}^{\mathbf{b}}\right) + \left[\mathbf{y_o} - H(\mathbf{x})\right]^T \mathbf{R}^{-1} \left[\mathbf{y_o} - H(\mathbf{x})\right] \tag{1}$$

$\mathbf{x}$ is the multidimensional model state vector, $\bar{\mathbf{x}}^{\mathbf{b}}$ is the ensemble mean of the model background, defined by the average of all ensemble members $\mathbf{x}^{b(i)}, i = 1..k$

$$\bar{\mathbf{x}}^{\mathbf{b}} = k^{-1} \sum_{i=1}^{k} \mathbf{x}^{b(i)} \tag{2}$$

$\mathbf{P}^b$ is the background error covariance matrix, $\mathbf{y_o}$ is the observation vector, H is the observation operator and $\mathbf{R}$ is the observation error covariance matrix. The forecast departures $\mathbf{d} = \mathbf{y_o} - H(\mathbf{x})$ measure the difference between observations and model equivalents. The ensemble background anomaly (EBA) $\mathbf{a}_i$ is defined by the difference of a particular ensemble member and the ensemble mean $\mathbf{a}_i = \mathbf{x}^{b(i)} - \bar{\mathbf{x}}^{\mathbf{b}}$.

Even though the LETKF is by construction a mean-preserving ensemble square-root filter and thus should be less prone to problems with non-Gaussianity it is worth looking at how well the convection permitting COSMO model meets the assumption of the BLUE theory, namely how well the forecast departure statistics and the ensemble background anomalies can be approximated by a Gaussian distribution. The questions to be answered are

- What form take the distributions of forecast departures and EBA from a short-range high-resolution (ensemble) COSMO forecast ?
- How does the distribution changes with forecast lead time ?

- Are there differences in the distribution between summer and winter ?

The results are expected to give a hint if the LETKF is feasible to be used with the convection permitting COSMO model.

2 Data and Evaluation Method

2.1 Data

2.1.1 Forecast Departures

The forecast departure statistics considered in this study are based on operational DWD convection permitting COSMO-DE (mesh size of 2.8 km, without parametrized deep convection, covering Germany and surroundings) and regional COSMO-EU (mesh size of 7 km, with deep convection parametrization, covering whole Europe) forecasts from two periods:

- Winter: 12/2007 - 02/2008 (91 days, 364 forecasts)
- Summer: 06/2008 - 08/2008 (92 days, 368 forecasts)

Since we are interested in short-range forecasts we consider departures for forecast lead times from +3h to +6h. In order to see how the statistics change with evolving forecast time, we compare them with departures for leadtimes from +9 to +12h. Forecast departures are calculated for all conventional observations that are routinely assimilated in the COSMO model at DWD, namely

- SYNOP (p_s,T,u/v,RH, and pp)
- Radiosondes (T,u/v and RH at 940, 850, 500 and 300 hPa)
- Aircraft data (T and u/v at 940, 850, 500 and 300 hPa)
- Wind profiler (u/v at 940, 850, 500 and 300 hPa)

All observations from the above list are actively assimilated, except surface precipitation (pp) from SYNOP stations, which is only used for the calculation of the departures.

For ease of comparison of COSMO-DE and COSMO-EU, only departures from observations inside the COSMO-DE domain are taken into account.

2.1.2 Ensemble Background Anomalies

The ensemble background anomalies are calculated from forecasts of the pre-operational high resolution German COSMO-DE EPS, running in a similar configuration as the COSMO-DE deterministic forecast. The 20 ensemble forecast members are initialized at 00 UTC from a regional EPS (COSMO-SREPS) driven by different global models and using different physical parametrization settings and are integrated out to 24 hours. The configuration of the boundary conditions and of the physical parametrisations are summarized in Table 1.

- Ensemble forecast from a summer period (8.8.2007 - 16.8.2007) are considered.
- Forecast lead times of +3h and +24h are compared
- The following variables are looked at
  - T and u at the terrain-following model levels at approximately 10 m, and 5500 m above surface.
  - pp at the surface

Ensemble members	Driving global model	
01-05	ECMWF	
06-10	GME	
11-15	NCEP	
16-20	UKMO	
Ensemble members	Physical parameter perturbation	Default value
01, 06, 11, 16	entrscv=0.002	entrscv=0.0003
02, 07, 12, 17	clc_diag=0.75	clc_diag=0.5
03, 08, 13, 18	rlam_heat=50	rlam_heat=1
04, 09, 14, 19	rlam_heat=0.1	rlam_heat=1
05, 10, 15, 20	tur_len=150	tur_len=500

Table 1: Configuration of the COSMO-DE EPS in terms of boundary conditions and physical parametrisation tuning values.

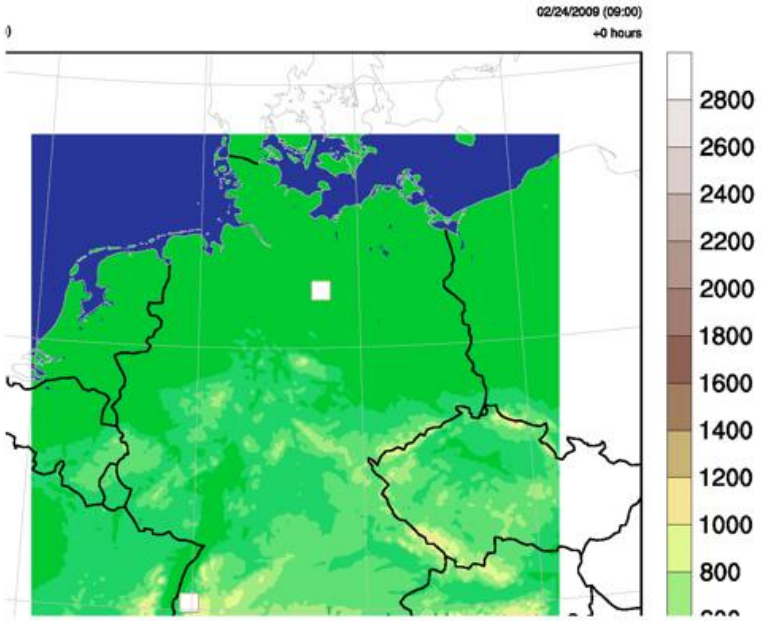

Figure 1: Computational domain of COSMO-DE and COSMO-DE EPS. The coloured domain depicts the plotting domain for the stamp maps in Section 4 and the two white squares marks the two verification domains South Germany and North Germany used for the calculation of the ensemble anomaly statistics.

2.2 Evaluation Method

In order to judge, how well the forecast departure and EBA distributions are approximated by the Gaussian distribution, we compare them, both qualitatively and more quantitatively with Gaussian pdf's fitted to the data. The forecast departure d_l of a single observation is

$$d_l = y_{o,l} - H(\mathbf{x})_l \tag{3}$$

where y_0 denote the observation and $H(\mathbf{x})_l$ the corresponding model equivalent obtained by the application of the observation operator H to the model state $\mathbf{x}$. $l = 1..N_l$ is the index specifying a particular observation from all N_l observations.

For the ensemble background anomalies we consider all k ensemble members and compute the distribution from all anomalies $a_{(i,j)}$, $i = 1..k$, $j = 1..N_j$, where N_j is the number of gridpoints of a 2d model field in a specified verification domain and at a certain terrain-following level.

The probability distribution $p(x)$ over a set of indices i (e.g. all temperature observations from radiosondes at $850 \pm 10hPa$ within a leadtime range of +3h to +6h using COSMO-DE forecasts in the summer period) is considered (near-)Gaussian if it approximates the Gaussian distribution

$$\tilde{p}(x) = N(\bar{x}, \sigma) = \frac{1}{\sqrt{2\pi}\sigma} e^{-\left(\frac{x-\bar{x}}{\sigma}\right)^2} \tag{4}$$

The mean $\bar{x}$ and the standard deviation σ of the distributions are calculated by

$$\bar{x} = \frac{1}{N}\sum_{i=1}^{N} x_i \tag{5}$$

$$\sigma = \sqrt{\frac{1}{N}\sum_{i=1}^{N}\left(x_i - \bar{x}\right)^2} \tag{6}$$

where N is the number of data in the considered set.

In the case of the forecast departures, $x = d, i = l$ and $N = N_l$. In the case of the ensemble background anomalies, $x = \mathbf{a}$ and $N = N_j \cdot k$. The qualitative evaluation of the Gaussianity of $p(x)$ is done graphically by plotting the pdf and its Gaussian approximation $\tilde{p}(x)$ calculated from (4) using (5) and (6). Figure 2 (upper panel) shows an example for a forecast departure distribution: the bold line represents the pdf $p(d)$ and the thin line its approximation $\tilde{p}(d)$. Note that in the semilogarithmic representation the normal pdf takes a parabolic form.

It is useful to not only estimate if the Gaussian approximation is fulfilled, but to estimate how well it is approximated. To this end we define the term "normrange" by the range of probabilities over which the Gaussian approximation is reasonable. A perfect Gaussian fit has a normrange of 100%. To calculate the normrange, a normal probability plot is drawn of $p(x)$. In this graph, the cumulative distribution function of $p(x)$ is transformed in a way that a Gaussian distribution represents a straight line. Any deviation from this line suggests non-Gaussianity. The reference Gaussian distribution, against $p(x)$ is compared, is obtained from the 25% and the 75% quantile of $p(x)$. It appears as the dash-dotted straight lines on the normal probability plots. The normrange is then calculated as the range, where $p(x)$ is close to the line. "Close" is defined such that $p(x)$ does not differ from the straight line by more than a threshold, defined by the difference of the 25% and the 75% quantile divided by 12 (subjective choice). Figure 2 (lower panel) shows an example of a normal probability plot. The crosses borders the normrange, i.e. the region where $p(x)$ can be reasonably approximated by the normal distribution.

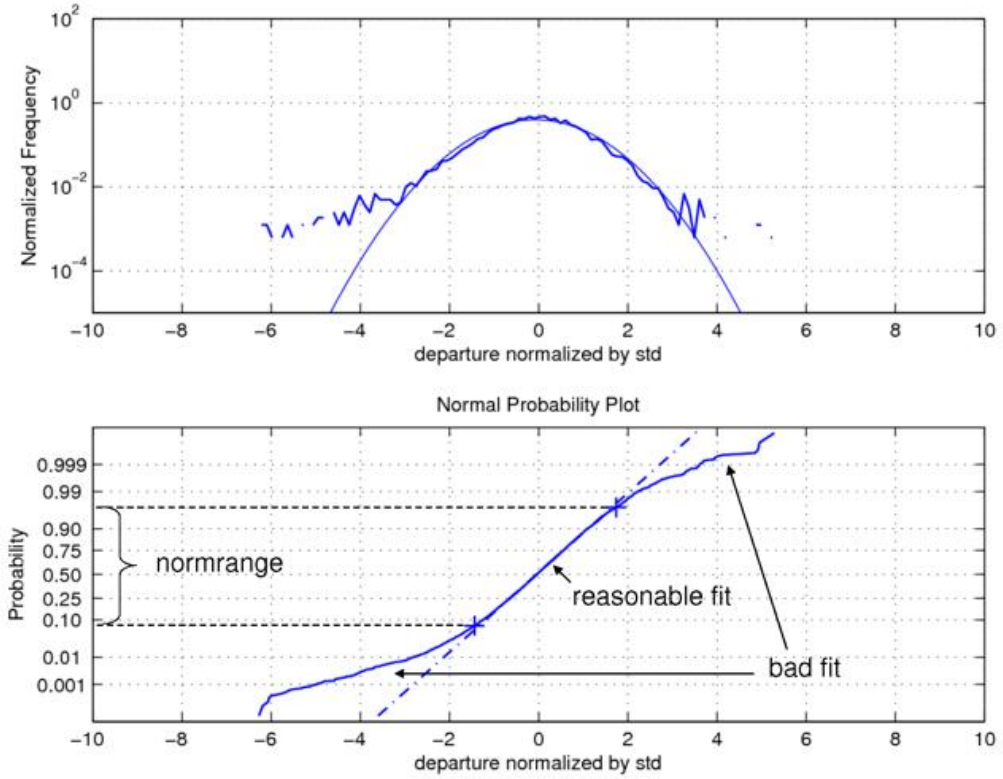

Figure 2: Example of the evaluation method used in this study. Upper panel: semilogarithmic representation of the departure distribution $p(d)$ (bold line) and its reference normal distribution $\tilde{p}(d)$ (thin line). Lower panel: normal probability plot and definition of normrange (see also text).

3 Forecast Departure Statistics

In this section we present COSMO-DE forecast departure distributions from all observations in the model domain mentioned in Section 2.1.

3.1 Near surface

3.1.1 Surface Pressure

Figure 3 shows the results for surface pressure. The distribution is near-Gaussian around the median and within approximatively ± 3 standard deviations, which corresponds to roughly ± 2.7 hPa, irrespective of the forecast lead time. At the end (tails) of the distributions, the departure distribution deviates from normality, i.e. there are more large deviations than what would be described by a Gaussian distribution. The distribution is slightly asymmetric at the tails, i.e. there are more large positive departures than large negative departures, meaning that the model more often largely underestimates pressure than largely overestimates it.

The negative pressure bias (i.e. in the mean, the model overestimates the pressure) increases by 17% in summer (26% in winter) with lead time (upper panels). The normranges amount to roughly 94% in summer and 87% in winter (lower panels) and do not change significantly during the first 12h of the forecast.

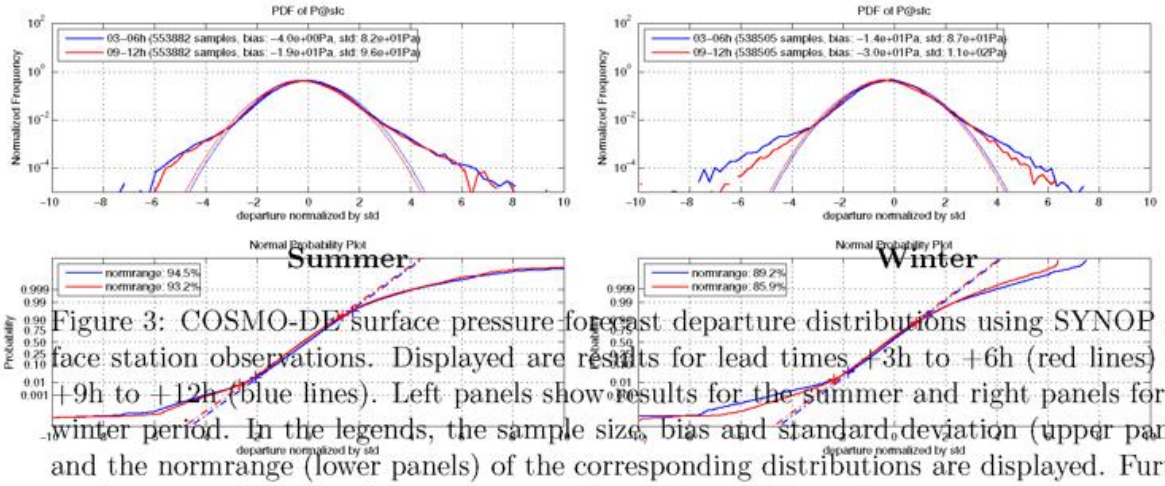

Figure 3: COSMO-DE surface pressure forecast departure distributions using SYNOP surface station observations. Displayed are results for lead times +3h to +6h (red lines) and +9h to +12h (blue lines). Left panels show results for the summer and right panels for the winter period. In the legends, the sample size, bias and standard deviation (upper panels) and the normrange (lower panels) of the corresponding distributions are displayed. Further explanations about the plots are given in Section 2 and Figure 2.

3.1.2 2m Temperature

The 2m temperature distributions differ from the surface pressure distributions in that they are less good approximated by a normal distribution (Figure 4). This is particularly obvious in winter (right upper panel), but to a less degree also in summer (left upper panel). The

lognormal curves have a more linear than parabolic shape, suggesting a more exponential than Gaussian nature. This behaviour is reflected in normranges of approx. 83% in summer and 75% in winter. The bias are below one degree and the standard deviations around 1.8 degrees. Both bias and standard deviation are nearly leadtime independent up to 12h.

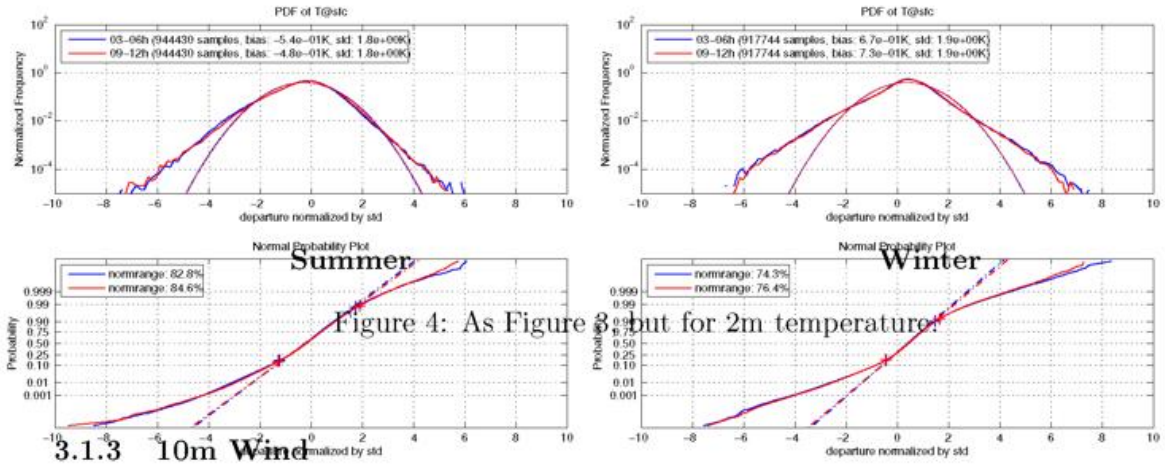

Figure 4: As Figure 3, but for 2m temperature.

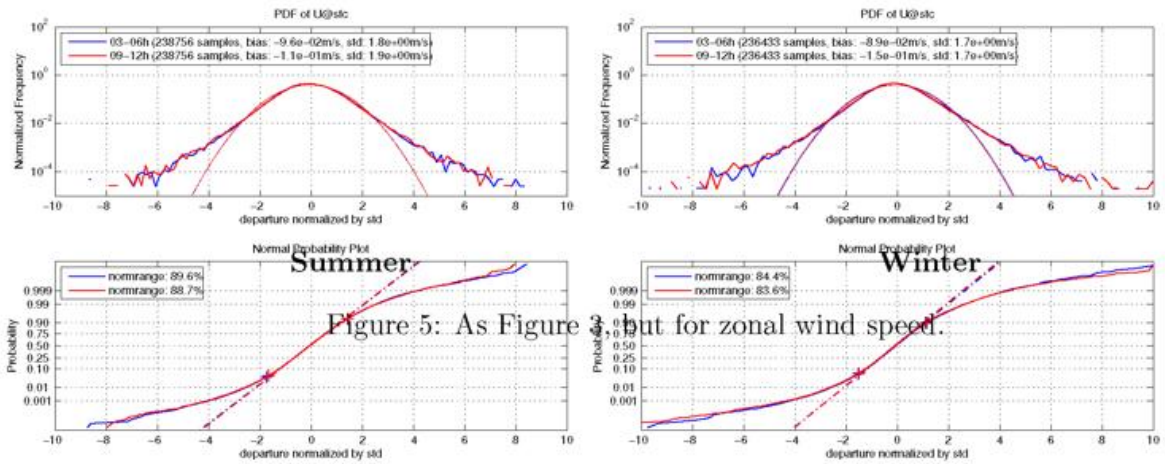
3.1.3 10m Wind

The distributions of 10m wind are better Gaussian approximated than those of 2m temperature (Fig. 5). Normranges are about 89% in summer and 84% in winter.

The bias is around -0.1 m/s and the standard deviation around 1.8 m/s and nearly independent from lead time and season. Zonal and meridional components behave almost identically, therefore only the zonal wind speed is shown.



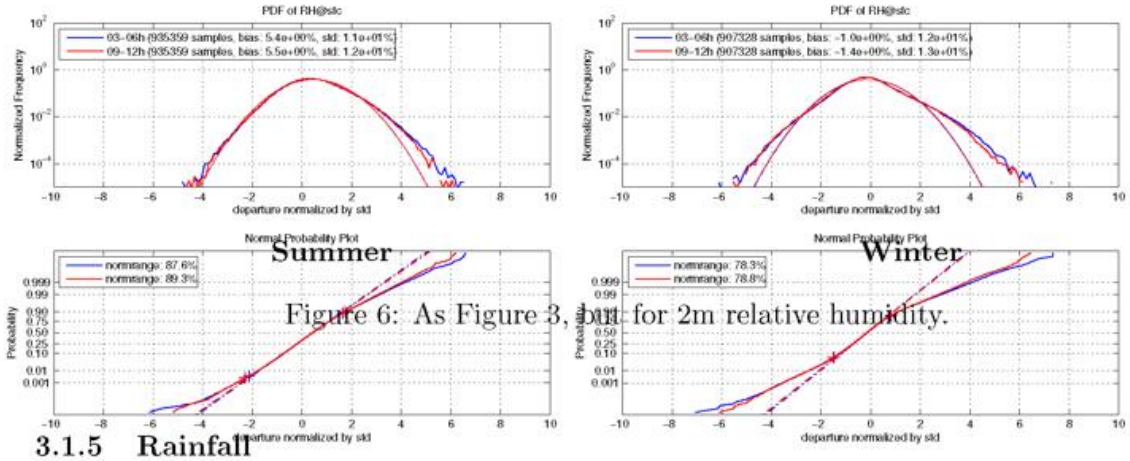


Figure 5: As Figure 3, but for zonal wind speed.

3.1.4 2m Humidity

The 2m relative humidity forecast departure distribution (Fig. 6) differs substantially between summer and winter. In summer the distribution is very close to normal, even the negative "fat tail" is absent, resulting in a high normrange of 88%. In winter the distribution is more exponential than Gaussian and thus the normrange does not exceed 79%. The distributions are nearly independent on lead time.

Also the bias is dependent on season and amounts 5.4% (-1%) in summer (winter). The standard deviation is in both seasons 11%.

Summer **Winter**

Figure 6: As Figure 3, but for 2m relative humidity.

3.1.5 Rainfall

Surface rainfall as observed by SYNOP stations is not actively assimilated in the model, but merely used to compute forecast departures. The distribution turns out to be far away from Gaussian both, in summer and winter (Figure 7). The normrange calculation is not reliably applicable for this type of distribution and is therefore omitted.

Summer **Winter**

Figure 7: As Figure 3, but for rainfall observed by SYNOP.

Forecast departures from radar rainfall have been computed using model output from the Swiss COSMO-2 (mesh size of 2.2 km, without parametrized deep convection) which runs in a similar configuration as the COSMO-DE model and from radar derived surface rainfall from the Swiss Radar Network (SRN). The model data is taken from 13 12UTC forecasts (same lead times as before) during the period from 1.6.2008 to 13.6.2008. A domain of 70x40 km with a very good radar visibility in the Swiss plateau has been chosen, in order to

obtain high quality observations. The departures are calculated gridpoint by gridpoint from hourly sums after a 3x3 gridbox filter application. Radar rainfall is assimilated in the high resolution COSMO-DE and the Swiss COSMO-2 using the latent heat nudging scheme.

As for SYNOP rainfall, the departures using radar rainfall (Figure 8) can not be approximated with a Gaussian distribution. A distinct peak at zero departure suggests the occurrence of many situations where rain is neither observed nor forecast. Beyond standard deviations of 1 (-1) the distribution shows an exponential rather than a Gaussian behaviour. Moreover the distribution is asymmetric and exhibits more large positive departures (i.e. underestimation by the model).

Figure 8: As Figure 7, but for Swiss summer rainfall derived from radar data.

3.2 Upper atmosphere

Upper air measurements are classified according to the pressure level, on which they are observed. Main pressure levels of 940, 850, 500 and 300 hPa are considered in this study. For the sake of increasing the sample size, observations within a pressure layer with thickness of 20 hPa centered around the main pressure level are also taken into account. Forecast departures have been calculated from radiosonde, aircraft and windprofiler observations. The distributions are of similar structure between corresponding observations, though they slightly differ in bias and standard deviation. Therefore, only the observations with the largest sample size are shown here (aircraft data for temperature and wind and radiosonde data for humidity), the rest of the results are shown in Section 5.

3.2.1 Temperature

Upper air temperature forecast departures can generally be well approximated by Gaussian distributions (Figures 9 - 12 and 38 - 41). Only in the winterly boundary layer (at 940 hPa and 850 hPa), deviations between 0 and -2 standard deviations are apparent. Normranges reach values of 86%-96% in summer and 79%-90% in winter. Values in the boundary layer are generally lower than in the middle and upper atmosphere.

Biases are well below 0.2 K and standard deviations below 1.5 K. Departures are larger in winter and in the boundary layer than in summer and in the mid/upper atmosphere.

3.2.2 Wind

Wind departures are found to be also very nearly Gaussian (Figures 13 - 16 and 42 - 61). Normranges are between 79% and 88%, generally higher in summer than in winter, but there is no clear dependence on height.

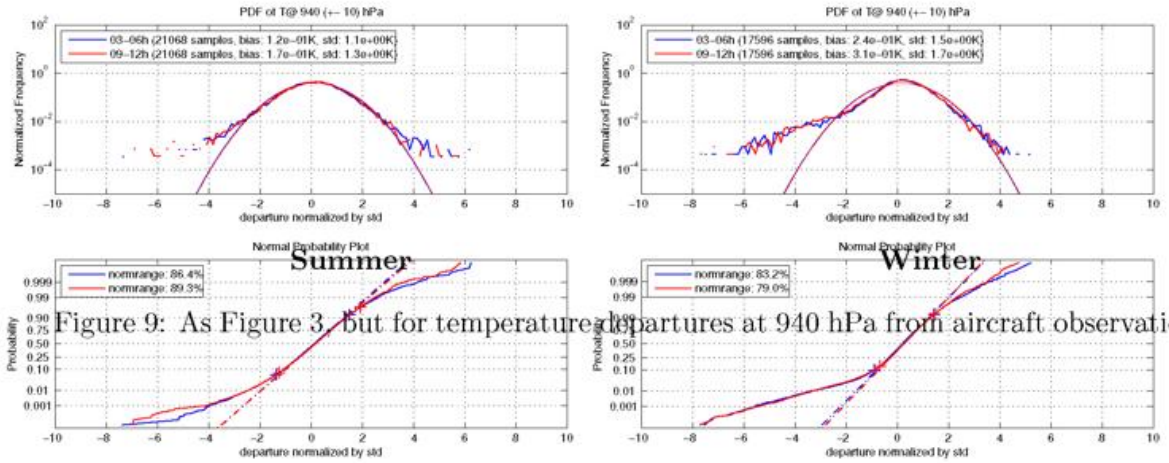

Figure 9: As Figure 3, but for temperature departures at 940 hPa from aircraft observations.

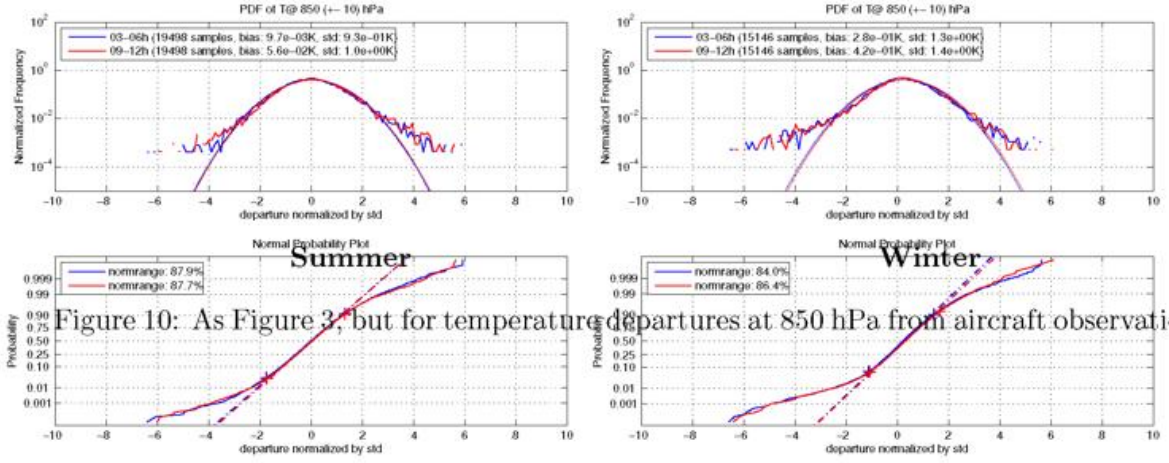

Figure 10: As Figure 3, but for temperature departures at 850 hPa from aircraft observations.

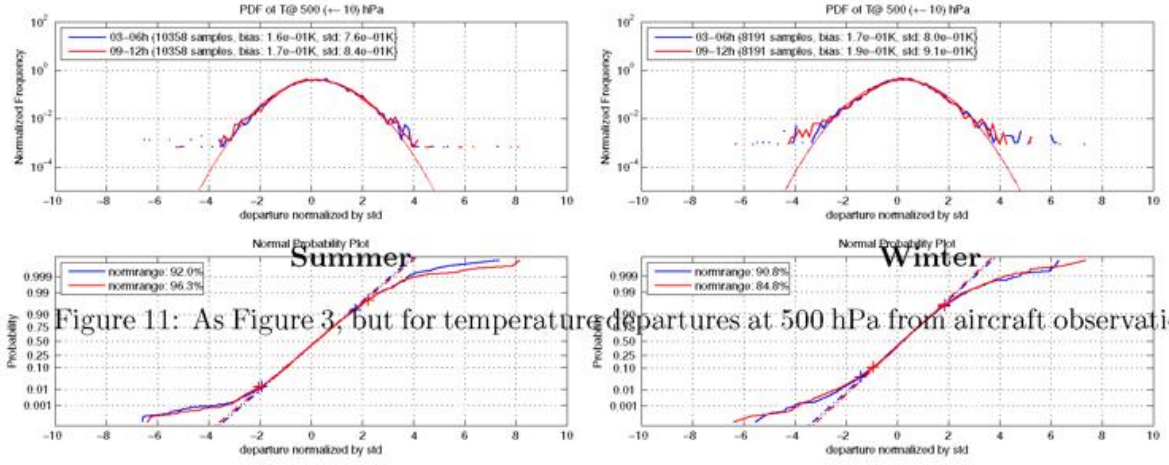

Figure 11: As Figure 3, but for temperature departures at 500 hPa from aircraft observations.

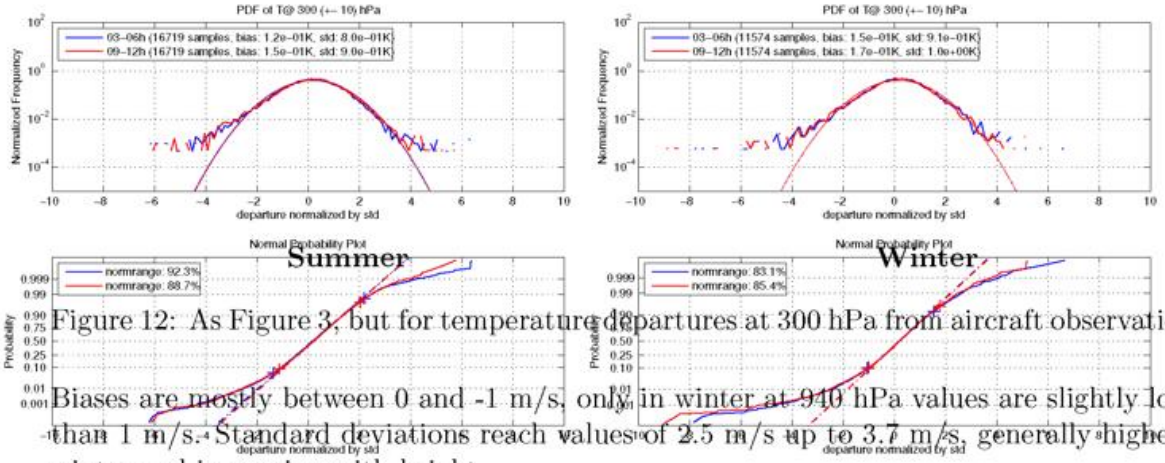

Figure 12: As Figure 3, but for temperature departures at 300 hPa from aircraft observations.

Biases are mostly between 0 and -1 m/s, only in winter at 940 hPa values are slightly lower than 1 m/s. Standard deviations reach values of 2.5 m/s up to 3.7 m/s, generally higher in winter and increasing with height.

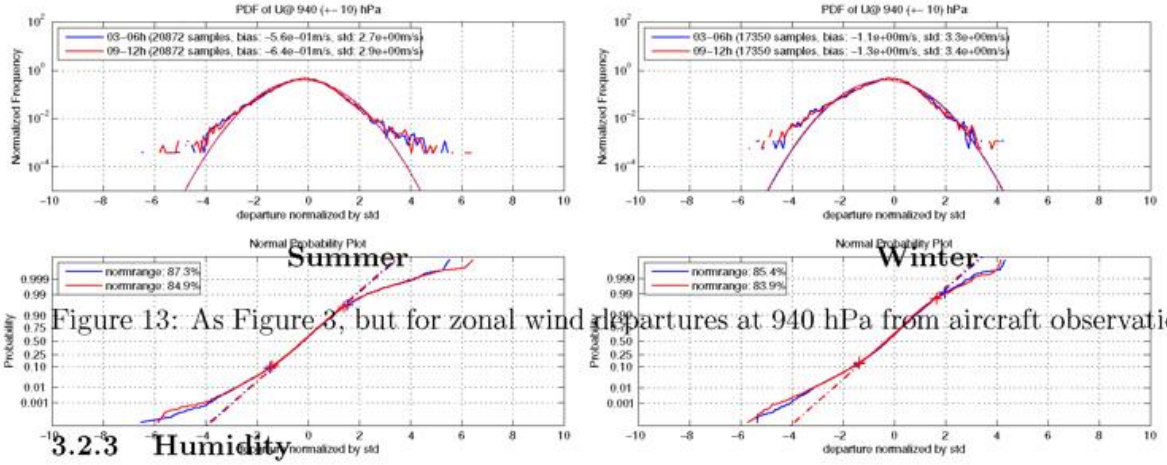

Figure 13: As Figure 3, but for zonal wind departures at 940 hPa from aircraft observations.

3.2.3 Humidity

Forecast departures of relative humidity can not be well approximated by a normal distribution (Figures 17 - 20). Especially in winter a distinct peak in the pdf is visible for zero departures in the boundary layer (940 hPa and 850 hPa, Figures 17 and 18). This peak origins from many winterly stratus situations, where both model and observations are saturated, resulting in zero departures (not shown). This peak is not apparent in summer and in the upper atmosphere. Winter distributions generally show a rather exponential, than Gaussian shape, resulting in generally low normranges, where summer distributions are more Gaussian.

Biases increase with height from less than 2% (940 hPa) to roughly -9% (300 hPa) in summer and 3% (940 hPa) to roughly -7% (300 hPa) in winter. Standard deviations are less height-

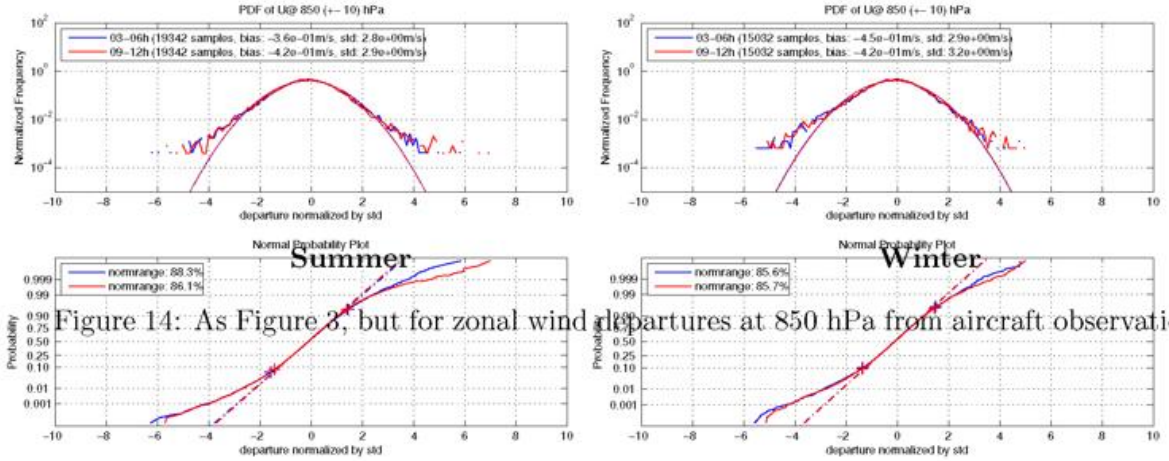

Figure 14: As Figure 3, but for zonal wind departures at 850 hPa from aircraft observations.

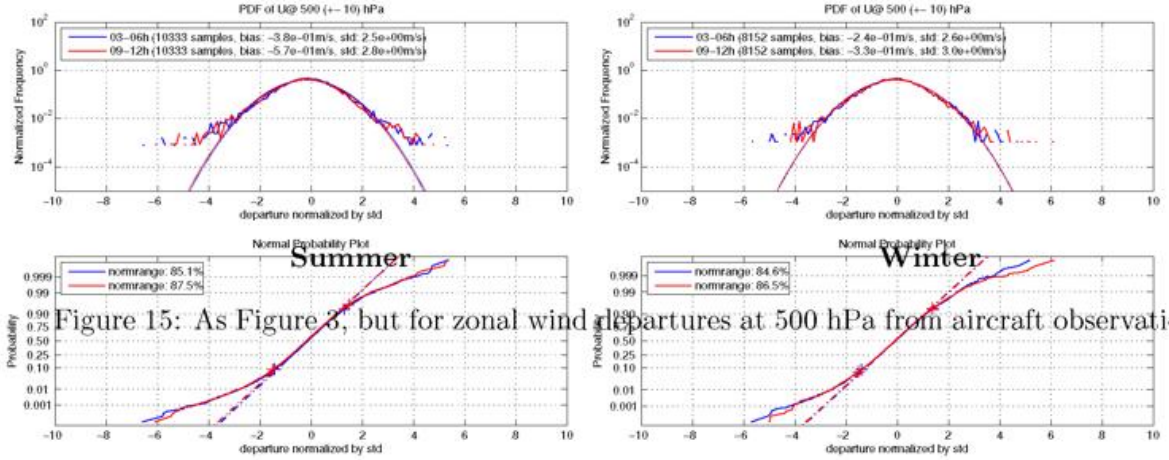

Figure 15: As Figure 3, but for zonal wind departures at 500 hPa from aircraft observations.

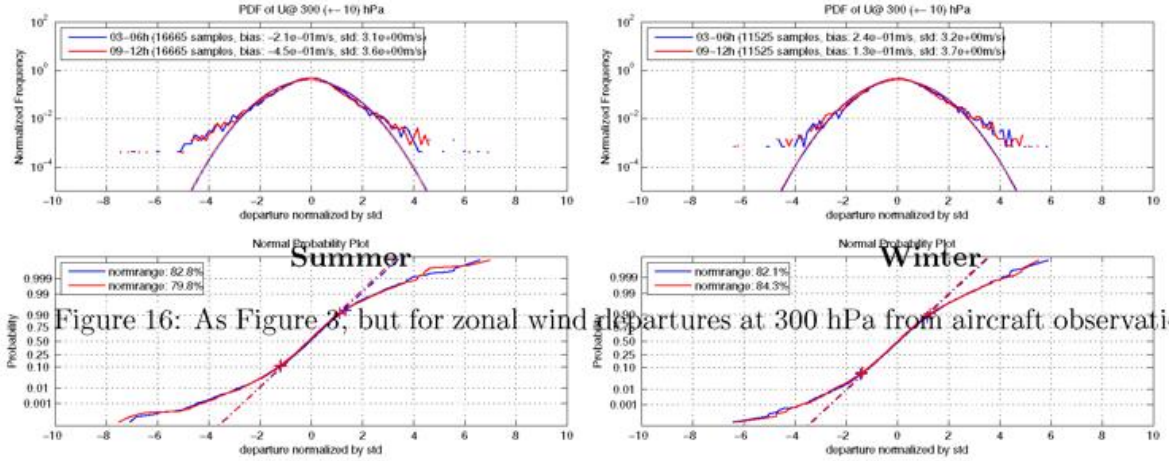

Figure 16: As Figure 3, but for zonal wind departures at 300 hPa from aircraft observations.

dependent and reach values of 15%-20% both in summer and winter. The errors only slightly increase in the first 12h.

3.3 Sensitivity studies

3.3.1 Dependency on Humidity variable

The forecast departure distributions of humidity and rainfall turned out to be the least Gaussian of all model variables. In this section other forms of humidity are investigated, namely specific humidity, the logarithm of specific humidity, a normalized relative humidity (Holm et al., 2002) and the logarithm of rainfall.

Humidity In this section, alternative humidity representations to the relative humidity are looked at. Holm et al. (2002) looked at different humidity variables for the assimilation in the ECMWF IFS model and proposed a normalized relative humidity (NRH) with appealing properties for the assimilation:

- the bias $\bar{d}$ is effectively eliminated, a prerequisite for a successful assimilation
- Forecast departure distributions are near-Gaussian over the whole range of relative humidity values, especially near saturation and in very dry situations, which is not the case for relative humidity departures

The normalized relative humidity departure (d_{NRH}) is calculated following Holm et al. (2002)

$$d_{NRH} = \frac{d_{RH}}{\sigma\left(RH_m + d_{RH}/2\right)}, \tag{7}$$

where the numerator is the standard relative humidity departure (d_{RH}) and the denominator is the standard deviation of the sum of model value (RH_m) and relative humidity departure divided by two.

Figure 21 shows results of COSMO-DE forecast departures using different representations of humidity observations from radiosondes at 850 hPa. Displayed are results for lead times +3h to +6h (red lines) and +9h to +12h (blue lines). Left panels show results for the summer and right panels for the winter period. Obviously, departures of specific humidity (first row) and its logarithm (second row) are less Gaussian than relative humidity (third row), particularly in summer (left panels). Departures of NRH (lowest row) show a similar Gaussian approximation but both bias and standard deviation are reduced by more than an order of magnitude as compared to those using relative humidity.

In order to see how the distributions behave in near saturated or very dry situations, forecast departures have been calculated conditional to the modelled relative humidity. Due to small sample sizes in summer, only the results of the winter period are shown. The upper panels

of Figure 22 show departures of relative humidity for situations where model values exceed 85% (blue lines) and very dry situations (relative humidity below 15%, red lines). Both distributions show a rather exponential than a Gaussian behaviour. Moreover, both, bias and standard deviation are clearly dependent on the modelled relative humidity. In the near saturated situations the model overestimates humidity by roughly 5% (std of 13%) , whereas in dry situations the model underestimates humidity by roughly 2% (std of 1%). Note that the peak at zero departure only appears in the near saturated situations.

When using NRH as variable both biases and standard deviations are reduced by an order of magnitude (right panel of Figure 22). Moreover, the distributions of both wet and dry situations appear to be near-Gaussian.

These results confirm the findings of Holm et al. (2002) and suggest that the normalized relative humidity should have superior properties for the assimilation than the relative humidity.

Summer **Winter**

Figure 21: COSMO-DE forecast departure distributions using different representations of humidity observations from radiosondes at 850 hPa. Displayed are results for lead times +3h to +6h (red lines) and +9h to +12h (blue lines). Left panels show results for the summer and right panels for the winter period. First row: specific humidity (q_v), second row: $\log(q_v)$, third row: relative humidity (same as Figure 18) and fourth row: normalized relative humidity.

Figure 22: COSMO-DE winterly forecast departure distributions of relative humidity (left panels) and normalized relative humidity (right panel) from radiosondes at 850 hPa and forecast leadtimes from +3h to +6h. Blue lines: departures for model (normalized) relative humidity above 85% (blue lines) and departures for model (normalized) relative humidity below 15% (red lines).

Rainfall Since rainfall amounts are nearly logarithmically distributed it is obvious to look at departures of the logarithm of rainfall. Figure 23 shows the resulting distributions for rainfall (upper panels, same as Figure 7) and the logarithm of rainfall (lower panels). The forecast departures of the logarithm of rainfall are clearly much more Gaussian than those of rainfall.

The same holds true for the departures using radar-derived rainfall (Figure 24). Since the logarithm of zero is not defined, only departures with non-zero observations and model forecasts are considered. Note that in situations where only a part of the domain shows rainfall in either the observations or the model forecasts, this can reduce the sample size of the departures by orders of magnitude. Also here the distribution using the logarithm of rainfall is much more Gaussian than that using rainfall.

Summer **Winter**

Figure 23: COSMO-DE rainfall forecast departure distributions using SYNOP surface station observations. Displayed are results for lead times +3h to +6h (red lines) and +9h to +12h (blue lines). Left panels show results for the summer and right panels for the winter period. Upper panels show distributions using rainfall (same as Figure 7) and lower panels using the logarithm of rainfall.

Figure 24: Same as Figure 23 but for COSMO-2 rainfall forecast departure distributions from radar observations. Only those departures are considered where both observations and forecasts are non-zero.

3.3.2 Dependency on Model Resolution

After having investigated the forecast departures of COSMO-DE model, we are interested in how the results differ from those of the regional model COSMO-EU with a model mesh width of 7 km. The largest difference between COSMO-DE and COSMO-EU, beside their resolution, is that in COSMO-EU deep convection is parametrized, where in COSMO-DE only the shallow convection is parametrized, but deep convetion is simulated explicitly. As a result of the better resolved topography in COSMO-DE, we expect the departures to differ mostly in the boundary layer. Therefore we compare the results of the forecast departures exemplarily on the 850 hPa pressure level.

When comparing the results of COSMO-DE and COSMO-EU it gets rapidly clear that the differences in the distributions are minor in all variables and independent on season (Figures 25 - 27). Normranges do not differ by more than 3%, whereas biases and standard deviations can vary considerably depending on model parameter. The same holds true for the other observation types and differences between the two models are even smaller in the upper atmosphere (not shown).

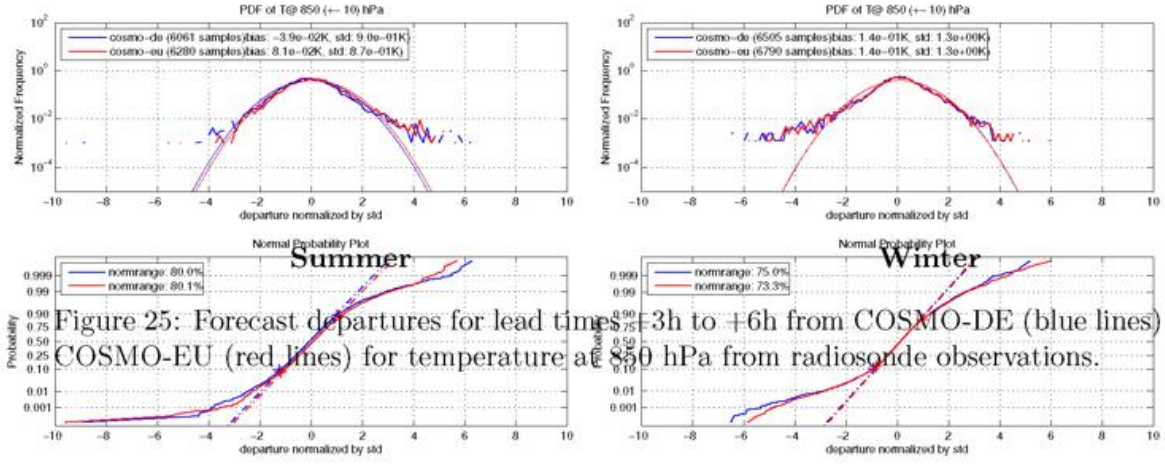

Figure 25: Forecast departures for lead times +3h to +6h from COSMO-DE (blue lines) and COSMO-EU (red lines) for temperature at 850 hPa from radiosonde observations.

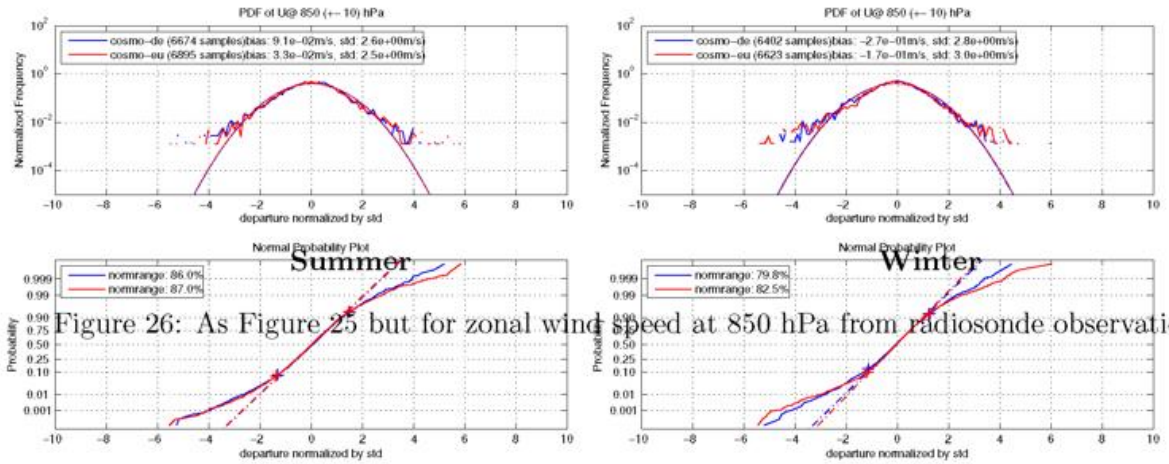

Figure 26: As Figure 25 but for zonal wind speed at 850 hPa from radiosonde observations.

Summer **Winter**

Figure 27: As Figure 25 but for relative humidity at 850 hPa from radiosonde observations.

3.3.3 Dependency on Weather Regime

All results presented so far were compiled using the whole summer (winter) period. In a sensitivity study, we stratified time according to the weather situation, i.e. we looked at the forecast departure distributions where only rainy days have been considered. We defined a rainy day as a day where a large part of the COSMO-DE domain was affected by precipitation. For this end daily accumulations from gridded raingauges have been used and a subjective separation has been made.

The resulting distributions were found to be slightly less Gaussian than those using all days for the statistics (not shown).

4 Ensemble Anomaly Statistics

In this section distributions of the ensemble background anomalies from COSMO-DE ensemble forecasts are presented. All distributions are calculated from gridpoint values of temperature and zonal wind speed at 10 m and 5400 m above surface and averaged spatially over 10x10 gridpoints of two verification domains (North and South Germany, see Figure 1) and temporally over the 9 days from 8 to 16 August 2007. Lead times of +3h and +24h are compared.

4.1 Near surface

4.1.1 Temperature

Figure 28 shows the ensemble background anomaly distribution of temperature at the lowest model level ($\approx$ 10m above surface) of the South Germany (left panel) and North Germany (right panel) verification domain. The +3h lead time distributions (blue lines) clearly show a significant deviation from normality (normrange well below 80%) for both domains. Beside the maximum around zero anomaly there is a second maximum around +2 (South Germany) and +3 (North Germany) standard deviations. On the other hand, the +24h lead time distributions (red lines) are much closer to normality (normrange above 90%) for both domains.

A closer look at the background anomalies of each ensemble member valid at 15 August 2007 03UTC (16 August 2007 00UTC) in Figure 29 (Figure 30) reveals the reason for the different distributions at +3h (+24h). At +3h (Figure 29) most members have small temperature anomalies due to the common analysis of all members. The anomalies are largely caused by the different physical parametrisations. Members 4, 9, 14, and 19 have much larger temperature anomalies than all other members. These members use a physical parametrisation tuning parameter rlam_heat = 0.1 instead of 1.0. This parameter influences the sensible heat fluxes from the surface and thus has an immediate impact on the near-surface temperature. At +24h the influence of the different boundary conditions of the driving global models on the anomalies has increased considerably (Figure 30). The amplitude of the anomalies are much larger and show more variation. The members 4, 9, 14 and 19 still show a clearly different anomaly distribution but the differences are smaller than at +3h. A similar behaviour can be found at the other days, leading to the systematic deviation from normality for the low level temperature at early lead times.

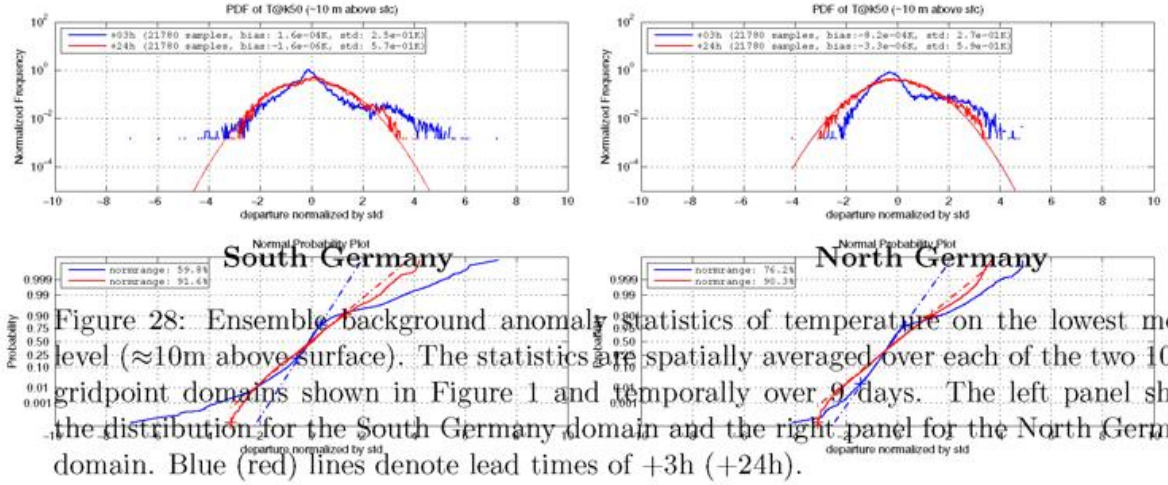

Figure 28: Ensemble background anomaly statistics of temperature on the lowest model level (≈10m above surface). The statistics are spatially averaged over each of the two 10x10 gridpoint domains shown in Figure 1 and temporally over 9 days. The left panel shows the distribution for the South Germany domain and the right panel for the North Germany domain. Blue (red) lines denote lead times of +3h (+24h).

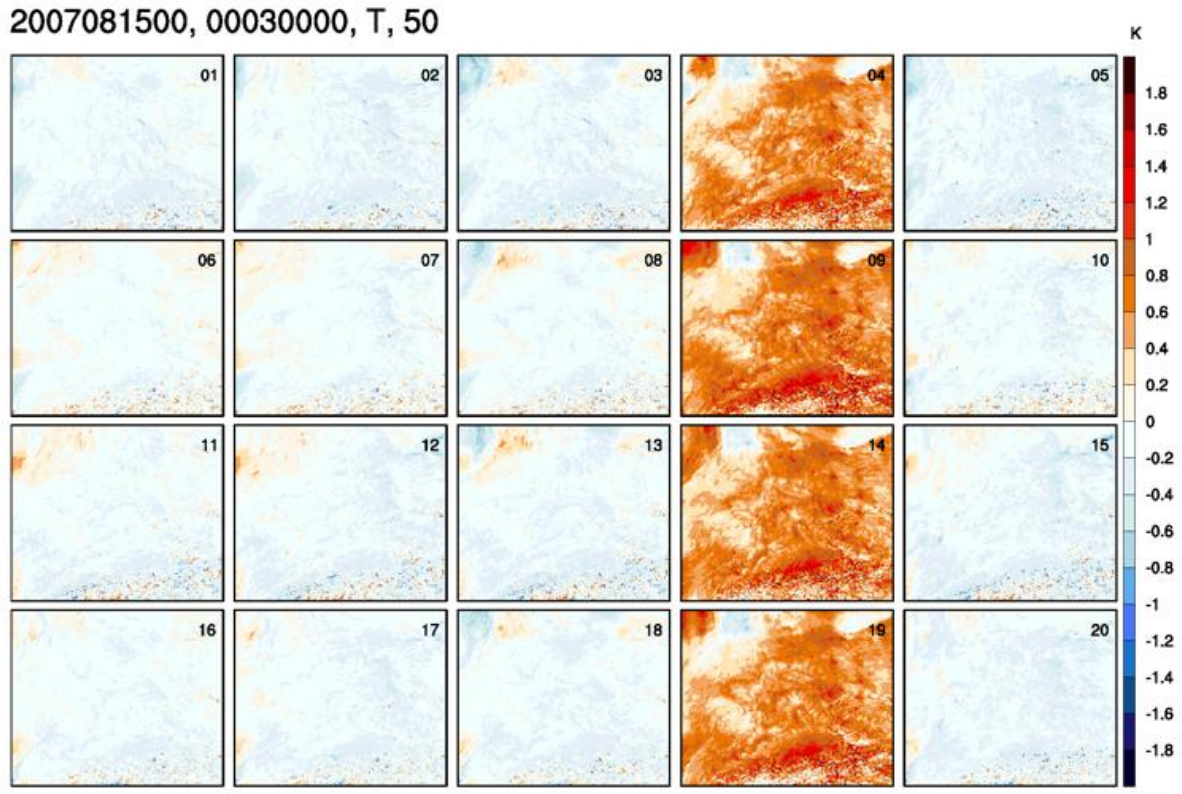

Figure 29: Stamp map of ensemble background anomalies of temperature at the lowest model level (≈10m above surface) valid at 15 August 2007 03UTC (i.e. at +3h). The domain corresponds to the coloured domain in Figure 1.

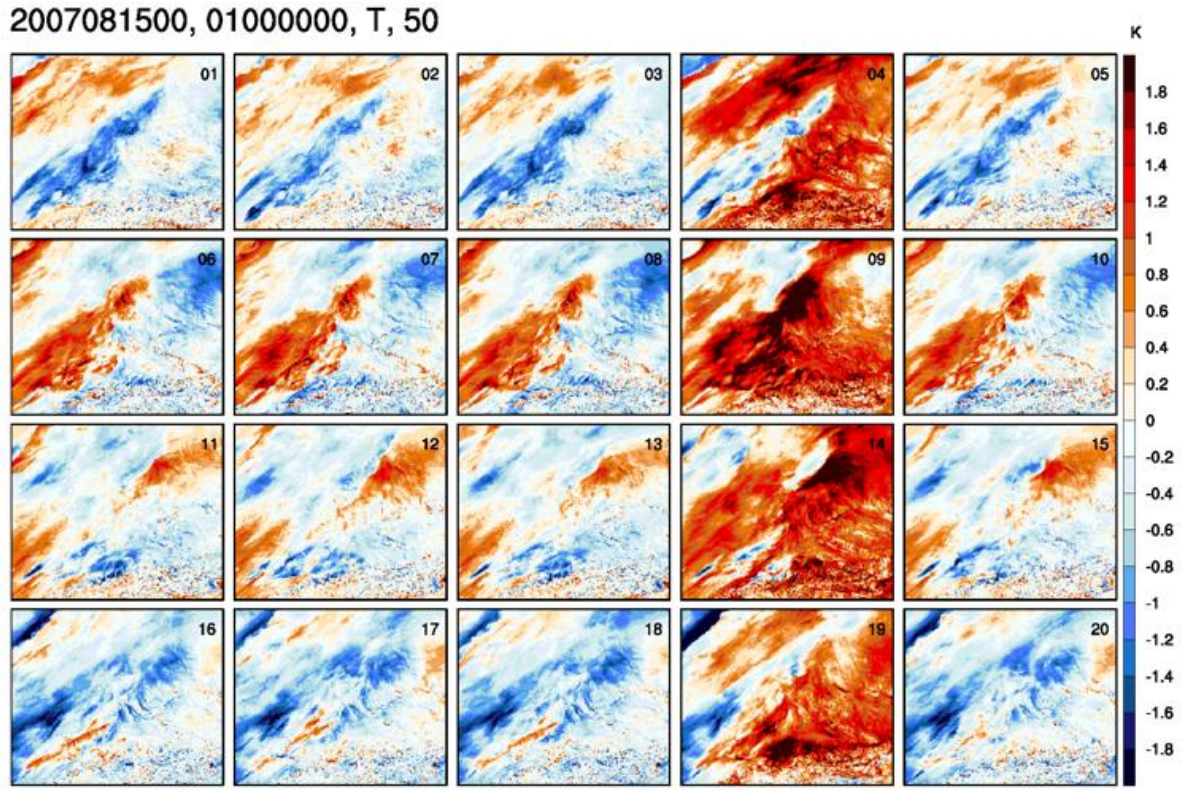

Figure 30: As Figure 29 but valid at 16 August 2007 00UTC (i.e. at +24h).

4.1.2 Wind

Figure 31 shows the distribution of zonal wind speed U at the lowest model level. The distributions at +3h and +24h are much more similar than for temperature in both domains. However, in the South Germany region, where topography is complex, the distributions show more deviations from normality than in the North Germany domain, which is essentially flat. The stamp maps in Figures 32 and 33 confirm that the anomalies are more evenly distributed in the two verification domains and all physical parametrisation settings show similar results in the wind speed.

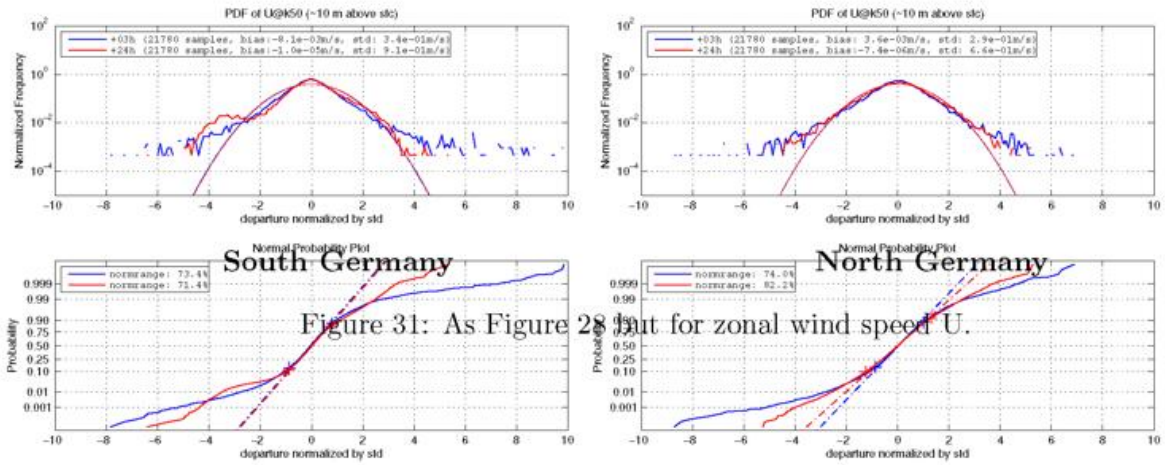

Figure 31: As Figure 28 but for zonal wind speed U.

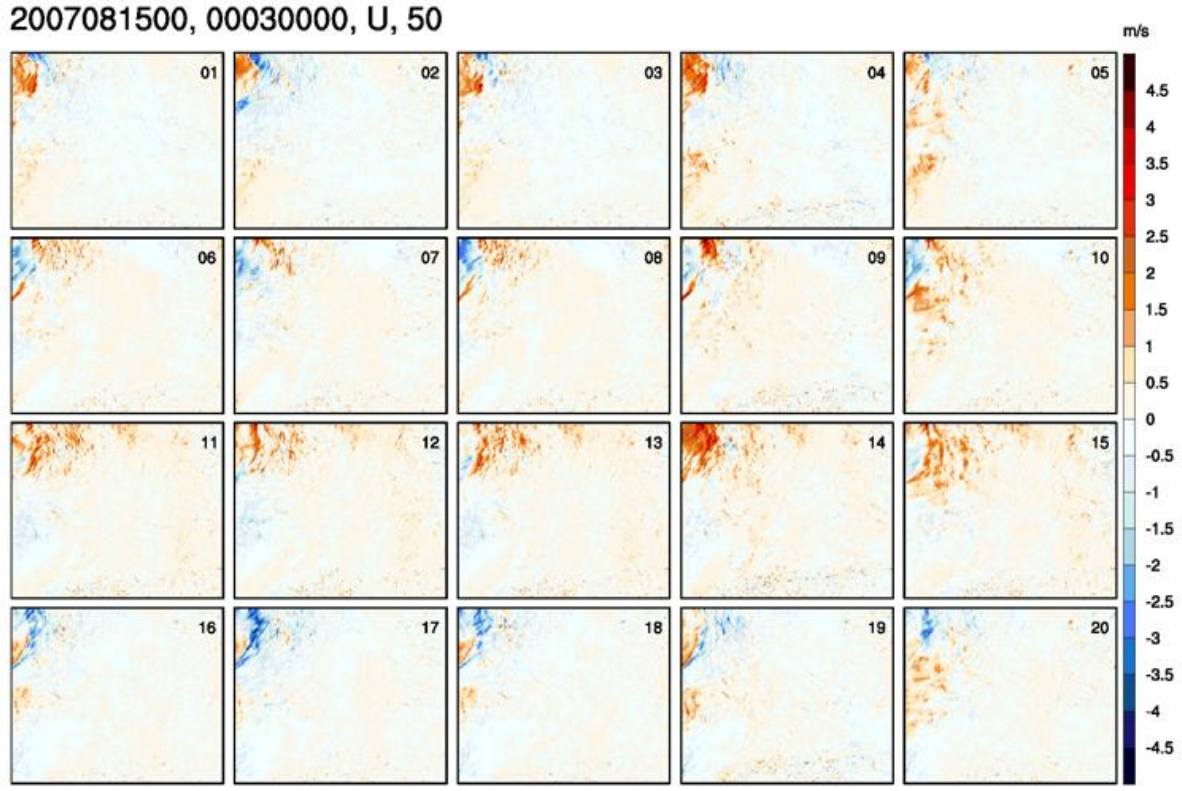

Figure 32: Stamp map of ensemble background anomalies of zonal wind speed valid at 15 August 2007 03UTC (i.e. at +3h). The domain corresponds to the coloured domain in Figure 1.

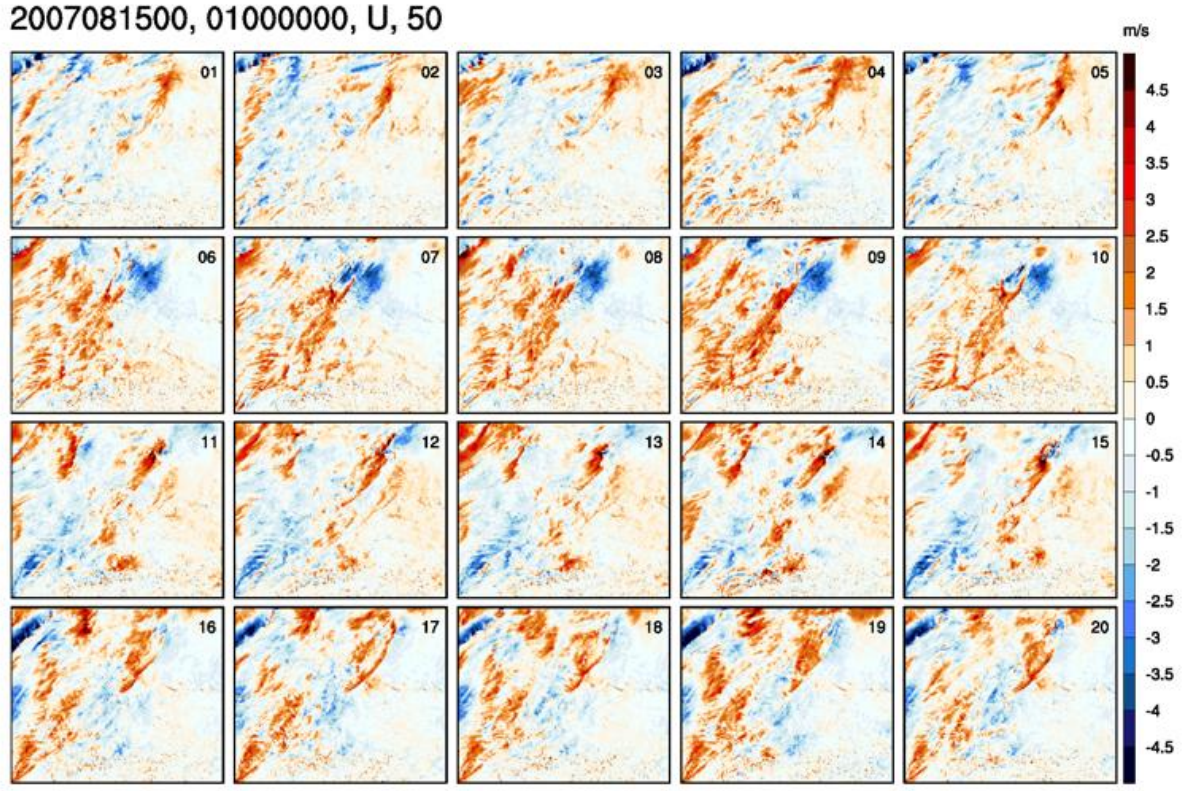

Figure 33: As Figure 29 but valid at 16 August 2007 0UTC (i.e. at +24h).

4.1.3 Precipitation

Figure 34 shows the distributions of hourly precipitation sums at lead times +2-3h and +23-24h. The distributions are clearly completely non-Gaussian at both lead times and verification domains. The stamp map in Figure 35 at +3h lead time valid at 15. August 2007 03UTC shows the reason for this. Most parts of the domain is precipitation-free and therefore anomalies are zero. In the sparse precipitation areas the anomalies take on large values, leading to a non-Gaussian distribution.

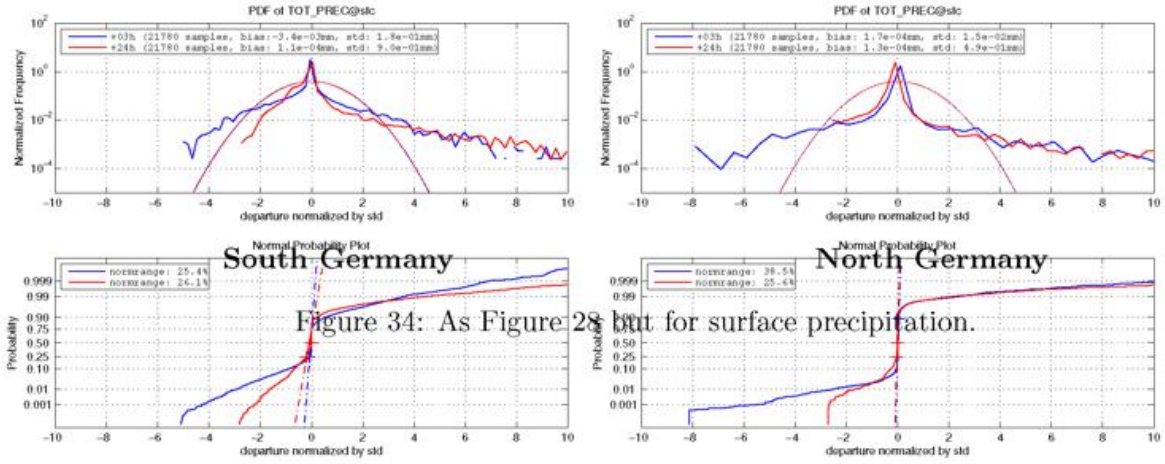

Figure 34: As Figure 28 but for surface precipitation.

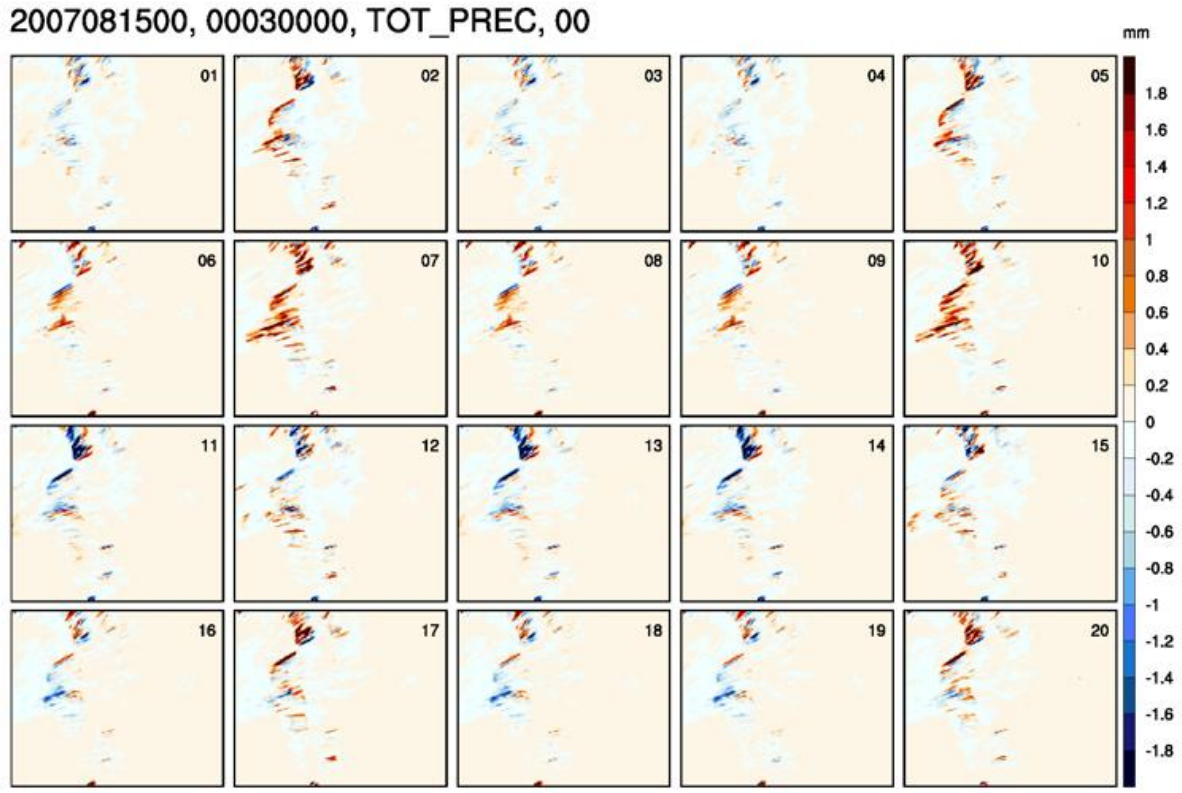

Figure 35: Stamp map of ensemble background anomalies of surface precipitation valid at 15 August 2007 03UTC (i.e. at +3h). The domain corresponds to the coloured domain in Figure 1.

4.2 Upper atmosphere

4.2.1 Temperature

Figure 36 shows the anomaly distributions for temperature on model level 24 ($\approx$ 5400 m above surface). The distributions are close to normality, both at +3h and +24 and in both verification domains. Obviously the physical parametrisation parameter affects the upper level temperature in a systematic way, as was the case in the low-level temperature.

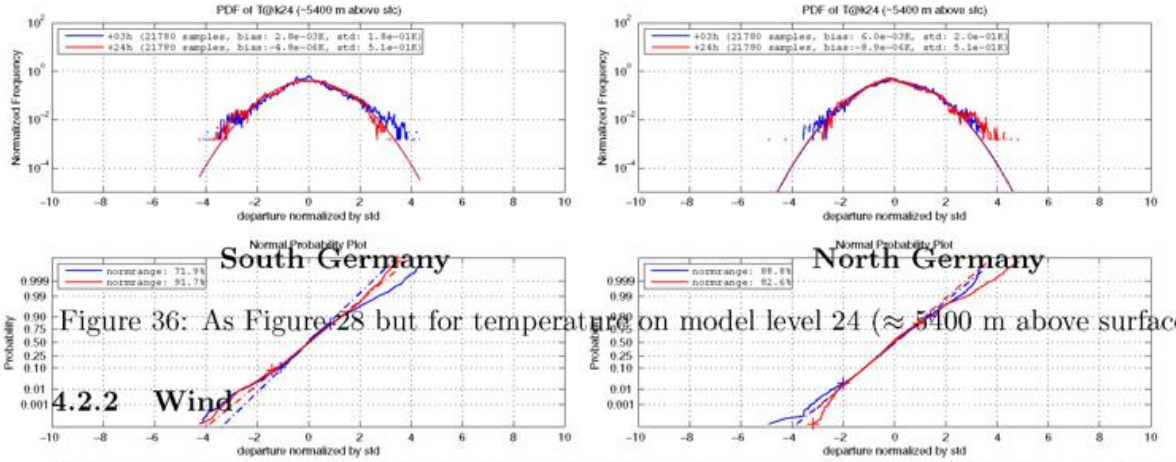

Figure 36: As Figure 28 but for temperature on model level 24 (≈ 5400 m above surface).

4.2.2 Wind

Figure 37 shows the anomaly distributions for zonal wind speed on model level 24 (≈ 5400 m above surface). The distributions are close to normality, both at +3h and +24. The distributions in the South Germany domain exhibits a slight deviation from normality, probably due to the more complex terrain which influences mid- and upper-level winds in a more systematic way than flat terrain.

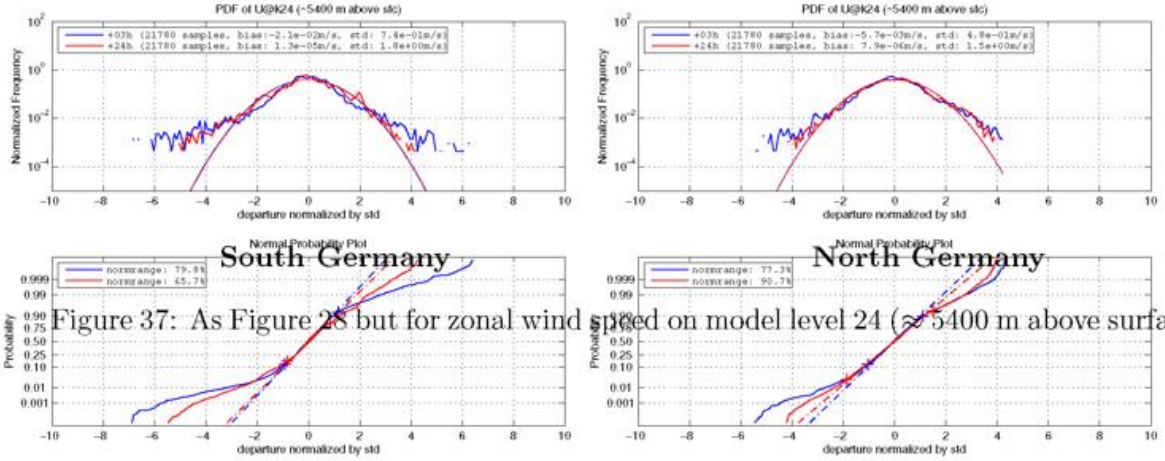

Figure 37: As Figure 28 but for zonal wind speed on model level 24 (≈ 5400 m above surface).

5 Further Results

In this section we list further results from forecast departure distributions of the COSMO-DE, which are not shown in Section 3.

5.1 Temperature from radiosondes

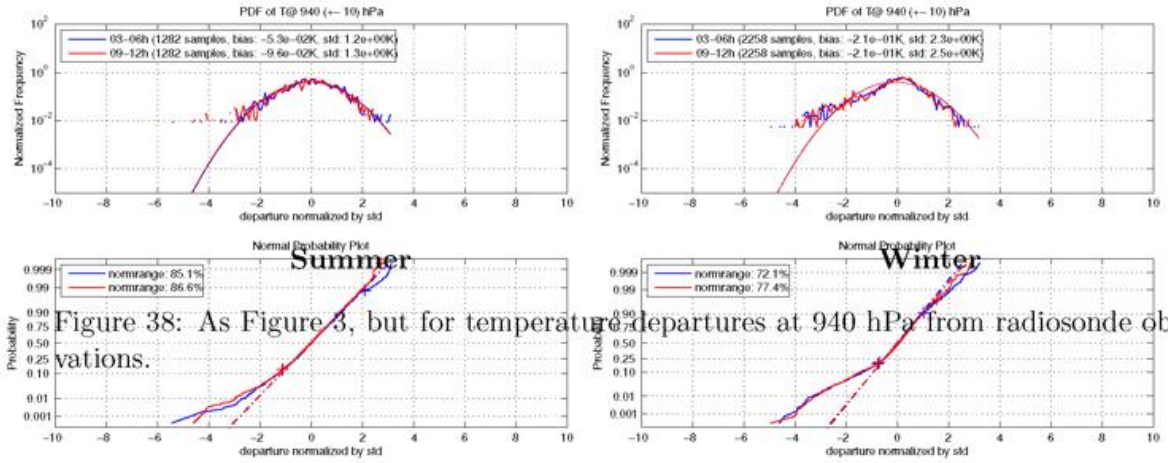

Figure 38: As Figure 3, but for temperature departures at 940 hPa from radiosonde observations.

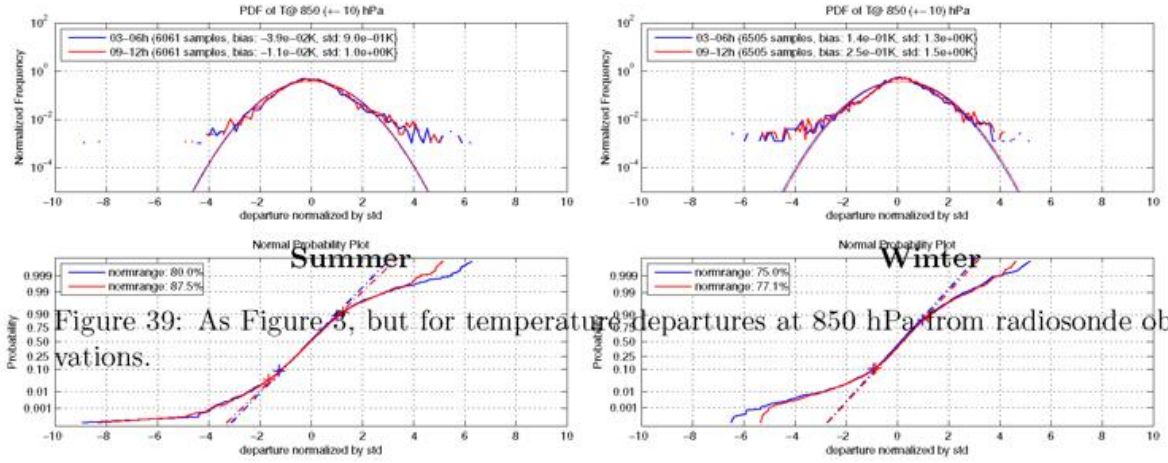

Figure 39: As Figure 3, but for temperature departures at 850 hPa from radiosonde observations.

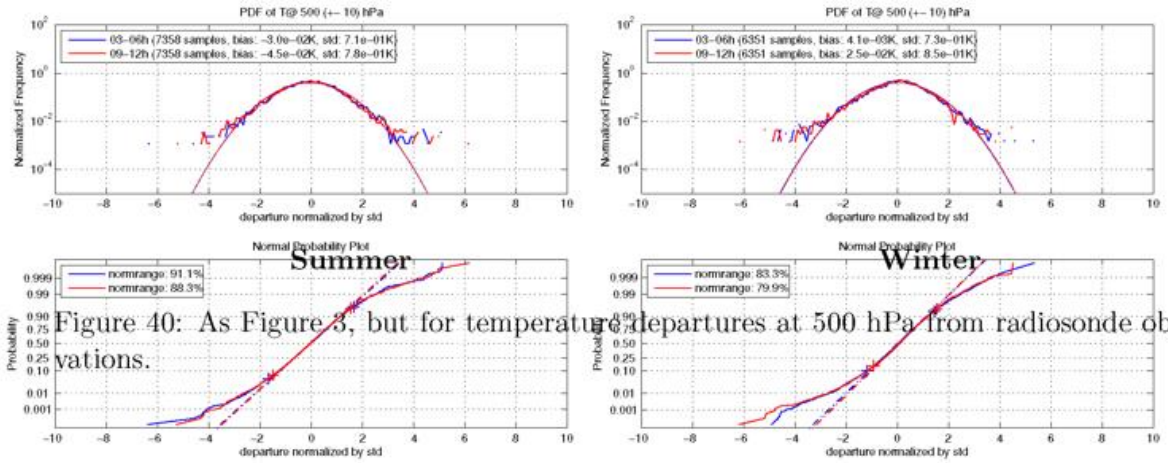

Figure 40: As Figure 3, but for temperature departures at 500 hPa from radiosonde observations.

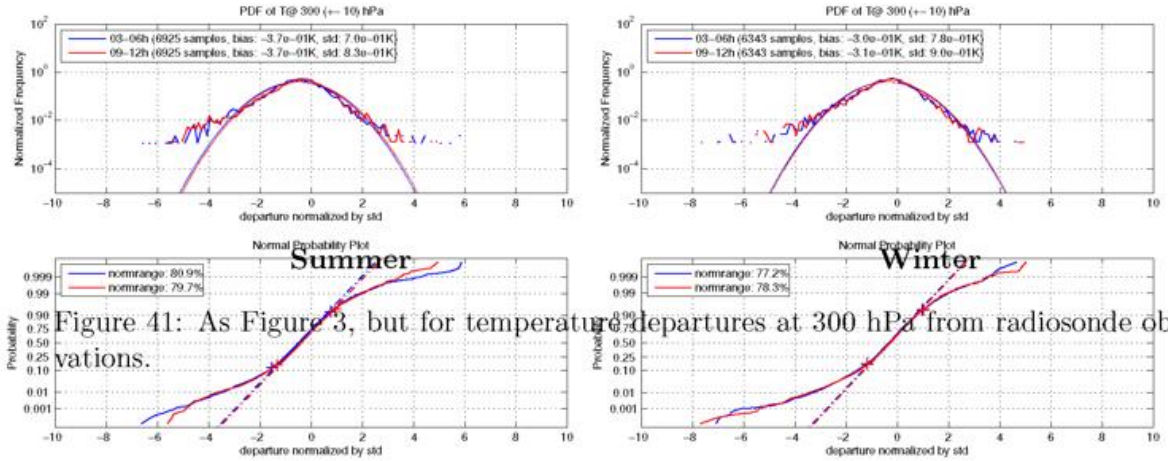

Figure 41: As Figure 3, but for temperature departures at 300 hPa from radiosonde observations.

5.2 Zonal wind from radiosondes and windprofiler

6 Summary and conclusions

In this study we have investigated forecast departure distributions and ensemble background anomalies from the convection permitting COSMO model in view of the new ensemble data assimilation system for COSMO, being currently developed. Emphasis was put on how close the distributions are to the normal distribution.

Overall, the departures of most of the investigated variables show a reasonable Gaussian behaviour around the median, but exhibit more larger departures (both negative and positive) than described by a normal distribution. This behaviour (known as "fat tails") is well known in NWP data assimilation (e.g. Andersson and Järvinen, 1999; Seaman, 2008) and can be interpreted as follows: the departures belong to either of two populations, one which follows the normal Gaussian distribution, representing random errors and one which is modelled by a flat distribution, representing the population of data affected by gross errors (Andersson and Järvinen, 1999)

The main results of the study are summarized and discussed in the two following paragraphs for the forecast departures and the ensemble background anomalies, respectively.

Forecast departures

- The forecast departures of temperature, surface pressure and wind can be reasonably approximated by normal distributions. Normranges are mostly above 80%. Results among different observation systems (radiosondes, aircraft observations and windprofiler) are very similar.
- Humidity departures show a rather exponential than Gaussian distribution, relative humidity departures are more Gaussian than specific humidity departures. Normalized relative humidity departures have a much reduced bias and standard deviation and their distributions are much less dependent on the humidity itself, as compared to relative humidity.
- Surface rainfall departure distributions show a rather exponential than Gaussian shape. Departures of the logarithm of rainfall can be much better approximated by normal distributions.
- Generally, distributions are less Gaussian near the surface and in the boundary layer than in the middle and upper atmosphere.
- There is a generally slightly better Gaussian fit in summer than in winter.
- Large deviations from the Gaussian shape are found in winterly boundary layer relative humidity as a result of many near-saturated situations (stratus).
- The distributions only slightly change during the first 12 hours of forecast with the exception of surface pressure, where an increase in the bias and standard deviation is already obvious.
- The results from the convection permitting COSMO-DE model are similar to those of the regional COSMO-EU model.

One reason for the good Gaussian fit of most of the variables may be found in the fact, that the departure distributions rely on a large statistics covering all sorts of weather conditions.

A sensitivity study considering only rainy days indeed indicated that the distributions are slightly less Gaussian. However, the main findings of this study are still valid for this subsample of days.

Overall, temperature, wind and surface pressure forecast departures distributions from the convection permitting COSMO model are reasonably Gaussian out to 12 hours forecast, both in summer and winter. Humidity and rainfall are less Gaussian, but using appropriate transformations, derived humidity and rainfall variables can be found with more Gaussian distributions (e.g. normalized relative humidity and logarithm of rainfall).

Ensemble background anomalies

- At short lead times (+3h) the ensemble background anomaly distributions can deviate significantly from normality. Especially low-level temperature has been found to have multiple modes.
- Precipitation shows the similar exponential distribution as the forecast departures.
- At longer lead times (+24h) the anomaly distributions are close to normality for both, temperature and wind.
- Upper-level variables are more Gaussian than their low-level counterparts.
- The shape of the distributions are dependent on the domain under consideration. Distributions over flat terrain have been found to be closer to normality than those over more complex terrain.

The large deviations from normality at short lead times are largely due to the way the current COSMO-DE-EPS is designed. Starting from identical initial conditions (zero anomalies at the start of the forecast) the growth of the anomalies with time is first dominated by the physical parametrisation perturbations, at later times the different boundary conditions and the internal model errors start to dominate the anomaly growth. Some of the model switches systematically influence certain ensemble members, leading to a non-normal anomaly distribution at short lead times in some variables and some regions of the model domain. Therefore, in the light of an ensemble assimilation, care should be taken in the design of the physical model perturbations. The use of boundary conditions from different global models is judged as a suitable method to perturb the boundaries of the COSMO-DE-EPS in view of data assimilation, since at longer lead times, the anomaly distributions appear to be close to normality.

The error distributions found in this study closely resemble those found by Bonavita et al. (2010) using the LETKF in a regional NWP system. In particular, their distributions showed similar "fat tails" as those of the COSMO model. This slight deviation from Normality did not seem to strongly affect the performance of their application. However, as pointed out by the authors, their results did not reflect situations with strong non-linearities, such as convection. It remains to be proven that the LETKF also works in strongly convective situations. Recently, Yang and Kalnay (2009) and Kalnay and Yang (2009) proposed ways to deal with non-linearity and non-Gaussianity using the LETKF. Although they are computationally more expensive that the standard LETKF they proved to reduce the spin-up of the LETKF in highly non-linear applications and improve the Gaussianity of the errors.

Overall, the results of this study suggest that, ensemble data assimilation systems relying on the BLUE theory may well be feasible for the use with the high-resolution COSMO

model, given that more suitable (i.e. more random) physics parametrisation perturbations are applied.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW) and Romania (NMA). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction

This document reports about the activities carried out in the SPRED Priority Project. The Project lasted from September 2015 to February 2018. The project was organized in 5 Tasks, with cross-cutting issues. The report reflects the structure of the Project, consisting of 5 sections. In Section 2, the work aimed at investigating the spread/skill relation of the ensembles run by the COSMO members is described. In Section 3, work on model physics perturbation is shown, while Section 4 deals with lower boundary perturbation. In Section 5, the activities carried out in the post-processing and calibration of the ensemble outputs are presented, also included in the SRNWP-EPS II Project of EUMETNET. Finally, in Section 6 is described the work on initial condition for the convection-permitting ensembles. Each Section is structured in subsections describing the contribution of the different COSMO members.

2 What we know (and what we do not know) about the spread/skill relation of our ensembles.

The spread/skill relation computed for the different COSMO ensembles highlights a common deficiency: the underdispersiveness of the ensembles for the surface weather parameters. Therefore it was decided to analyse this relation in greater detail, trying to provide indications about how to cure the problem. The general aim of this coordinated activity was to understand which factors determine the lack of spread for near-surface weather parameters and to propose solutions in terms of which elements of the modeling system should be perturbed to account for this uncertainty.

2.1 DWD contribution

During the PP, DWD was running operationally COSMO-DE-EPS, a 20 member ensemble based on the COSMO model run at 2.8 km horizontal resolution. At the beginning of PP SPRED, both the boundary and initial conditions of COSMO-DE-EPS were based on forecasts of four global models (ICON of DWD, IFS of ECMWF, GFS of NCEP, GSM of JMA) dynamically downscaled with a COSMO model to 7 km grid spacing. These four COSMO runs (called BC-EPS) were used as boundary conditions for COSMO-DE-EPS and contributed to the perturbation of the initial conditions. The deterministic operational analysis of COSMO-DE was perturbed with anomaly fields of BC-EPS runs with respect to 3h-forecasts of the operational COSMO-EU (ICON-EU since July 2016) resulting in the IC perturbations. For perturbation of model physics, a non-stochastic approach with perturbed parameters was used. Different model configurations were defined by setting one of 5 (later 7) parameters to non-default values. This set of perturbed parameters did not change during the forecast lead time and was identical for all forecast runs, i.e. each member of COSMO-DE-EPS was characterized by a specific parameter set-up being identical for all forecasts. More details (including the soil moisture perturbations) of the member generation of COSMO-DE-EPS at the beginning of PP SPRED are described in Peralta et al. (2012). During the SPRED PP, several improvements were applied to the member generation. In November 2016, the parameter perturbation method was enhanced by including additional parameters: thick_sc, radqi_fact, radqc_fact, a_stab, and c_diff. These new perturbations focus on the improvement of EPS forecasts for variables being relevant for renewable energy applications (wind at wind hub height, global radiation connected to cloud forecasts) and resulted in

a positive impact on the wind forecast. Furthermore, a randomization of the parameter selection methodically allowed for the inclusion of more parameters and lead to a slight increase in spread. Further improvements of the parameter perturbations during SPRED imposed that the value of rlam_heat x rat_sea is kept fixed in the parameter perturbation, otherwise a detrimental effect in 2m temperature was observed (too high spread over sea). In March 2017, the use of BC-EPS has been ceased in favour of IC perturbations based on KENDA (see Section 6.1) and boundary conditions provided by forecasts of the ICON-EPS calculated on the nested grid over Europe with approx. 20 km grid spacing. The use of Initial Conditions derived from KENDA analyses increases the spread of the ensemble, thereby improving the skill of relevant variables, keeping it constant. Results are briefly described in Section 6. The use of ICON-EPS mainly improved the spread of several parameters in particular for later lead times. A summary evaluation of the spread/skill relation for COSMO-DE-EPS in different configurations is shown in Fig. 1.

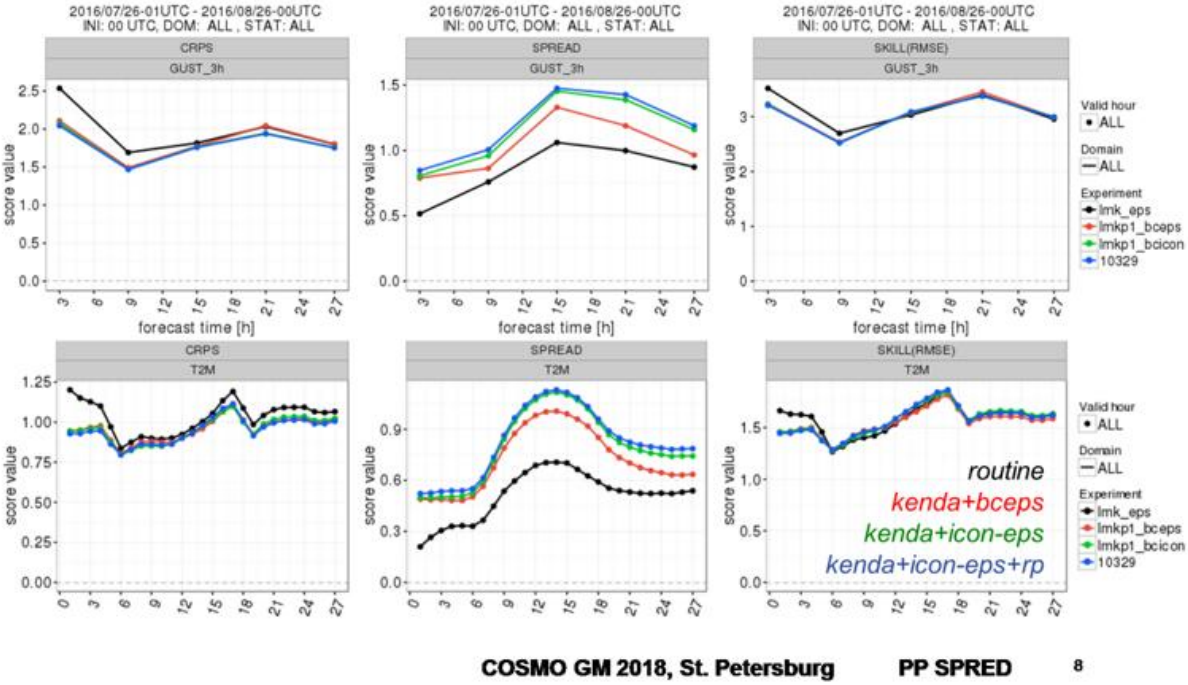

Figure 1: CRPS (left), spread (middle) and RMSE (right) of 4 different configurations of COSMO-DE-EPS, as a function of the forecast lead time, in terms of wind gusts (upper row) and 2m temperature (lower row). Black line: operational set-up before modifications; red line: use of KENDA for initial conditions, but BC-EPS for boundary conditions; green line: use of KENDA and ICON-EPS; blue line: use of KENDA, ICON-EPS and randomized physics perturbations.

The scheme for model error developed by Ekaterina Machulskaya (EM-scheme) has been tested (see presentation by Gebhardt et al. at WG7 parallel session during COSMO GM 2017, Jerusalem). It was found a bug in the code, the correction of this which led to a much smaller response of the model to perturbations as it should be. The point was that the diffusion of the model error, that is intended to represent spatial correlations, effectively (and artificially) decreases the noise level, the parameters of which are determined on the theoretical basis as if there were no spatial diffusion. This means that the effective parameters of the perturbations in the presence of the diffusion should differ from those that were determined according to the theory. The expressions for the effective values of the parameters were derived and

preliminary experiments (for selected days) were performed quite successfully.

2.2 MeteoSwiss contribution

MeteoSwiss was running operationally COSMO-E, a 21 member ensemble based on the COSMO model with 2.2 km grid-spacing. It was performed twice a day (00 and 12 UTC) and for a lead-time of 120 hours. Initial conditions are taken from a kilometer-scale ensemble data assimilation (KENDA) cycle running at the same resolution. Boundary conditions are taken from IFS-ENS control and the 20 first perturbed members. Model physics is perturbed with the SPPT scheme (Buizza et al., 1999; Palmer et al., 2009). COSMO-E is generally underdispersive in the lower troposphere, even though SPPT is effective in increasing the spread, except in winter when the physical tendencies are small. As shown in Fig. 2 taken from Klasa et al. (2018), the lack of spread is largest in winter, in particular for 2m temperature and 2m relative humidity (RH2m). In summer the ensemble is rather well dispersed or even overdispersive for RH2m when considering observation errors according to Saetra et al. (2004) with observation error estimates from Bouttier et al. (2016). Furthermore, as compared to ECMWF ENS, COSMO-E shows a better spread/error ratio, in particular for convective cases.

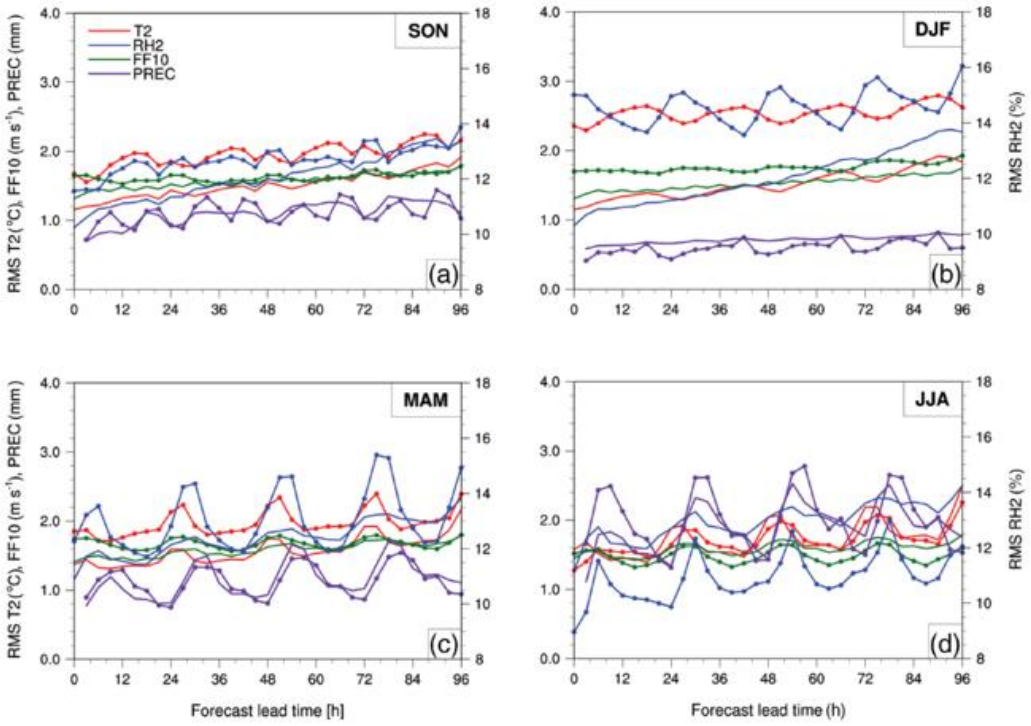

Figure 2: Unbiased forecast error (lines with symbols) and ensemble spread boosted by an observation-error estimate (lines without symbols) for the seasonal verification of COSMO-E forecasts initialized at 1200 UTC in 2016/2017 for Switzerland: 2m temperature (red), 2m relative humidity (blue), 10m wind speed (green), and 3 h accumulated precipitation (purple). Left-hand y-axes are for temperature, wind speed, and precipitation, while right-hand y-axes are for relative humidity. (Klasa et al., 2018).

In addition, dynamical processes determining the time evolution of difference kinetic energy (DKE) have been investigated (Klasa et al., 2019). DKE is quantified by means of ensemble

variance of the irrotational and nondivergent horizontal wind, respectively. Three case studies characterized by contrasting predictability levels of precipitation have been investigated with the convection permitting ensemble COSMO-E for a forecasting period of 4 days. The results suggest that the large-scale flow and diurnal solar forcing, associated with higher spatiotemporal predictability, determines the overall evolution of limited-area ensemble variance of the horizontal wind, which increases in the presence of moist convective activity or strong synoptic-scale forcing, and stagnates or decreases otherwise, rendering forecasts of convection-permitting ensembles valuable beyond the very short forecast range.

2.3 Arpae contribution

2.3.1 Convection-parametrised ensemble (COSMO-LEPS)

In the framework of enhancing the spread/skill relation for the COSMO-LEPS system, the use of SPPT was tested. For two sets of periods (from 22/11/2014 to 31/01/2015 and from 2/6/2015 to 20/7/2015), the operational COSMO-LEPS (referred to as OPER) was tested against a test version (referred to as SPPT_SNGL) characterized by the following features: use of SPPT and executable compiled in single-precision mode. Both systems ran at 7 km of horizontal resolution, 20 members, and with a forecast range of 132 hours. The performance of the two systems was analyzed in terms of 12-h cumulated precipitation as well as in terms of spread/skill relation of 2-metre temperature. The verification network included the SYNOP reports covering Central and Southern Europe, with an availability of about 1000 reports/day (see Fig. 3). Here, we consider the results relative to the summer period (June-July 2015). As for total precipitation, the 2 panels of Fig. 4 reports the probabilistic forecast skill of OPER and SPPT_SNGL in terms of the ROC area for total precipitation exceeding 1 and 10 mm over 12 hours (left and right panel, respectively).

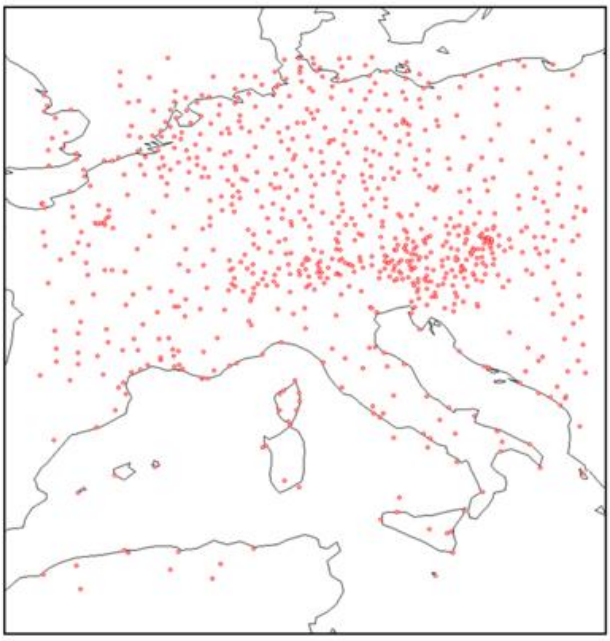

Figure 3: Verification network used for the intercomparison between OPER and SPPT_SNGL. Each red dot denotes a station.

It can be noticed that SPPT_SNGL provides a slight better performance than OPER for

both thresholds. This is especially true for in the short range, until, say, fc +72h. These results are confirmed also by other verification scores, either threshold oriented (e.g. Brier Score, Bier Skill Score) or not (e.g. Ranked Probability Score, Percentage of Outliers).

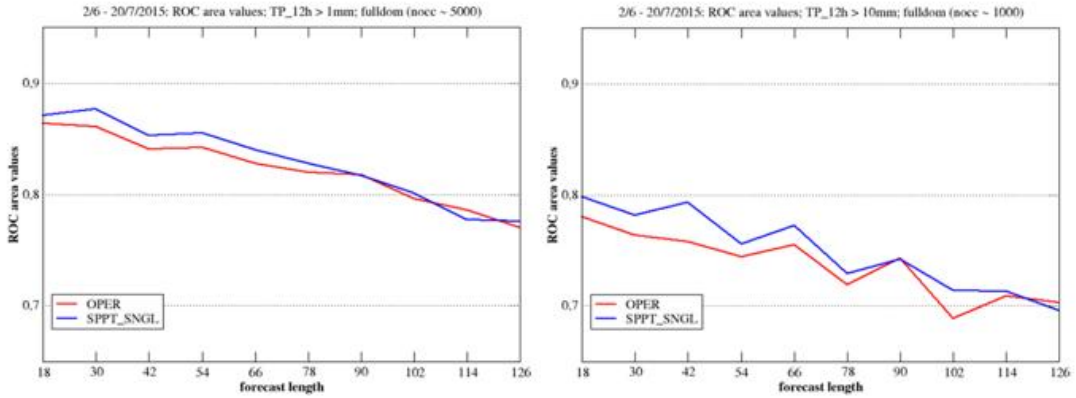

Figure 4: ROC area values for operational COSMO-LEPS (denoted with OPER, red lines) and test COSMO-LEPS (denoted with SPPT_SNGL, blue lines) for 12-hour precipitation exceeding 1 mm and 10 mm (left and right panel, respectively) as a function of the forecast range (in hours). Verification is performed over the station points of Fig. 3 and averaged over the verification period.

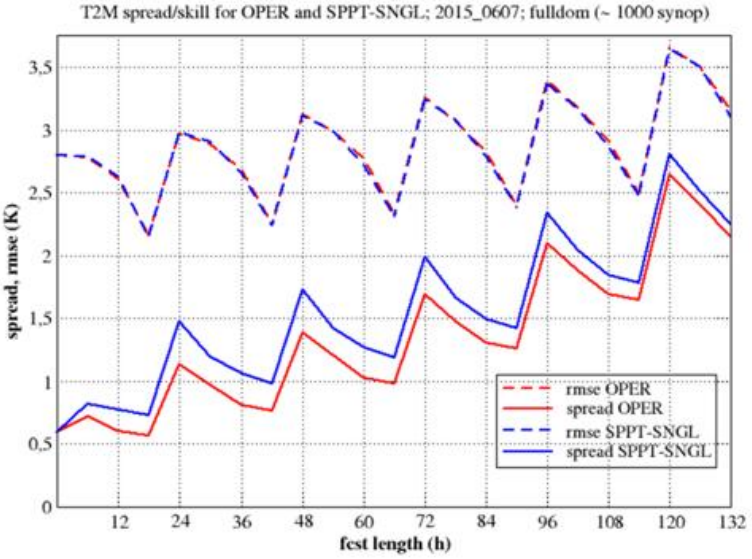

Figure 5: Root-mean-square error of the ensemble mean (dashed lines) and ensemble spread (solid lines) for operational COSMO-LEPS (denoted with "OPER", red lines) and test COSMO-LEPS (denoted with SPPT_SNGL, blue lines) for 2-metre temperature (in Kelvin) as a function of the forecast range (in hours). Verification is performed over the station points of Fig. 3 and averaged over the verification period.

As for 2-metre temperature, the results of the experimentation are summarized in Fig. 5, which reports the root-mean-square-error of the ensemble mean (dashed lines) and the ensemble spread (solid lines) for both OPER and SPPT_SNGL (read and blue, respectively). Both systems turn out to be under-dispersive, the ensemble-mean errors being about twice the

dispersion of the ensemble members. On the other hand, it can be noticed that SPPT_SNGL provides larger spread than OPER at all forecast ranges and especially for the shortest ones. This happens without a deterioration of the average skill of the system, as the forecast errors are approximately identical in both configuration (read and blue dashed lines). Although these results are relative to the summer experimentation, the outcome of the winter experimentation (NDJ2014-2015) provides the same findings and confirms the positive benefit of using SPPT in the description of model uncertainties.

2.3.2 Convection-permitting ensemble (COSMO-2I-EPS)

During the experimental phase of the COSMO-IT-EPS convection-permitting ensemble (now operational with the name COSMO-2I-EPS), the ensemble was run for selected periods in order to test the model perturbation methodology, assessing its spread/skill relation. COSMO-IT-EPS has been run for the month of October 2015, one run per day at 00 UTC, with Initial and Boundary Conditions from COSMO-ME-EPS, the 10-km ensemble of COMET, running over a Mediterranean domain. Model resolution was 2.8 km and the ensemble had 10 members. COSMO-IT-EPS was run in 3 different configurations:

- without model physics perturbation (ensemble CTRL);
- with SPPT (Stochastic Perturbation of Physical Tendencies) (ensemble SPPT);
- with SPPT and perturbation of dew parameters of the physics schemes (turbulence, microphysics, land surface) (ensemble SPPT-PP).

The spread/skill relation of the three configurations in terms of 2m temperature (above) and 6-h precipitation (below) is shown in Fig. 6.

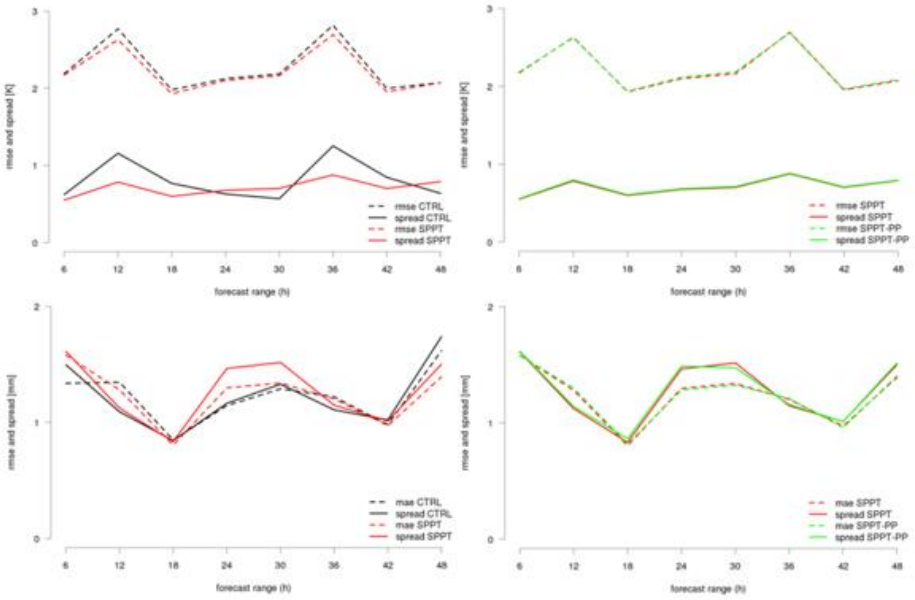

Figure 6: Error of the ensemble mean (dashed lines) and spread (solid lines), as a function of the forecast range, in terms of 2m temperature (upper row) and 6h precipitation (lower row), for the three experiments as indicated in legend. Error is RMSE for temperature and MAE for precipitation.

Temperature is compared against observed values at the SYNOP stations covering the Italian domain, while precipitation is compared against accumulated values recorded by the raingauges of a dense network covering Italy. In terms of 2mT, all configurations are underdispersive. Adding the SPPT does not yield an increase of the spread, in contrast with what was found in other configurations (e.g. COSMO-E). Adding parameter perturbations does not increase the spread and does not influence the error. In previous studies (Marsigli, 2009) it was noticed that parameter perturbation may have a highly localized impact, temporally and spatially, and dependent on the weather situation, therefore it is difficult to detect an impact in a statistical evaluation over a period. A spatial verification is applied to the precipitation fields, accumulated over 6 hour periods (Fig. 7). The verification method is the DIST method DIST (Marsigli et al, 2008). According to this method, the verification domain is first covered with boxes of selected size (here 0.2 x 0.2 deg). Then both forecasts (each ensemble member separately) and observations are aggregated in each box, by computing the average or the maximum (or other parameters of the precipitation distribution). Finally, common probabilistic verification scores are computed for both the average and maximum values belonging to each box and aggregated over the whole domain.

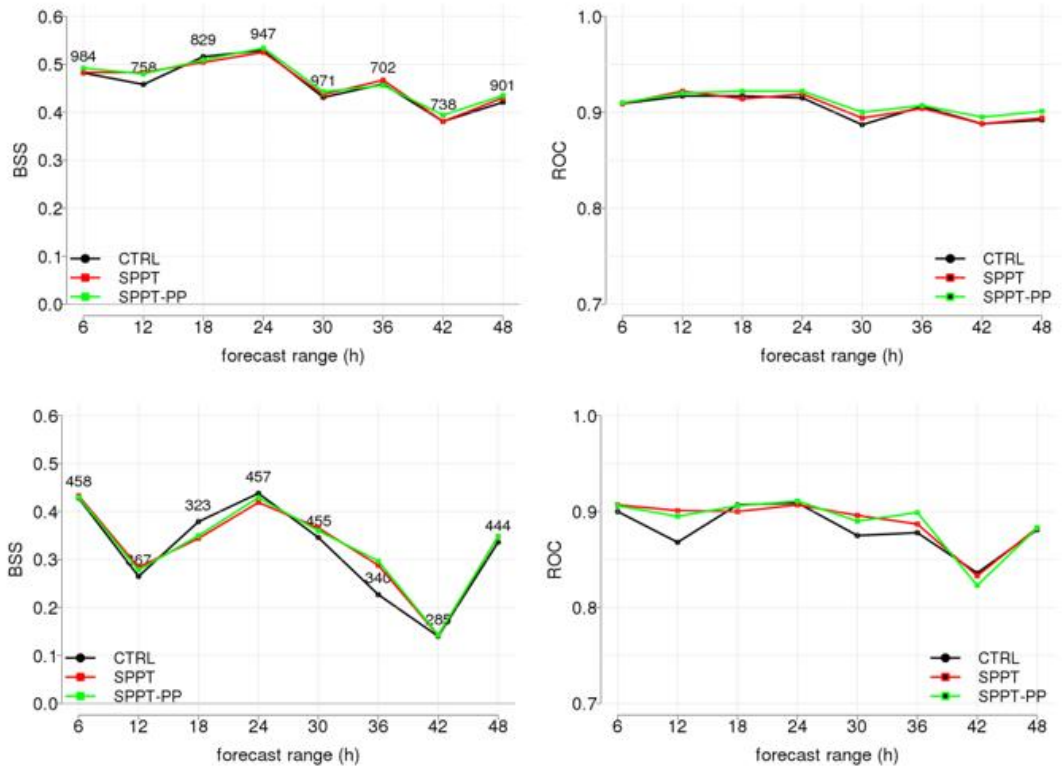

Figure 7: Brier Skill Score (left) and ROC area (right) as a function of the forecast range, for the 6h accumulated precipitation average values exceeding 1mm (top) and 5mm (bottom).

Results for average precipitation greater than 1mm/6h (upper row) and 5mm/6h (lower row) are shown in Fig. 7. While the ROC area indicates a better performance of the ensemble with perturbed physics, the Brier Skill Score shows mixed behavior. Parameter perturbation has a very little impact. How to assess the spread of the forecast in terms of precipitation is not straightforward, particularly for the convection-permitting scale. Following the development of spatial approaches for the verification of a high-resolution forecast, also the spread of the ensemble needs to be assessed in terms of spatial metrics. For this purpose, the methodology

proposed by Dey et al (2014) has been tested, where a dispersion Fraction Skill Score is computed as a measure of ensemble spread, evaluating the difference between couples of ensemble members in terms of FSS over boxes of increasing size. As an example, it is shown the mean over all couples of the dispersion FSS as a function of box size, for a case of intense precipitation occurred in the considered period (Fig. 8). The three experiments are compared, showing that the physics perturbations have an impact on the spread and that also the addition of Parameter Perturbation is able to increase the diversity of the members at all scales.

A different method has been also proposed in the Project for evaluating the ensemble spread: by computing its components using the SAL metric (Wernli et al 2008). The idea is that the different physics perturbations may address different components of the forecast uncertainty; therefore they may produce spread in different features of the resulting forecasted fields. The three component of the SAL (Structure, Amplitude and Localization) are computed for each couple of the ensemble members: 45 couples in a 10 member ensemble. The 45 dots are represented on a modified SAL-diagram in Fig. 9, where the Localisation is shown in the x axis, the Structure in the y axis and the Amplitude with the colour scale. This choice has been made to highlight the impact on the localization.

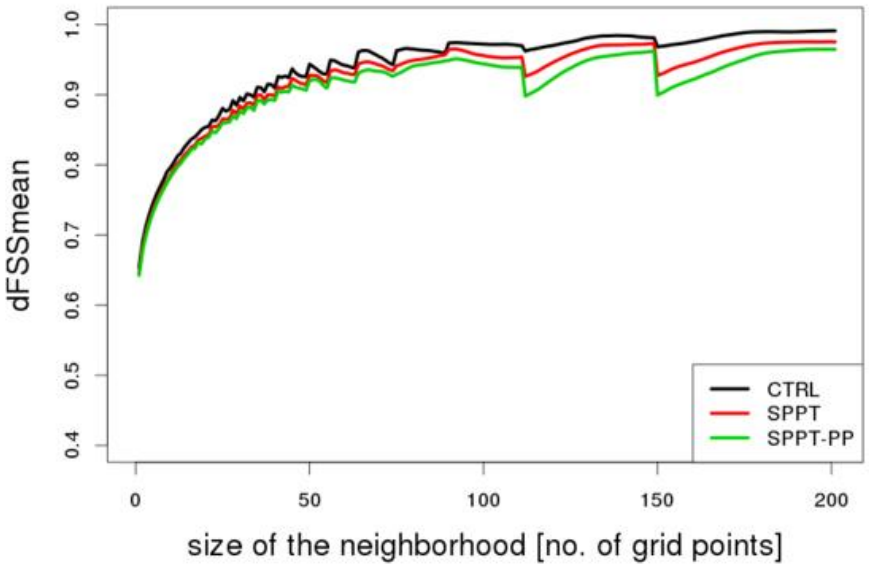

Figure 8: Mean value of the dispersion Fraction Skill Score a function of the forecast range, for the 24h accumulated precipitation for the even of the 31st October 2015.

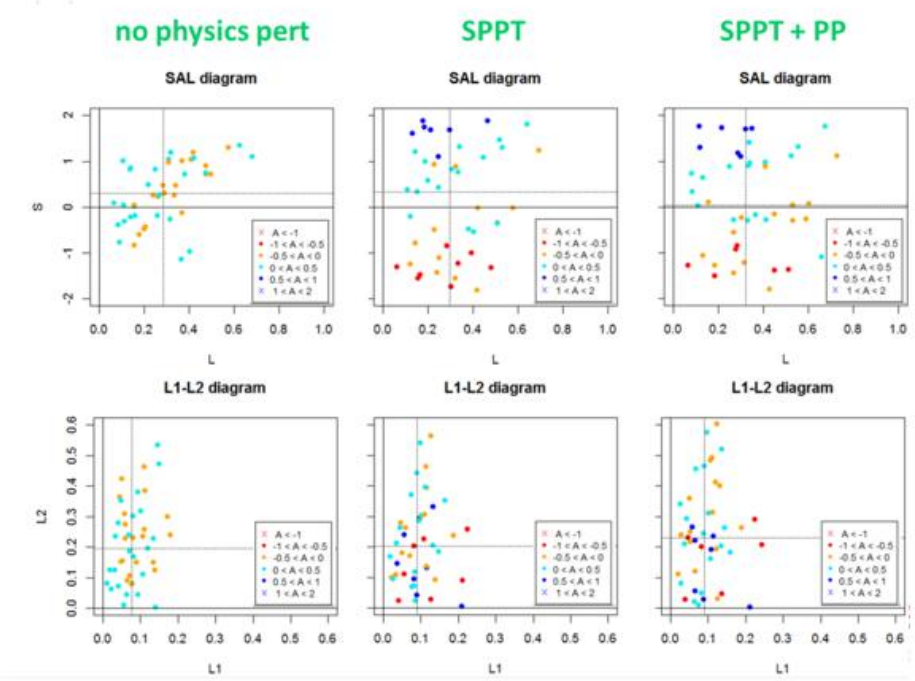

Figure 9: Dispersion of the members of the 3 ensembles (one in each column) represented as the three components of the SAL metric (top row), for the 24h accumulated precipitation for the event of the 10th October 2015. In the bottom row, the two sub-components of the L term are shown.

The impact of the physics perturbation in increasing the ensemble spread in terms of precipitation is now evident, and not only in Amplitude, but also in the Structure and in the Localization of the fields. It is now possible to detect an impact of the Parameter Perturbation, which determines more dispersion of the points in both L and S components. It is reminded that the L component consists of two terms: L1, measuring the distance of the centres of mass of the structures, and L2, measuring the difference in the degree of dispersion of each field around its centre of mass. How the increased dispersion is divided between these 2 components is shown in the bottom row, where an L1-L2 diagram is plotted. Introducing SPPT (central plot) both L1 and L2 are affected, and adding also the Parameter Perturbation (right plot), the spread in both components is further increased. This metric seems to be promising for the purpose of highlighting the contribution of a perturbation to the overall spread and to detail in which component this contribution takes place.

2.4 IMGW contribution

At IMGW, the COSMO model runs in a deterministic mode using initial and boundary conditions from the ICON global model, as shown in Fig. 10. The COSMO model with 7 km horizontal resolution (COSMO-7 km) applies nudging-based data assimilation to correct global model forecasts, ingesting the most recent set of meteorological data acquired from the GTS/WMO network. Forecast results from the COSMO-7 km are further used as IC/BCs for a nested instance of a COSMO model with a higher resolution of 2.8 km and 36-hour forecasts. A set of the deterministic COSMO-2.8 km forecasts define the basis for the operational configuration of an ensemble forecasting system.

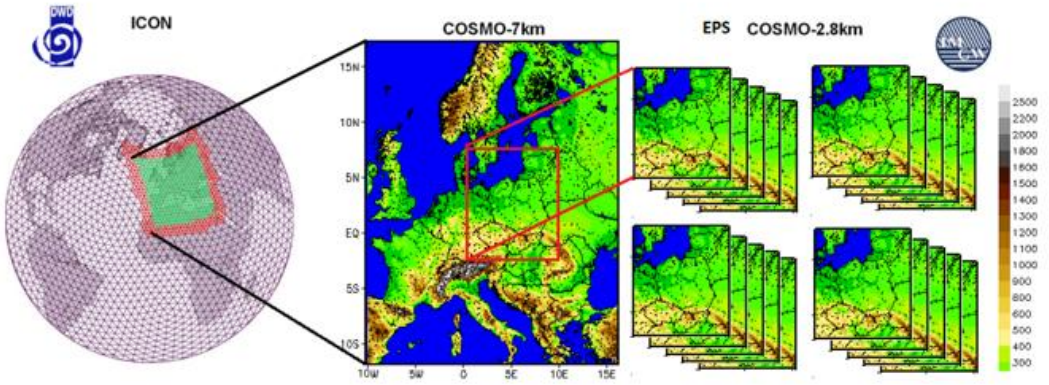

Figure 10: Operational configuration of deterministic COSMO-7 km model and 2.8 km resolution EPS runs at IMGW. From left to right domain of ICON global model, domain of COSMO-7 km model running at IMGW, and a set of nested COSMO-2.8 km domains.

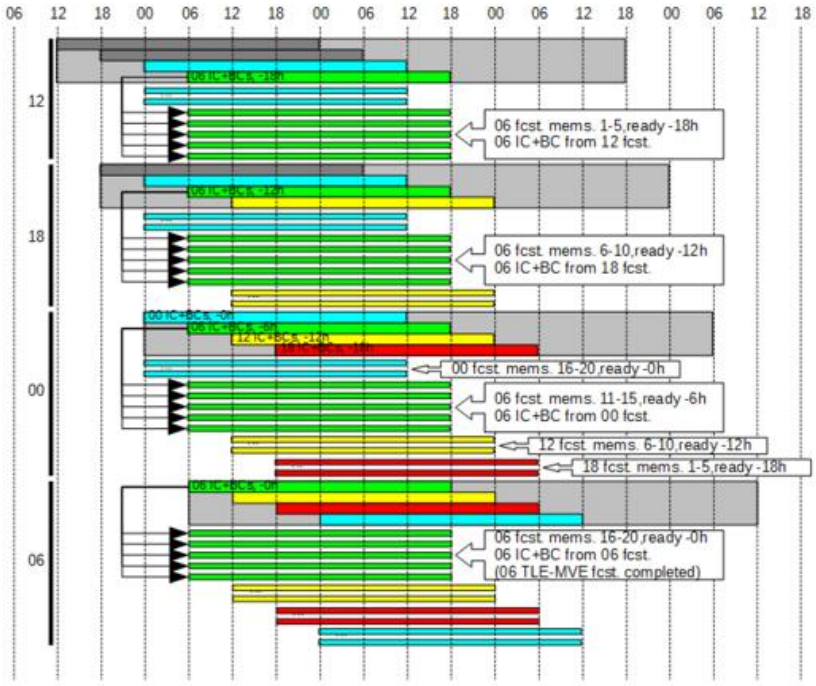

Figure 11: Operational setup of EPS based on Time-Lagged IC/BCs. X-axis lead time (UTC), Y-axis forecast individual initial time. The four different colours distinguish forecast nominal start time: blue 00 UTC, green 06 UTC, yellow 12 UTC, and red 18 UTC.

In the recently developed EPS configuration, twenty ensemble members were selected, based on the COSMO-2.8 km convection permitting (CP) forecasts. Every member of an ensemble applies perturbed lower boundary conditions, composed of the random noise of specified amplitude added to parameters of the soil-model physical parameterization (see e.g. Mazur and Duniec, 2015). In the basic EPS configuration, the whole set of IC/BC was nested from a single 78-hour run of a deterministic COSMO model with spatial resolution of 7 km, as shown in Fig. 11. In order to increase the spread of model parameters generated by forecasts, we have further adopted the concept of time-lagged IC/BCs (see e.g. Lu et al., 2007; Chen

et al., 2013), in which the set of deterministic CP forecasts is subdivided into groups starting at the consecutive time windows: 00, 06, 12, and 18 UTC.

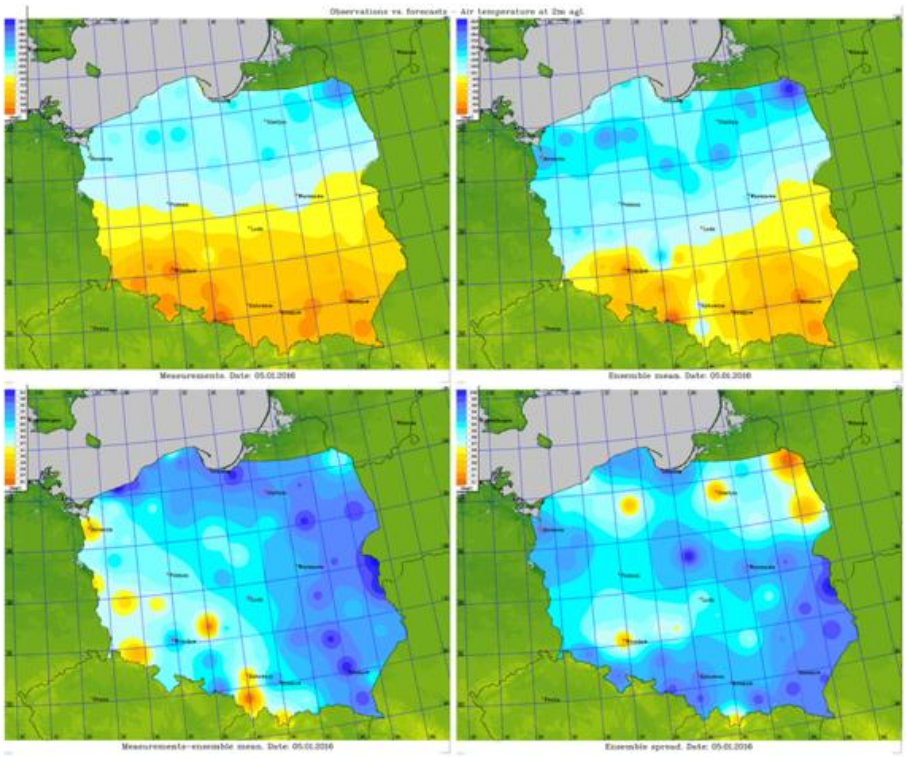

Figure 12: Comparison of the EPS derived temperature: ensemble mean (upper right), spread (lower right) with measurements (upper left), the absolute value of difference between measurement and ensemble mean (lower left).

The EPS results (in terms of EPS mean) are compared with observations collected from 61 Polish SYNOP stations. In Fig. 12 a representative analysis of the model generated temperature forecast averaged for the whole day of 5-01-2016 is presented, while Fig. 13 shows a similar verification for dew point temperature. In both cases, the EPS mean reproduces the main spatial features of the large-scale temperature distribution. The observed temperature is in a similar range (-20.7 ℃, -2.5 ℃) to the computed EPS mean (-20.8 ℃, -3.8 ℃). Similarly, the observed dew point temperature is in a similar range (-20.7 ℃, -2.0 ℃) to the EPS computed mean (-20.6 ℃, -1.6 ℃). In both cases, the model shows a bias when compared to observations with an absolute error of up to -6.1 ℃ for temperature and -5.7 ℃ for dew point temperature. For the temperature, larger error values (above 3 ℃) are well correlated with the air masses that came after the warm front crossing Poland during 5 January, 2016. Dew point temperature generally shows a small error - below 2 ℃ - except in the north-eastern part of Poland, where a persistent lack of cloud coverage can be observed for the selected date and in south-western areas, which may be correlated to a larger exceedance of precipitation intensity that started in the afternoon hours of 5-01-2016 and developed further during the night and the morning hours of the following day.

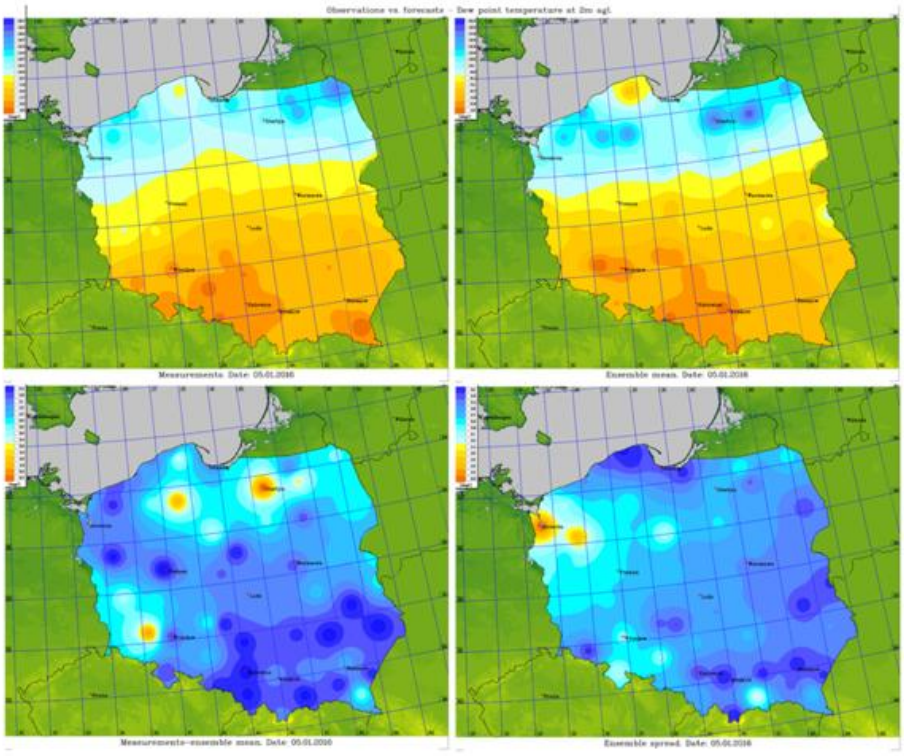

Figure 13: Same as in Fig. 12 but for dew point temperature.

A larger EPS spread implies more uncertainty in the forecast mean and hence in the ensemble members. The EPS spread is typically underestimated near the surface (Tennant and Beare, 2014) where the relations between prognostic parameters are controlled with higher fidelity parameterizations, not accounting enough for observation errors. Thus, in general EPS leads to overconfident forecasts of near-surface weather elements, especially in winter conditions where the natural variability of soil parameters is lower. In this approach, as shown in these examples, the perturbation of the evaporating fraction in the soil has a significant impact on the forecast due to the increased stimulation of energy exchange between the surface and atmosphere. The maximum spread for the temperature is 1.1 °C, with increased value covering the entire northern and western parts of Poland. For the dew point temperature, we observe a higher spread of the amplitude up to 2.0 °C, localized only in the north-western corner of the country. More advanced analysis of the EPS scores and the correlation between EPS error (skill) and spread is provided in the context of specific applications. First, selected parameters (air temperature, dew point temperature, wind speed and total precipitation) were studied for trimesters of 2016 and the entire year of 2016. The analysis was then carried out continuously in following periods. The quality of EPS forecasts, expressed in terms of skill and of spread in subsequent years seemed to improve, as shown in the following figures.

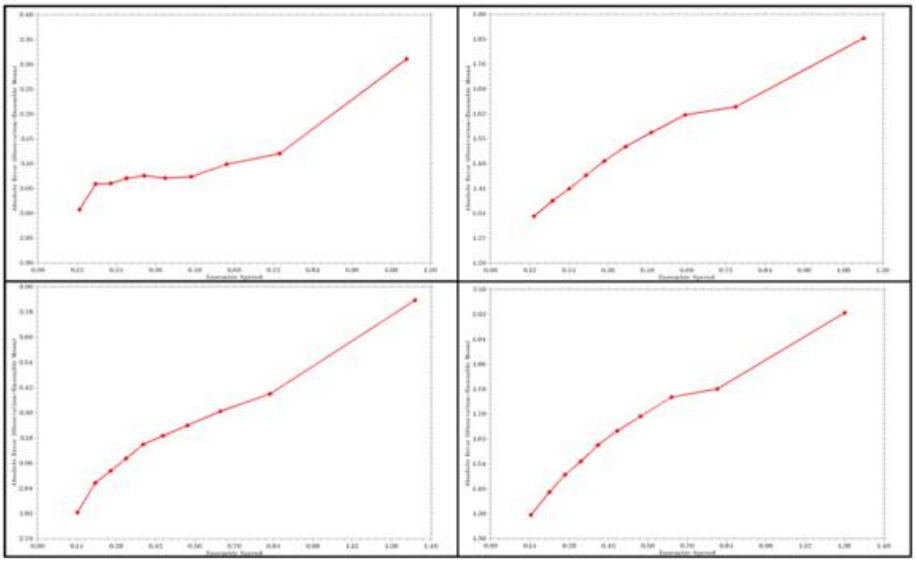

Figure 14: Left - skill-spread diagram for T2M, right - for U10M. Average values for the entire year 2016 (top row) and 2017 (bottom row).

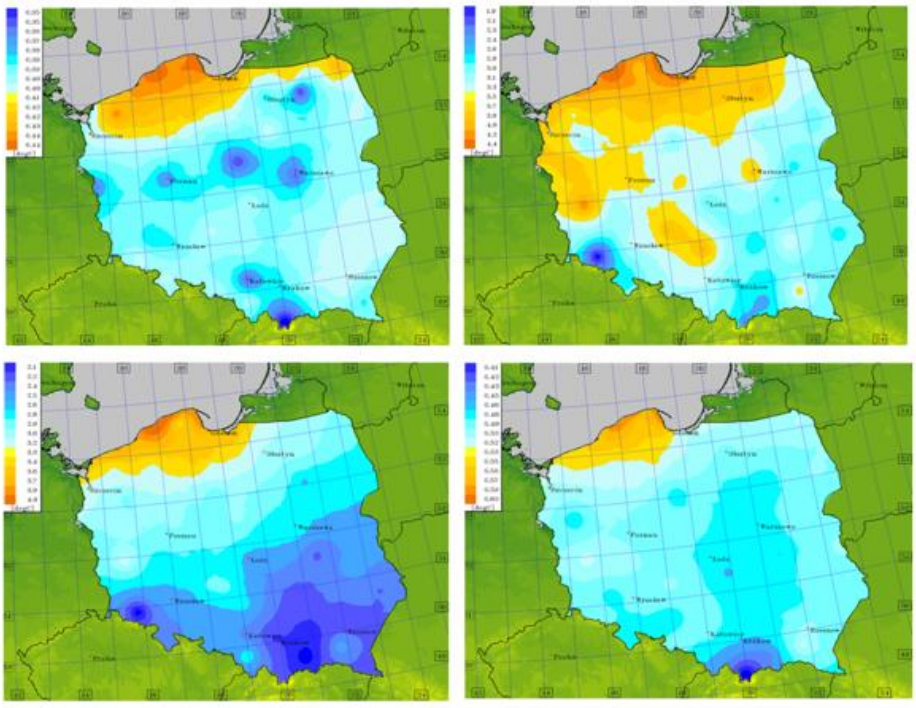

Figure 15: Spatial distribution of skill (left) and spread (right) for T2M (upper - average for year 2016; lower - for 2017).

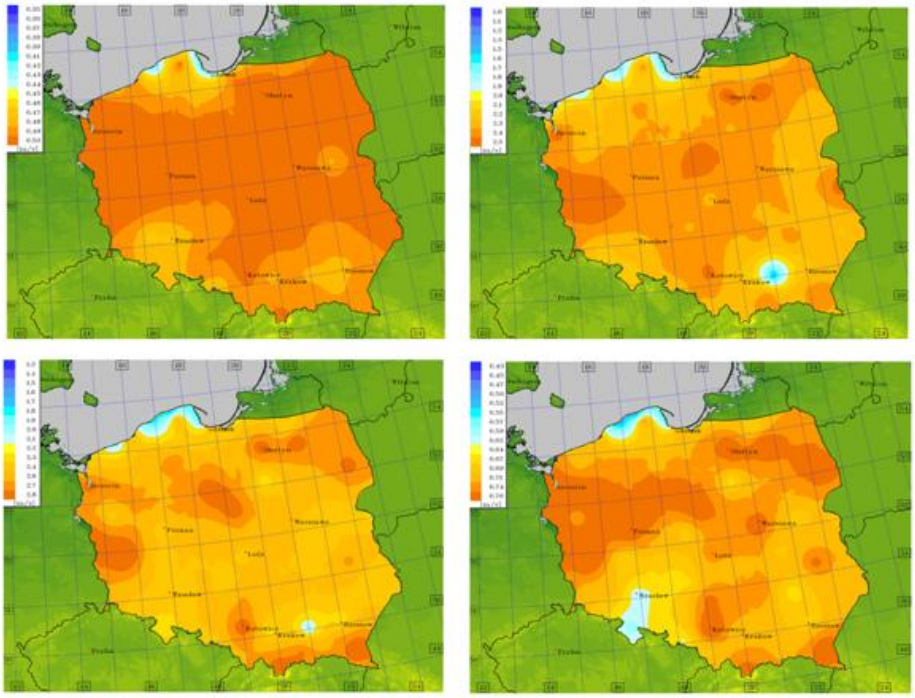

Figure 16: Same as Fig. 15, but for U10M.

The monthly analysis of skill/spread relation was done as well, starting from 2016. The representative results for the entire year 2016 are shown below.

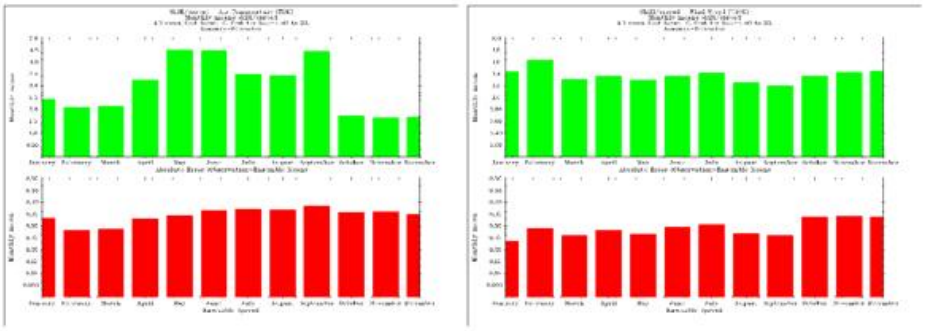

Figure 17: Monthly average skill (green) / spread (red) of T2M (left) and U10M (right). All runs/all stations, January to December 2016.

In conclusion to this part, it should be stated that skill/spread relation was studied thoroughly, using operational EPS results. Study has been carried out for months, seasons, entire year and, simultaneously, for runs (00, 06, 12, 18), forecast hours (0-36) and hours (0-23). Average spread is in general 2x to 10x lower than skill measured as MAE, which (as it was pointed out above) shows the under-dispersiveness of the system. As far as the spatial relations are concerned, one can observe that skill is in general better (i.e., smaller, as measured as MAE) for central and southern part of the domain. This is probably due to the way of generation EPS. Similarly, spread is bigger (meaning, better) in central and northern part of Poland. Similarly for time relation (monthly means) - skill is in general better (i.e., smaller) for warm months - probably due to EPS generation (perturbation of

lower boundary conditions - soil parameters - composed of the random noise of a specified amplitude added to parameters of the soil-model physical parameterization, as written above). Since it pertains to soil features, it may be less effective in winter (frozen ground) and more effective in warm and wet season. In turn, spread is been found in general bigger for warm months - again, probably due to the way the EPS members are prepared. Finally, another outcome of this part of Priority Project was a publication of paper at Meteorology Hydrology and Water Management - Research and Operational Applications (Grzegorz Duniec, Witold Interewicz, Andrzej Mazur, Andrzej Wyszogrodzki; MHWM recently became JCR journal), see: http://www.mhwm.pl/Operational-setup-of-the-soil-perturbed-time-lagged-Ensemble-Prediction-System-at,71048,0,2.html.

2.5 RHM contribution

Ideally, for a good ensemble, the behavior of the ensemble spread should follow that of the ensemble mean error and reflect the predictability of a meteorological situation. It is usually expected that a higher-resolution system has better skill (but in reality, it is not always so), thus theoretically the spread should decrease with resolution. However, the situation is not so straightforward when we are speaking about a pair "driving EPS-nested EPS" (as it is always the case with mesoscale EPSs), in which the spread at the lateral boundaries of the nested EPS is defined by the coarser-system spread.

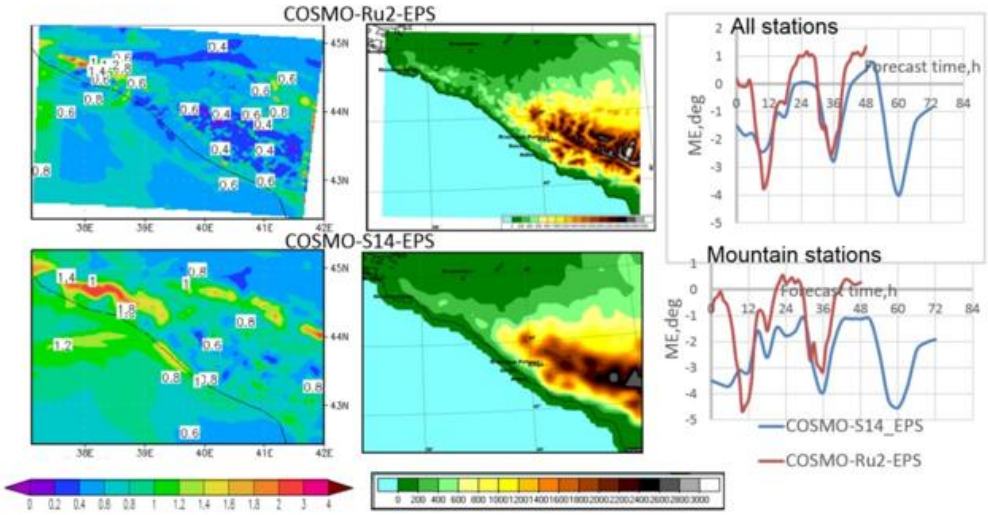

Figure 18: T2m ensemble spread (left) for 48h forecasts starting on 22 February, 2014 00UTC and orography (center) for COSMO-Ru2-EPS (top) and COSMO-S14-EPS (bottom). On the right: T2m mean error for the same date as a function of forecast lead-time for all stations in the region (top panel) and only for mountain stations (bottom panel).

Therefore, w decided to analyze the spread spatial distribution and temporal variations for two EPSs of different resolutions for the case when the higher-resolution system was nested to the coarser-resolution one. For this purpose, we applied the Sochi Olympics archive (Astakhova et al, 2016) and examined the runs of the 7-km COSMO-S14-EPS and the 2.2 km COSMO-Ru2-EPS (Montani et al, 2014). COSMO-Ru2-EPS was nested to COSMO-S14-EPS over a small region of about 350*300 km with a complex topography (containing mountain, valley, and sea points). For both systems, we considered 2-m temperature for the

1-month period from 1 to 28 February 2014 over the area corresponding to the integration domain of COSMO-Ru2-EPS. We considered both individual cases and monthly mean characteristics. Analysis of individual forecasts over the entire domain demonstrated that the higher-resolution EPS had less spread, however, its skill was not always convincingly better (see Fig. 18 for February 22, 2014). The geographical distribution of spread is correlated with orography, showing smaller spread over mountainous areas. Notably, the mean error decreased following the smaller spread over this high complex terrain (the Caucasus).

In fact, in a reliable forecast system we can expect a good spread-skill correspondence mostly for the results averaged over many forecasts ($\overline{Error^2} = \overline{Spread^2}$). Fig. 19 demonstrates the time evolution of T2m spread averaged over a month interval from February 1, 2014 to February 28, 2014 for two EPSs. As the forecasts were run twice a day (starting at 00 UTC and 12 UTC), the sample includes 56 forecasts. It can be seen that both systems start from approximately the same spread, but the spread of coarser-resolution forecasts grows with forecast time faster. The differences in spread between EPSs increase with lead time and are up to 0.8-1 deg. The smaller spread for the higher-resolution system corresponds to its smaller error (see Fig. 20 which shows the mean absolute error (wrt to all available station data in the region) of the two EPSs obtained using the FROST-2014 online verification tool for February 2014).

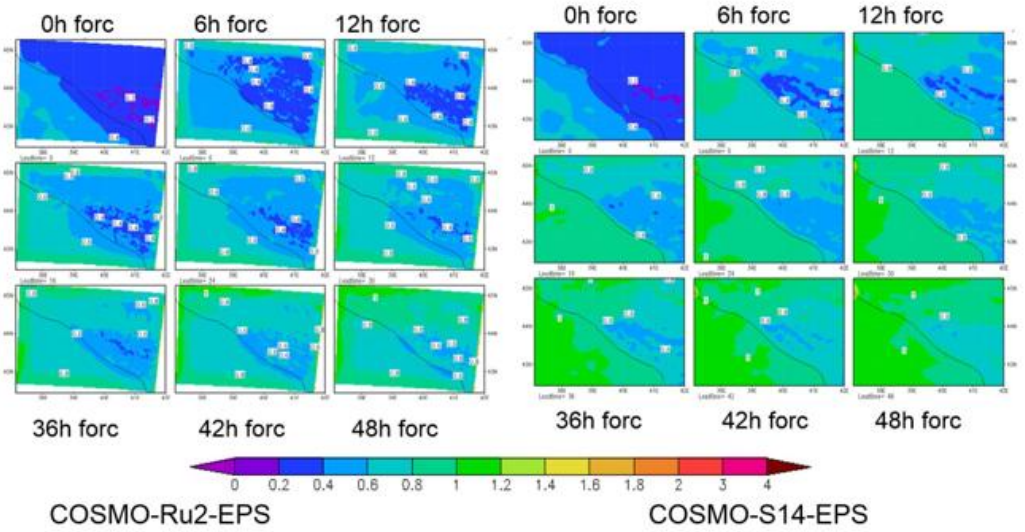

Figure 19: Evolution of 2m temperature spread with forecast time for two EPSs with different resolutions. Averaged over 56 forecasts in February 2014.

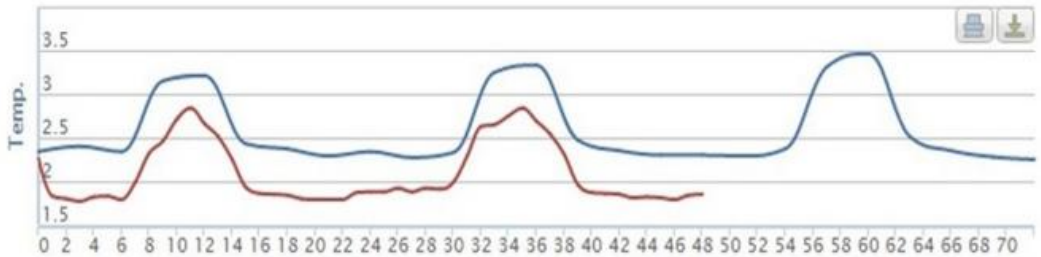

Figure 20: Mean absolute error of 2m temperature over the Sochi area averaged over 56 forecasts in February 2014. Red - COSMO-Ru2-EPS, blue - COSMO-S14-EPS.

It is also worth noting that for the T850 spread the differences between systems of different resolutions were much smaller (not shown). This indicates the important role of surface in forecast perturbations. We have examined EPSs not only with different resolutions but also with different integration domains. Looking at the spread fields in detail, we found that when regions with high T2m spread appeared near the lateral boundaries of COSMO-Ru2-EPS (near the borders of our post-stamp plots in Fig. 21), they occupied larger area and tended to propagate inside the domain in COSMO-S14-EPS being smaller and staying near the border in COSMO-Ru2-EPS. This indicates that the size of the EPS integration domain can also matter.

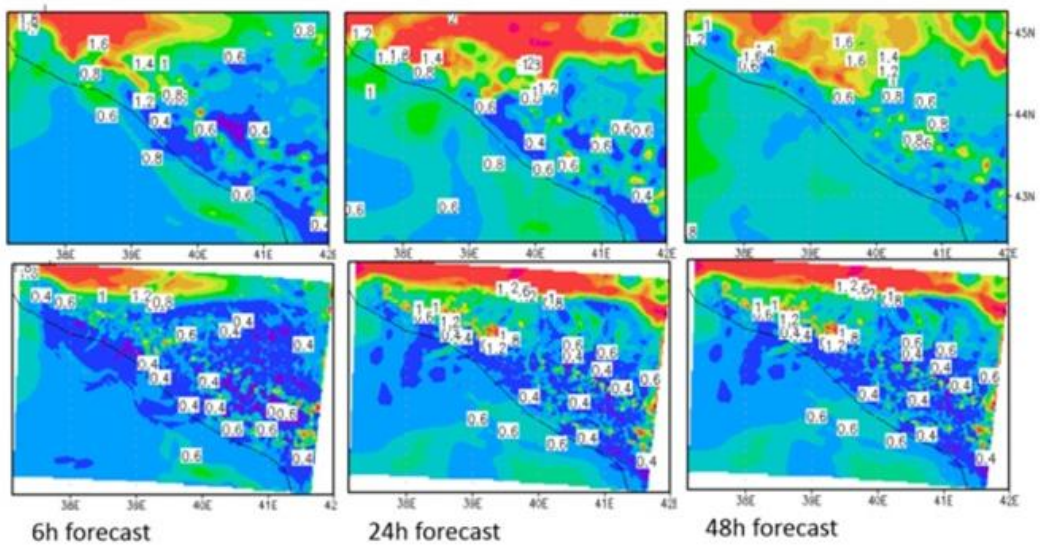

Figure 21: Evolution of the T2m spread with the forecast time in two EPSs. Upper panel: COSMO-S14-EPS; lower panel: COSMO-Ru2-EPS. Forecast from 22 February 2014 00UTC.

To explore this aspect, additional experiments were performed changing the size of the integration domain for COSMO-Ru2-EPS. The archive COSMO-Ru2-EPS data were obtained with model version 4.22 and with double precision. The new experiments were run with model 5.01 in single precision. Comparing the archive and the new results (with different model versions) we found non-zero differences in spread fields for one and the same date. Thus, we had to rerun the previous experiments for COSMO-Ru2-EPS. Finally, the experiment set was as presented in Fig. 22. The reruns of COSMO-Ru2-EPS were made for two different domains called LITTLE and BIG, while the COSMO-S14-EPS runs covered the domain S14. The comparison was made for the area, corresponding to the LITTLE domain. In addition to T2m temperature, the free atmosphere temperature was considered as well.

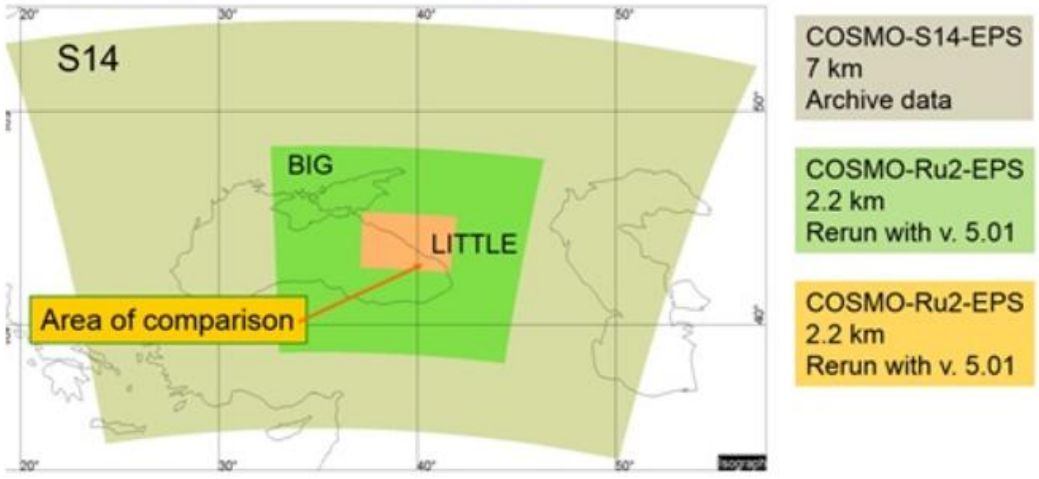

Figure 22: Experiment setting.

The resulting spread was found to depend on the size of the integration domain considerably (see Fig. 23). The effect is related to weather situation and is most pronounced near the surface and in regions with complex topography. The choice of integration domain can differently affect different prognostic realizations. Depending on location and air mass motions both ensemble mean and spread can be increased or decreased (in some cases - considerably) when the integration domain is changed. Choosing the integration domain for EPS, especially in mountain regions, one should be very careful and take into account the prevailing weather types and air mass motions.

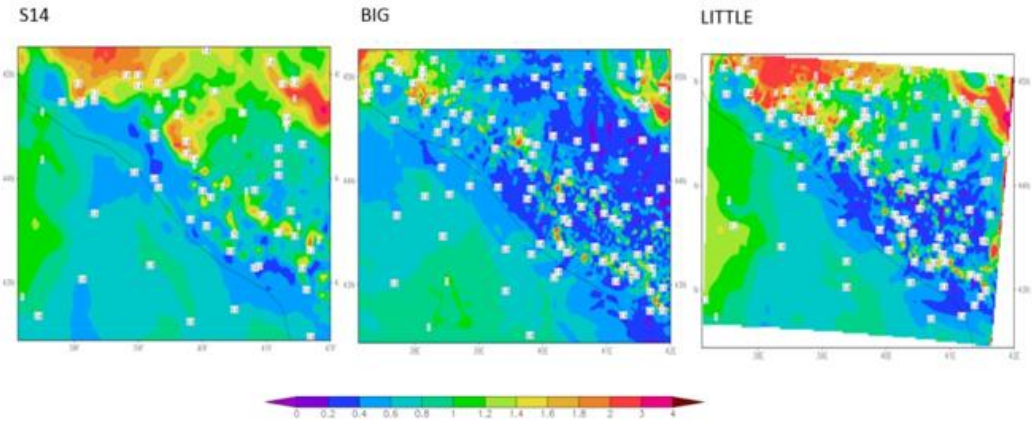

Figure 23: T2m spread fields obtained for integration domains S14, BIG and LITTLE (presented for LITTLE area). 48-h forecast starting from February 22, 2014 00 UTC.

We can conclude that generally the ensemble spread decreases for higher-resolution nested EPS but the effect depends on the size of the EPS integration domains and the dominating weather patterns.

2.6 Remarks from the discussion of the results

This Project activity has lead to a better shared understanding of the spread/skill relation of our ensembles, highlighting also the main deficiencies. Some conclusions have been drawn:

- it is important to consider also the day-by-day variation of the spread, which should follow the day-by-day variation of the error;
- it is suggested to investigate the impact of the Boundary Layer perturbations recently introduced in the COSMO model following the work by K. Kober (perturbations proportional to the variance of the tendencies coming from the turbulence scheme). Results are shown in Section 3.3;
- it is suggested to compute also the spread/skill relation on vertical profiles, to assess the vertical structure of the error and its representation in terms of spread
- it is highlighted the possibility of using Fraction Skill Score and SAL for computing the spread of the ensembles in a spatial verification sense;
- it is considered the work of Pirkka Ollinaho (ECMWF) on the introduction of parameter perturbations in their ensemble. This approach could be useful also for the COSMO Consortium but it requires strong link with the physics developers;
- it was mentioned that perturbation of parameters usually has a detectable impact on particular weather situations, therefore it is difficult to see an impact on a long statistics. Following this remark, it is suggested to perform also verification/evaluation on selected cases or collections of cases;
- it is suggested to compute also the spread/skill relation with respect to analysis, not only to observations, to reduce the influence of systematic model error;
- it is considered also how to include the observational error in the spread/skill evaluation. It is suggested to start from the literature and try the previous works of Neill Bowler and Marion Mittermaier.

3 Test and development of model perturbation

The methodologies available in the Consortium for model physics perturbations have been subjected to further study.

3.1 EM-scheme and Parameter Perturbation at DWD

The work has been described in Section 2.1.

3.2 SPPT and BLPERT schemes at MeteoSwiss

SPPT scheme

The SPPT scheme is used in the operational COSMO-E forecasts of MeteoSwiss. Several issues with SPPT could be solved within the SPRED priority project and a consolidated version of the scheme implemented by Lucio Torrisi (Italian Meteorological Service, Rome,

COMET) with support for GPUs is implemented in the official COSMO version 5.05. The main findings are:

- SPPT has significant impact only with large correlation lengths in space and time in the random pattern. COSMO-E thus uses 5deg and 6h, respectively. The sum of the parameterization tendencies for temperature and humidity are largest in summer and are then dominated by those of the turbulence scheme. This explains why SPPT enhances the spread mainly in summer, but hardly in winter;
- in order to avoid an effect on the total water content in the atmosphere by SPPT, all humidity variables (Qx) should be perturbed (itype_qxpert_rn=2). Other settings caused extensive precipitation in a few members during the test period;
- the COSMO advection scheme causes unphysical temperature anomalies in specific conditions and locations in complex topography. The model physics counteract against these anomalies. However, if SPPT reduces the physical tendencies the counteraction is weaker and thus less effective. Therefore, a new switch has been implemented in COSMO to switch off SPPT locally where temperature anomalies are diagnosed (ltargetdiff_mask=.true.).

BLPERT scheme

The boundary layer perturbation scheme (BLPERT) suggested by Kober and Craig (2016) includes stochastic perturbations related to turbulent fluctuations in kilometer-scale numerical weather prediction models. It has been implemented in a COSMO test version by Uli Blahak, DWD. Since COSMO-E shows a lack of convective precipitation in the Swiss Plateau, we tested whether the scheme is able to enhance the triggering of convection based on case studies for both strongly and weakly forced synoptic weather situations. The experiments confirmed the potential of the BLPERT scheme to improve forecasts in weakly forced cases by intensifying the triggering of convection as shown in Kober and Craig (2016). However, the factor that controls the amplitude of the perturbations, blpert_const, has been set to twice the value suggested by the authors to reveal a significantly positive impact in our case. More importantly, the scheme has a clearly negative impact on the convection characteristics in our cases with rather strong forcing. It produces too many small-scale unorganized cells with short lifetime and breaks up larger cells and squall lines, also with the recommended setup. Therefore, the benefit of the scheme in the current version is questionable for COSMO-E.

General remarks

Model perturbations by BLPERT or SPPT have an impact on the physical processes that keep a convective system alive and they can be disruptive. The chances that perturbations are disruptive are particularly high with BLPERT with new random numbers every 10 minutes, but it seems to be a general problem of stochastic model perturbation schemes in convection-resolving ensembles that are based on an additional term for prognostic model equations. Hence, the impact of new model perturbations on the convection characteristic or on physical processes in general, should be carefully investigated.

3.3 Stochastic pattern Generator for model perturbation at RHM

A Stochastic Pattern Generator (SPG) has been developed at the Hydrometcenter of Russia within the framework of PP KENDA (Tsyrulnikov, Gayfulin, 2016, 2017). The goal of this study was to try SPG for generation of model-error perturbations in the COSMO-Ru2-EPS.

SPG in a nutshell

The SPG produces Gaussian pseudo-random 3-D and 2-D spatio-temporal fields with realistic and tunable structure on a limited-area domain. The SPG benefits from the fact that it generates fields with realistic space-time interactions (the spatio-temporal covariances obey the "proportionality of scales" principle: larger (shorter) spatial scales are associated with larger (shorter) temporal scales (Tsyroulnikov, 2001). The SPG model is

$$(\frac{\partial}{\partial t} + \mu\sqrt{(1-\lambda^2\Delta)})^3\xi(t,s) = \sigma\alpha(t,s))$$

where $\xi(t,s)$ is the model-error random field to be generated, α is the white in space and time driving noise, t is time, s=(x,y,z) is the spatial vector, Δ is the spatial Laplacian, σ controls the variance, λ controls the spatial length scale, and μ controls the time scale. The SPG was first coded as a stand-alone version; it was later embedded in COSMO model versions 4.22 and 5.01. Modifications of the model code include the supplemental new modules mod_spsp.f90 and src_gen.f90; changes in some old modules, and introduction of additional tuning parameters in INPUT_ORG namelist. The SPG is easily tunable. Its main tuning parameters are defined in the namelist INPUT_ORG:

- the standard deviation of the random field (separate for u, v, T, qv: {u,v,T,qv}_rand_field_std);
- the distance in km at which the spatial correlation falls to 0.5 (separate for u, v, T, qv {u,v,T,qv}_L05);
- the time in sec when the temporal correlation falls to 0.2 (separate for u, v, T, qv: {u,v,T,qv}_t02).

In our experiments we varied these parameters to get a good spread/skill relation. The SPG was applied in the additive mode. The random field $\xi(t,s)$ was generated on an SPG coarse grid (with 64 grid points in x and y directions and 32 levels) and tri-linearly interpolated to the model grid. For each element F (i.e. u, v, T) its individual perturbation field rand_field on the model grid was recalculated every timeslice=1200s. The perturbations were added at each model timestep as follows

$F_{pert} = F_{unpert} + rand_field/timeslice.$

That is, the perturbations were smoothed in time and space and were different for each element and level. Humidity was not perturbed.

Experimental set up

Experiments were carried out with COSMO-Ru2-EPS system developed for the Sochi Olympics within the CORSO project (Montani et al, 2014). The following experimental set up was applied:

- Δx= 2.2 km, L50, 10 members;
- IC&BCs from COSMO-S14-EPS (a clone of COSMO-LEPS for Sochi region, Δx=7km, L40);
- forecast length 48h;
- period: February 1-7, 2014 (00UTC);

- domain: Sochi area (172*132 gridpoints);
- verification against observations (∼40 stations) using VERSUS;
- model version 5.01 (with SPG implemented);
- single precision runs.

Each set of experiments included reference experiments and experiments with different sets of the SPG parameters. There were two reference experiments:

- experiment NOPERT without model perturbations at all (both SPPT and SPG were switched off);
- experiment SPPTSW with SPPT turned on and the SPPT parameters recommended by MeteoSwiss (hinc_rn=6 h; dlat_rn=dlon_rn=5 deg; stdv_rn=1.0; range_rn=0.8; itype_qxpert_rn=2 ; tapering in the stratosphere, no tapering near the surface).

The focus was on the possibility of increasing the T2m spread with SPG-generated model perturbations. Temperature and wind spreads in the free atmosphere were considered as well. It was demonstrated that the SPG perturbation patterns were sensitive to pre-defined spatial and temporal correlations ({u,v,T}_ L05 and {u,v,T}_t02 parameters). However, no definite conclusions could be drawn from that analysis. Therefore, most experiments with SPG were run with fixed spatial and temporal correlations: we assumed that for random fields of all variables (T, u, v) the spatial correlation was 0.5 at a distance of 50 km ({u,v,T,qv}_ L05=50 km) and the temporal correlation becomes equal to 0.2 in 4800s {u,v,T,qv}_ t02=4800s). Then we varied the random field standard deviations, specifying them separately for temperature and wind fields. First experiments demonstrated that perturbations with standard deviations about 0.02-0.03 m/s per hour for wind and 0.01-0.02 K per hour for temperature had a negligible effect on the T2m ensemble spread. After some additional tests for individual dates, two versions of SPG setting were selected. The experiment SPGBIG2 was run with the standard deviations for wind u,v_std=0.15 m/s per hour and for temperatures T_std=0.045 K per hour. bit greater deviations were specified in the experiment SPGBG: u,v_std=0.21 m/s per hour, T_std=0.06 K/h.

Experimental set results

We ran the experiments NOPERT, SPPTSW, SPGBIG2 and SPGBG for 7 days and examined the behavior of ensemble mean and spread for temperature, wind, and mean sea level pressure. The application of both SPPT and SPG resulted in an increase of the ensemble spread. In the free atmosphere, the increase was much greater for SPG both in temperature (see Fig. 24) and wind (not shown). Fig. 24 demonstrates the high sensitivity of ensemble spread to the standard deviations of the random fields generated by SPG. This implies that tuning the SPG setup is a tricky task.

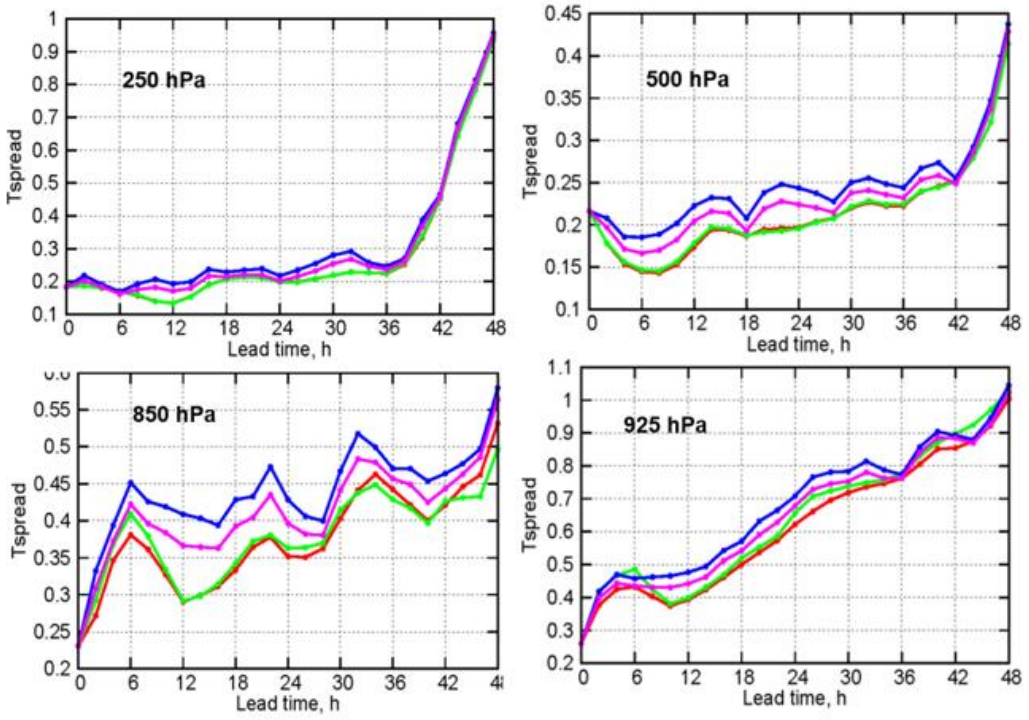

Figure 24: Temperature spread as a function of forecast time for experiments NOPERT (red), SPPTSW (green), SPGBIG2 (magenta), SPGBG (blue). Forecast start time is February 6, 2014 00UTC.

For individual days, the T2m spread with SPPT and SPG were comparable (see Fig. 25). The results of experiment SPGBG (with greater standard deviations of the SPG-generated random fields) seem to be superior.

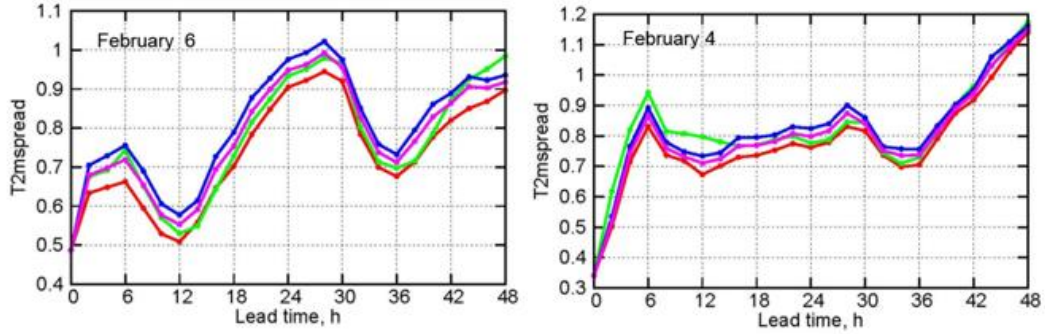

Figure 25: T2m spread as a function of forecast time for experiments NOPERT (red), SPPTSW (green), SPGBIG2 (magenta), SPGBG (blue) for forecasts starting on February 6, 2014 00UTC (left) and February 4, 2014 00UTC (right).

The ensemble forecasts of T2m were verified against the station data using VERSUS for the period of 7 days (February 1-7, 2014, 00UTC). In Fig. 26 the T2m spread for SPPT is slightly bigger than for SPG, while the latter slightly improved the T2m error. Note that all the above presented spread plots demonstrate the results of averaging over all grid points using the grib_api tools. On the other hand, VERSUS interpolates the forecasts to the points

of observations and the spread in Fig. 26 is averaged over observation points only.

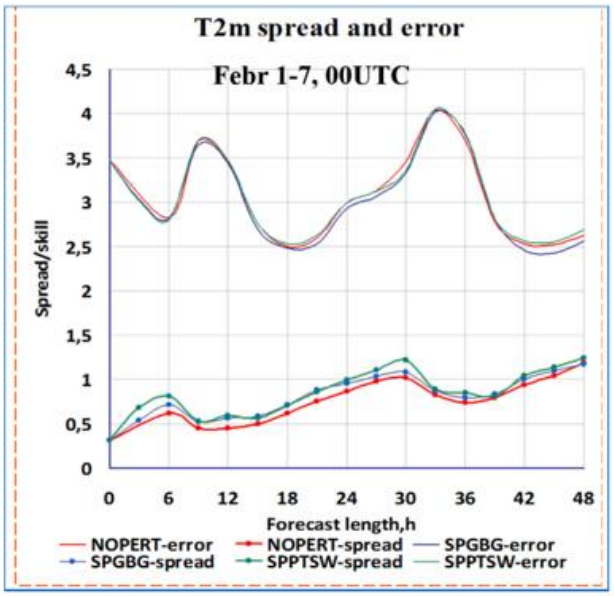

Figure 26: The error (upper curves) and the spread (lower curves) of T2m temperature for experiments NOPERT (red), SPPTSW (green) and SPGBG (blue) calculated for a 7-day period starting from February 1, 2014 00UTC. Sochi area.

Fig. 26 implies a possibility of a further increase of T_std and u,v_std in the SPG setup. An additional experiment with T_std=0.09 K/h and u,v_std= 0.3 m/s per hour was carried out. The T2m spread increased, but the effect on the free-atmosphere temperature spread was much greater, which does not look physically reliable. Thus, it was suggested to revise the way SPG is used for model perturbations and now the work continues within the APSU Priority Project.

Conclusions

- The application of SPG for perturbing model in COSMO-Ru2-EPS looks promising and results in increasing the ensemble spread;
- the application of SPG improves T2m forecasts;
- the ensemble spread is very sensitive to the SPG settings. Even a small increase in the standard deviation of the random fields leads to a spread growth. Variations in correlation lengths and times also have a visible effect but it is not so unequivocal and will be addressed later;
- in the free atmosphere, the temperature and wind spread is bigger with SPG than with SPPT;
- for T2m, the ensemble spreads in experiments with SPG and SPPT are comparable.

A new way of applying SPG (in which the number of parameters to be specified and tuned is reduced) will be considered in the Priority Project APSU.

4 Test and development of perturbation for the model lower boundary

The perturbation of the model lower boundary (surface/soil) has also been further developed, consolidating the methodologies developed in the COTEKINO PP.

4.1 Soil moisture perturbation in a complete ensemble set-up (ARPA Piemonte)

In the framework of the COTEKINO PP, a method for the perturbation of the soil moisture has been developed by Arpa Piemonte (Bonanno and Loglisci, 2018). The method is based on the Stochastic Pattern Generator developed by RHM (Tsyrulnikov and Gayfulin, 2016).

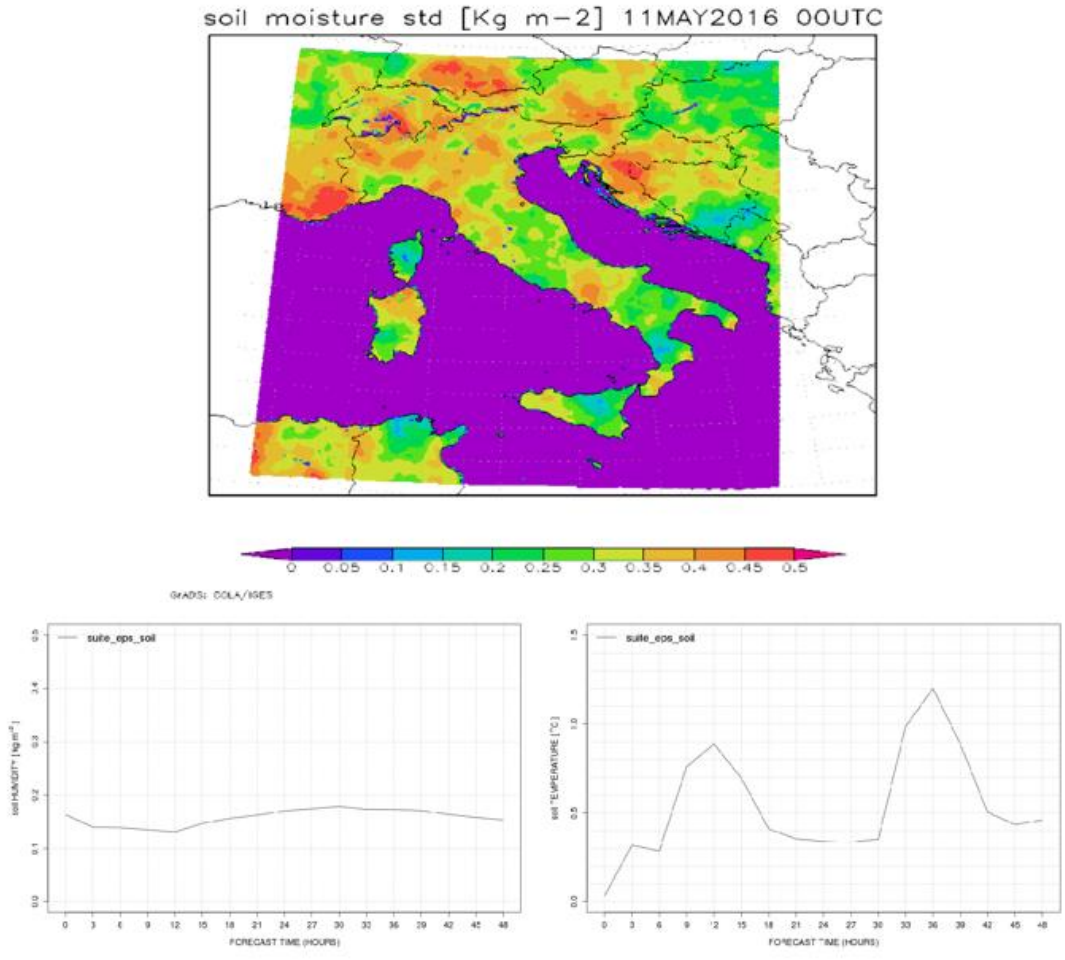

Figure 27: Soil mositure perturbation in the initial condition for the event of the 11 of May 2016 (top panel). Temporal evolution of the spread in terms of soil moisture (bottom left) and soil temperature (bottom right).

In the SPRED PP, the purpose of the task was to assess the benefit of the methodology by introducing the perturbation in an ensemble with "complete set-up", with perturbed Ini-

tial and Boundary Conditions, as well as physics perturbations. An experimental suite of COSMO-IT-EPS was created for this purpose. The ensemble was run in a complete ensemble set-up: Initial and Boundary Conditions from ECMWF ENS, SPPT and Parameter Perturbation applied to the COSMO model. The suite was run with and without soil moisture perturbation, for the month of May 2016. This period was selected due to the occurrence of several convective events over Italy. A statistical analysis of the results has not been completed due to a lack of resources. As an example of the perturbation applied, the field of the soil moisture perturbation is shown for the event on the 11 of May 2016 (top panel), together with the temporal evolution of the spread in terms of soil moisture (bottom left panel) and soil temperature (bottom right panel).

4.2 Soil parameters and soil temperature perturbation (IMGW)

At IMGW, the ensemble forecast was prepared in such a way that each member of the ensemble starts with a different value of the initial state of c_soil, the parameter describing the fraction of evaporating soil, and of soil surface temperature. The c_soil parameter is varied using the new random number generator. In addition to the variation of parameters that describe the state of soil surface, the collection efficiency coefficients (eff-coeff, see below) in the clouds were also perturbed to add perturbation in the physical parameterization of precipitation processes. The following perturbations were considered:

(a) *c_soil*: perturbation of a parameter describing evaporation from soil using RNG (described in Section 5.2);

(b) *eff-coeff*: perturbation of the collection efficiency coefficient;

(c) *eff-c_soil*: perturbation of the collection efficiency coefficient together with evaporation from the soil surface;

(d) *laf-pert*: perturbation of the surface temperature of the soil;

(e) *laf-c_soil*: perturbation of soil surface temperature in the set of initial conditions simultaneously with evaporation from the soil surface;

(f) *laf-eff*: perturbation of the soil surface temperature (as in (e)) together with a variation of the collection efficiency coefficient;

(g) *eps-all*: perturbation of all the above quantities (fields and parameters) at the same time.

The warm period (June-September) of 2013 was chosen for numerical simulations. The study was focused on ensemble forecasts of three meteorological fields: air temperature at 2 m above ground level (TE2M), dew point temperature at 2 m (TD2M), and wind speed at 10 m (U10M). For each meteorological field, the monthly average values of the spread (standard deviation of forecasts, calculated using all the members of the ensemble) and an indicator of skill S (mean absolute error, MAE, of the forecasts) were calculated (Jolliffe and Stephenson, 2012). In the next step the average values of spread and skill were compared with the average values of air temperature, the deviation of the average monthly air temperature in a given month in relation to the long-term average of 1971-2000 (Bulletin, 2013), the monthly precipitation sum and deviation of the monthly sum of atmospheric precipitation as a percentage of the long-term norm for 1971-2000 (Bulletin, ibid.). The results were cross-checked for correlation with the average values of spread and skill for the given type of soil that occurred in the analyzed area. The most effective perturbations (combinations) in

Period/Field	TD2m	T2m	U10m
June	eff-coeff	?	?(∼eff-c-soil)
July	c-soil	eff-coeff	?(∼laf-c-soil)
August	eff-coeff	eff-coeff	?(∼laf)
September	c-soil	eff-coeff	?
Jun-Sep	laf-c-soil	eff-coeff	?

Table 1: Most effective perturbations, see explanations in text above. Values averaged for June to August 2013. The ? means hard to establish, the ∼ means small tendency.

terms of skill and spread, averaged over the period of study, are presented in the following table.

The following figures present the most effective perturbation schemes in terms of skill (MAE) and spread on the period June-August 2013.

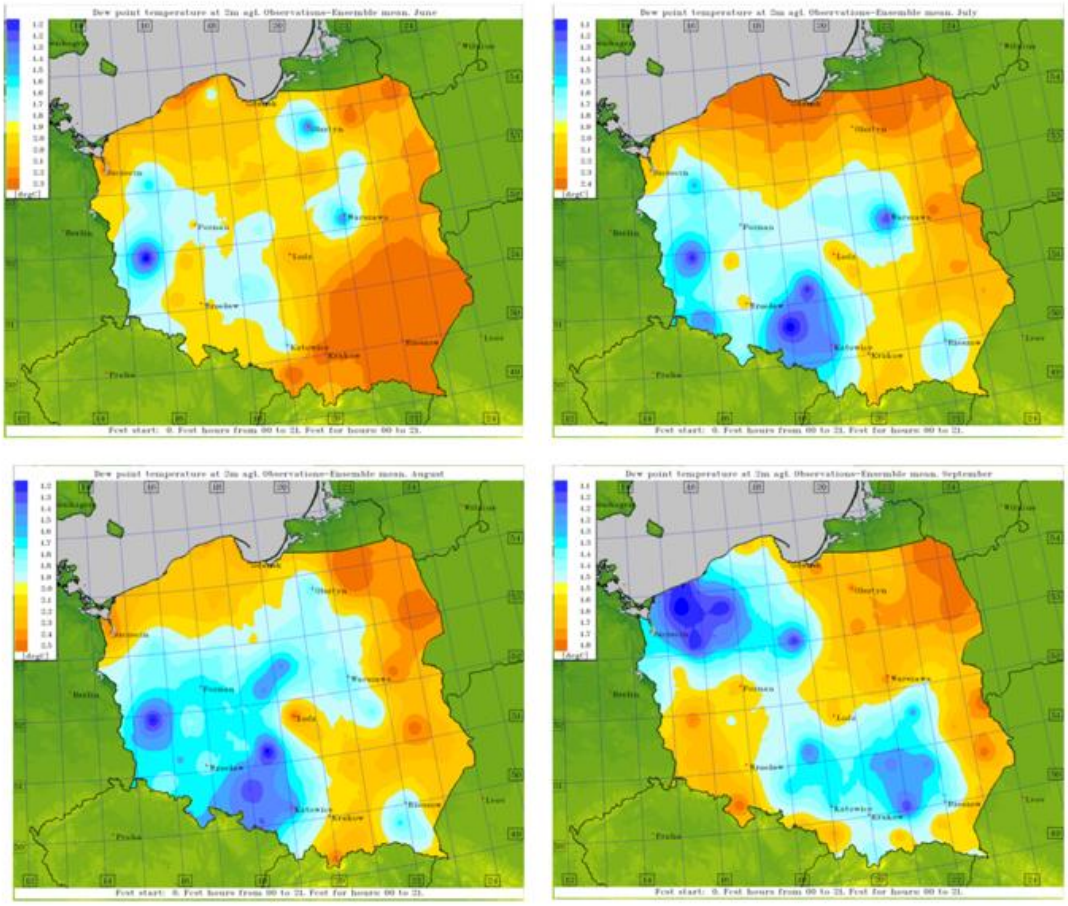

Figure 28: MAE (skill) spatial distribution for TD2M - most effective schemes. Upper left - June (eff-coef), upper right - July (c-soil), lower left - August (eff-coef), lower right - September(c-soil).

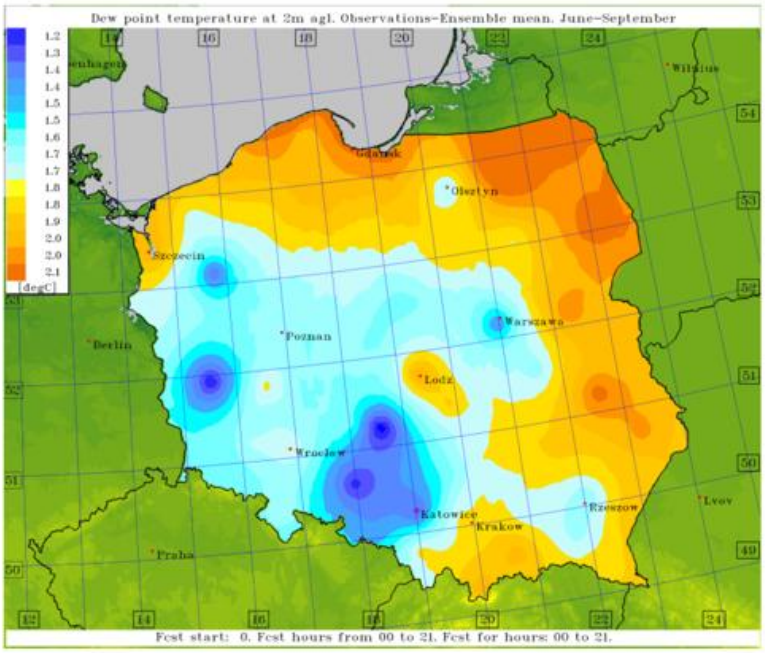

Figure 29: MAE (skill) spatial distribution for TD2M - most effective scheme for the entire period June-September 2013 - laf-c-soil.

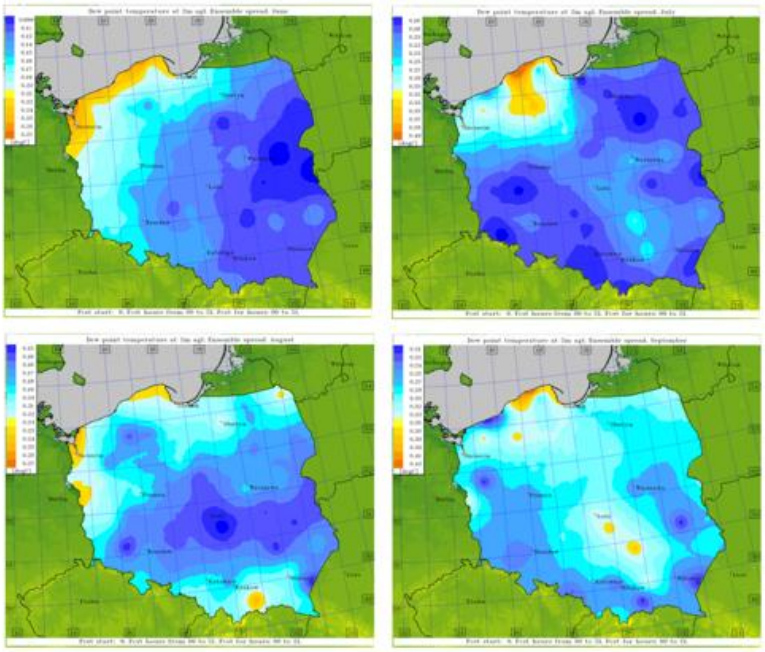

Figure 30: Spread spatial distribution for TD2M - most effective schemes. Upper left - June (eff-coef), upper right - July (c-soil), lower left - August (eff-coef), lower right - September(c-soil).

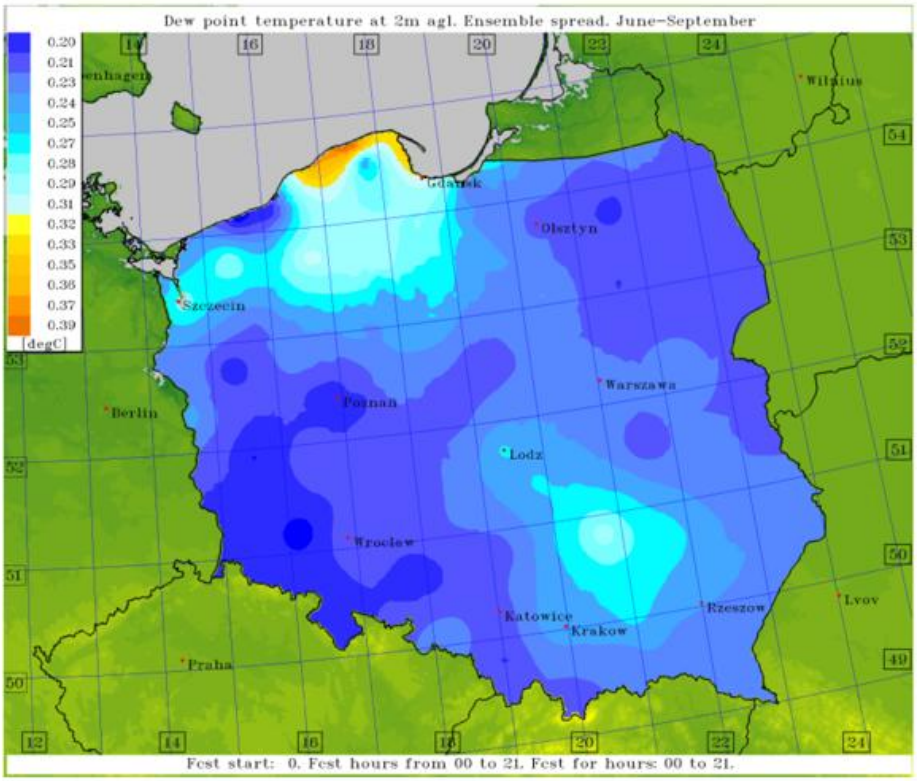

Figure 31: Spread spatial distribution for TD2M - most effective scheme for the entire period June-September 2013 - laf-c-soil.

Conclusions drawn from this part of study were as follows:

- values of spread/skill are in general independent on soil type;
- average values of spread of dew point temperature/air temperature/wind speed are inversely proportional to average monthly air temperature and to deviation of the mean monthly air temperature (T and ΔT) climatologically calculated for the period of 1971-2000;
- if long-term monthly sum of precipitation (P) is above a climatologically calculated average then the average values of spread of TD2M, T2M and U10M are low (EPS results are highly underdispersive);
- the correlations between the values of skill of TD2M, T2M, U10M and T, ΔT, P, and ΔP are similar to the ones between spread of TD2M, T2M, U10M and T, ΔT, P, and ΔP;
- average value of skill is independent on type of disturbed field or parameter. The distribution of the average values of skill is more or less similar to each other.

5 Ensemble post-processing

5.1 Development of probabilistic products at COMET

The work of generation of probabilistic products for the forecast of thunderstorms and fog is performed in the framework of the SRNWP-EPS II Project of EUMETNET. The main aim of the Project is to contribute to build very high-resolution ensemble systems in Europe, resolving the convection-permitting scale phenomena. First a review of literature on post-processing methods for prediction of fog and thunderstorms, with focus on ensembles, has been performed. Then the development of a software dedicated to this purpose has started, in particular a product for probabilistic prediction of fog has been implemented. The developed FORTRAN code provides surface visibility forecast starting from standard NWP models outputs. The following methods have been selected and implemented:

- "Zhou method" (Zhou, 2011). It is a new method, working properly for radiation and advection fog, based on the asymptotic liquid water content (LWC) vertical distribution. The asymptotic LWC distribution is a consequential balance among cooling, droplet gravitational settling and turbulence in the liquid water budget of radiation fog. Including the advection term, it is possible to write a partial differential equation as the governing equation for LWC [g/kg], with appropriate initial and boundary conditions for the one it is proposed an asymptotic solution that can be used to compute visibility through the Gultepe and Milbrandt (2007) formula;

- "Boudala method" (Boudala et al., 2012). This algorithm is based on the Stoelinga and Warner empirical equation that allows to compute visibility using information about relative humidity and dew point temperature;

- "LWC algorithm": it is the traditional approach that computes horizontal visibility using model forecastof specific cloud water content;

- "UPS method" (Baker et al., 2002). It is an empirical method proposed by UPS Airlines forecasters to forecast the radiation fog. It is based on the comparison of the low level atmospheric temperature and the so called crossover temperature, defined as the minimum of dew point during the warmest daytime hours. Following this approach it is possible to determine whether a station will radiatively cool enough for saturation. In a second step, in order to assess if boundary layer turbulence supports the fog formation process, a quantitative index of boundary layer turbulence mixing is used.

The code takes also into account the precipitation contribution to visibility reduction through an empirical formula.

Visibility forecast from different methods using deterministic COSMO-ME (5km hor. resolution) and COSMO-IT (2.8 km hor. resolution) model outputs have been compared with SYNOP observation over the Italian domain. The Zhou method seems to be the best candidate because it is able, in principle, to forecast both radiation and advection fog, but, as one of the trigger condition is the relative humidity from the NWP model output greater that 95 % (or other established threshold), results are highly influenced by this parameter. Looking at the results, the pattern of visibility seems to be much more reliable with Zhou with respect to the other methods, even if the visibility values seem to be underestimated (further tuning is needed through the configuration namelist). In order to overcome the sensitivity to the forecasted relative humidity (generally underestimated by the model), a combination of Boudala and Zhou methods has been proposed and used operationally at

the Italian AirForce Met Service. As an example, visibility forecasts with different methods applied to COSMO-ME deterministic model and COSMO-ME EPS (7 km resolution) probabilistic model, for a test case of 18 October 2017 06UTC (low visibility over Pratica di Mare airport), are shown in the figures below. Only Boudala and Zhou approaches forecast fog/mist in this region, in particular, Zhou approach has better correspondence with SYNOP observations.

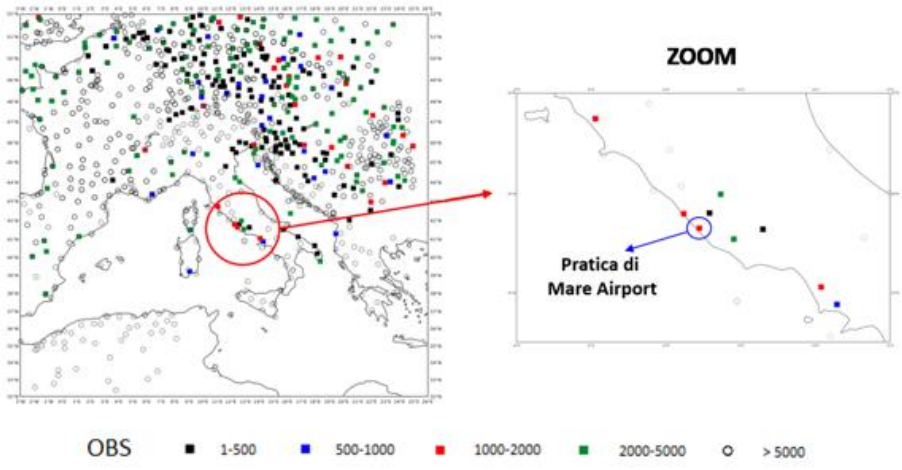

Figure 32: Test case of 18/10/2017 (intense fog event at Pratica di Mare airport): distribution of synop observations from 05 UTC to 07 UTC.

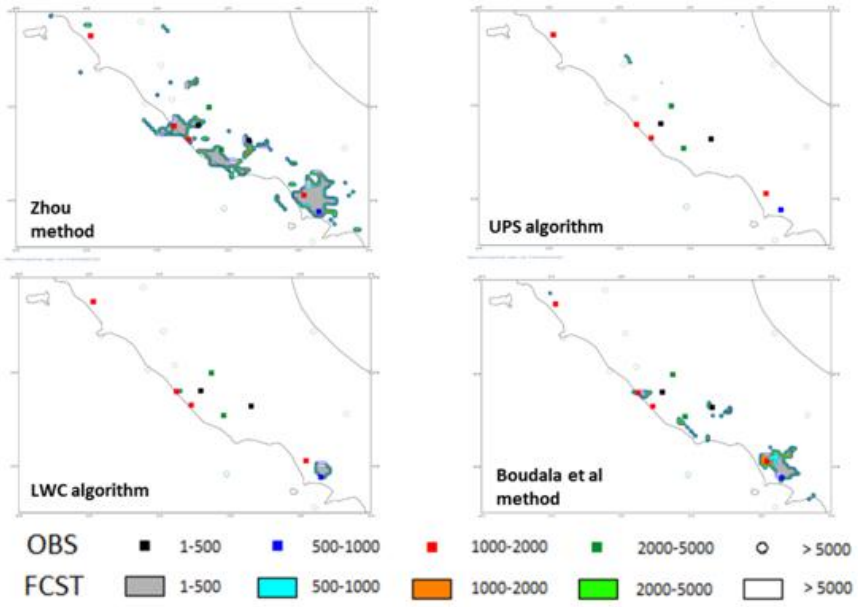

Figure 33: Test case of 18/10/2017 (intense fog event at Pratica di Mare airport): visibility forecast from different methods applied to the COSMO-ME (5 km) model outputs (run 00UTC of 18/10/2017, fc+6h).

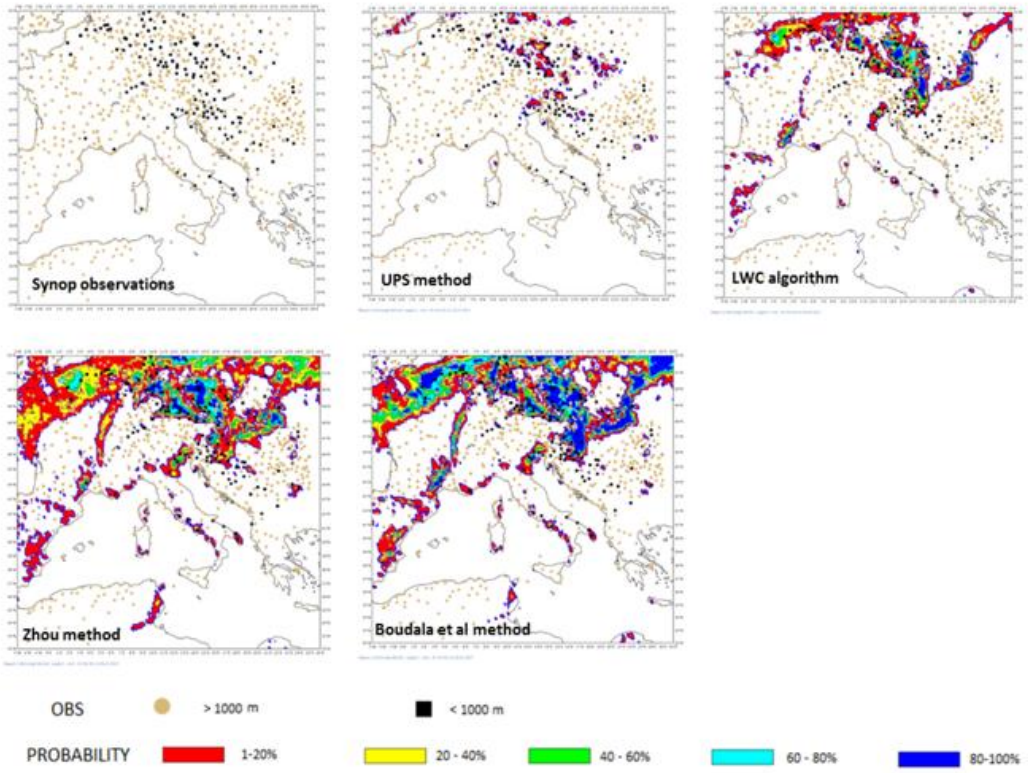

Figure 34: Test case of 18/10/2017: Forecasted probability of fog (visibility ¡ 1000 m) from different methods applied to the COSMO-ME-EPS (7 km) model outputs (run 00UTC of 18/10/2017, fc+6h).

Verification over an extended period has been planned together with the subjective verification from operational forecasters.

5.2 Calibration of ensemble output at IMGW

A review of literature concerning ensemble calibration methods and alternative perturbation patterns/random number generators has initially been performed. First, a new (alternative) Random Number Generator (RNG) has been introduced.

Alternative random number generator

Motivation for new (modified) initialization or seed of RNG was that seeding of RNG commonly is based on machine time (in general, milliseconds). This may results in seed(s) being identical for all processes (threads). This would lead to the situation, that with increasing number of parallel threads the probability of an occurrence of identical seeds would significantly increase. Having four hundred threads (like in case of IMGW EPS operational setup) vs. 999 milliseconds, it becomes more and more probable that some threats have an identical seed. This would results in an identical chain of RNG numbers generated, which in turn means a very poor stochasticity of EPS. One should also realize that using fast machines does not have 999 milliseconds, but much, much less. So, another initialization scheme has been selected combination of machine time with a thread ordinal number as in the figure below.

Spread values	*Ctrl (operational RNG)*	*Modified RNG*	*Ctrl (operational RNG)*	*Modified RNG*	*Ctrl (operational RNG)*	*Modified RNG*
	T2M (K)		**TD2M (K)**		**RH2M (%)**	
Mean	0.108191	0.238555	0.118675	0.272361	0.705627	2.120926
Max	2.262	2.458	3.284	3.536	12.261	14.758
	U10M (m/s)		**Surface pressure (hPa)**		**Total precipitation (mm)**	
Mean	0.139599	0.180653	0.023892	0.027456	0.286905	0.379897
Max	2.041	2.903	0.747	0.652	13.203	18.515

Table 2: Average spread values for June 2013, reference (operational RNG) vs. modified RNG.

```

! Initialize target RNG using 3rd seed
  call construct(akrngs,iseed)
```

Figure 35: Block scheme of new seeding for RNG.

This procedure was tested first using archive data, with no time-lagged ICs/BCs to avoid influence from side effects other than change of seed. An average value of spread significantly increased as shown in the Table 2 below.

An example of spatial distribution of spread with/without new seeding scheme is shown in the Fig. 36.

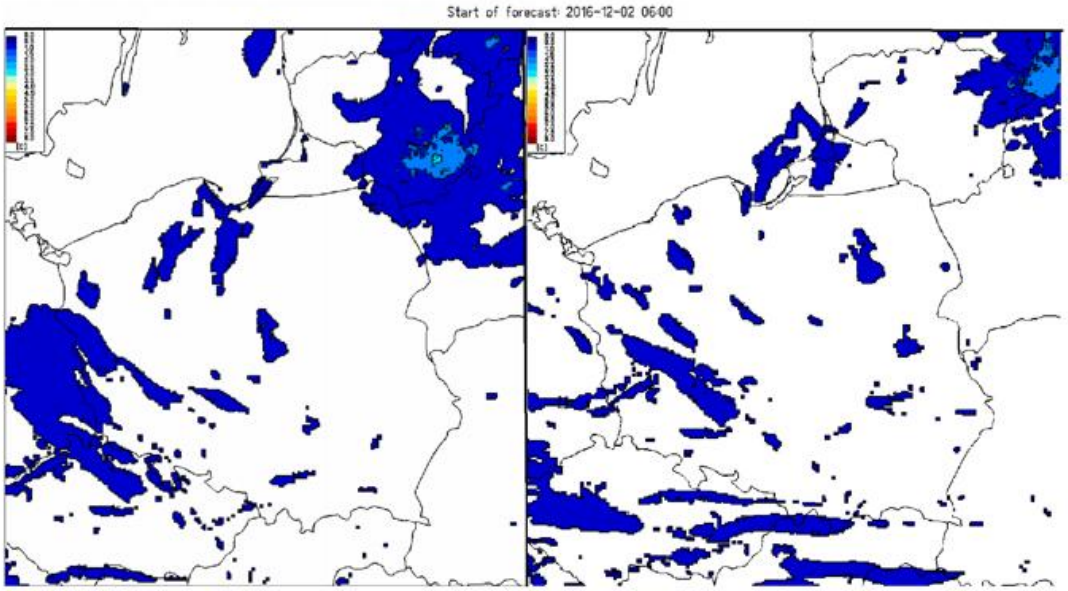

Figure 36: T2M spread for new (left) and old (right) seeding of RNG; 12 hour of forecast, December 2nd, 2916, 06:00 UTC.

This procedure is very efficient in terms of spread value (increasing average spread even 3 times comparing to "standard" RNG) especially on fast machines. It is also more realistic as far as spatio-temporal distribution of spread is concerned. At IMGW, it became operational in January 2017.

Post-processing multi-linear regression, logistic regression, Artificial Neural Networking

The most common procedure for calculating EPS mean is to use an arithmetic average as in the equation below (further Simple Mean):

$$\langle y \rangle = \frac{\sum_{i=1}^{m} x_i}{m}$$

An alternative approach can be described as (multi-)linear regression (MLR), where previously prepared forecasts from all members (X) of an EPS are compared with observations (learning phase). Then weights (β) of every member is computed to assess, how "important" for overall EPS-mean is a selected member (how big the contribution to EPS-mean from the member should be). The weights are calculated e.g. via least squares method, any potentially important factor(s) like geographical coordinates, terrain elevation etc. may also be considered. The following equation is a representation of the procedure, with an additional condition of normalization of weights to one. The "new" EPS mean y is calculated as a scalar product of vectors X and β:

$$\langle y \rangle = \vec{X} \cdot \vec{\beta}$$

Finally, an Artificial Neural Network (ANN) was studied to test if this approach could be a valid replacement for Simple Mean or MLR Mean. Basic idea is that the weights, with the same scheme as in MLR calculation, are calculated (learned) using a concept of layer of neurons, properly activated in learning phase. Basically, the representation of an ANN is presented in the following figures.

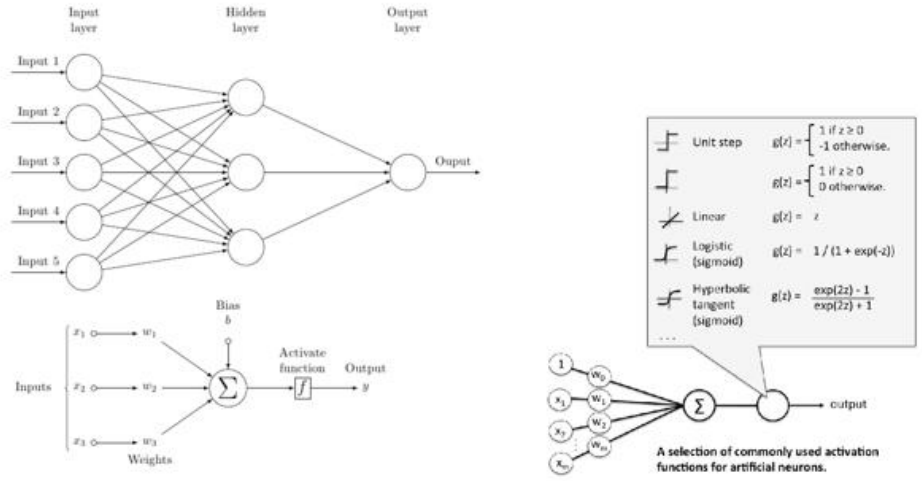

Figure 37: Basic concept of the Artificial Neural Network.

Pros and cons of the latest method are as follows: **Pros**:

1. ready-to-use dedicated software with source codes (FORTRAN);
2. sophisticated but elegant and intuitive concept;
3. improvement in preliminary case study observed;
4. forecasts are improving with the extension of learning period.

Cons (with answers to mitigate the cons):

1. complicated pre- and post-processing (answer: once the procedure is set-up and established, it can be further on done in an automatic way);
2. need for big data sets (archives), and for relatively huge computational resources (answer: this is a common feature of numerical forecasting - the need for huge volumes of data is a routine and a normal practice);
3. long computational time for training (answer: to avoid delays in operational post-processing, it can be done more or less frequently, with the acceptable quality of computations).

Results for case studies and for more extended periods (quasi-operational) are presented in the following tables and figures. First, case study for August 2017, with assorted number of predictors (input neurons) was analyzed. Learning period is July 1st, 2016 - July 31st, 2017, testing period is August 1st, 2017 - August 31st, 2017. The outcomes are presented in Table 3.

The spatial distribution of the average MAEs are presented in the Fig. 38.

Fields	Input Neurons* → / MAE ↓	24	22	20	Simple avg.**
U10m	Avg.	0.409	0.416	0.430	1.373
	Max	1.324	1.361	1.538	2.519

MLR	-0.310	1.989	2.755	0.475	2.252	3.206	0.113	1.488	1.978
ANN	-0.244	1.981	2.750	0.066	2.214	3.135	-0.200	1.436	1.814

Table 4: ANN tests for April 2018, comparison with Simple Mean and MLR Mean.

For the further operational calculations the following setup has been chosen:

- 24 input neurons (20 members + λ, φ, ts, tc, with λ, φ - geographical coordinates, ts being start of forecast and tc - current hour of forecast in progress);
- 5 neurons in a single hidden layer (referring to 4 blocks of TL-ICs/BCs and spatial/temporal coordinates - blocked);
- every forecasted element, like temperature, wind speed, pressure, etc. is treated independently;
- activation function: hyperbolic tangent (symmetric with respect to 0,0, commonly used function);
- training method: backward propagation of errors (back-prop);
- optimization: gradient descent.

The following table and figures present an example results of EPS forecasts for April 2018, with the extended learning period (July 2016 - March 2018).

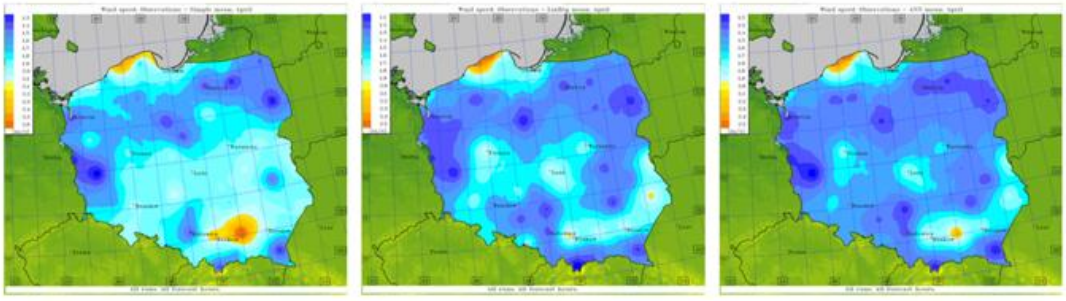

Figure 39: Results of different methods of computations of EPS mean. Left - observations vs. Simple Mean. Middle - observations vs. MLR mean. Right - observations vs. ANN mean. Wind speed forecasts, average values for April 2018.

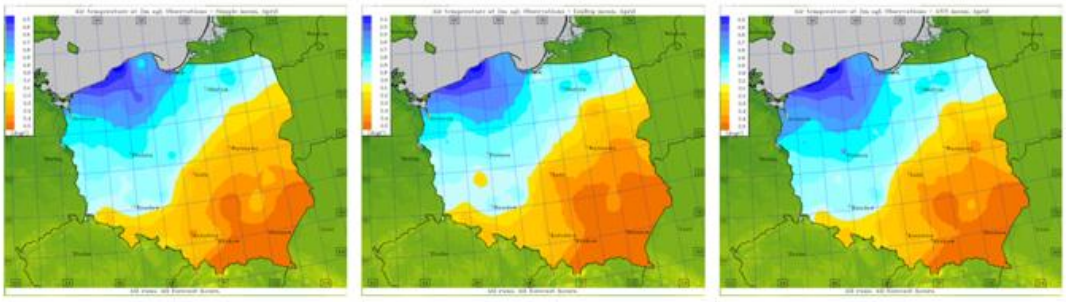

Figure 40: Results of different methods of computations of EPS mean. Left - observations vs. Simple Mean. Middle - observations vs. MLR mean. Right - observations vs. ANN mean. Air temperature forecasts, average values for April 2018.

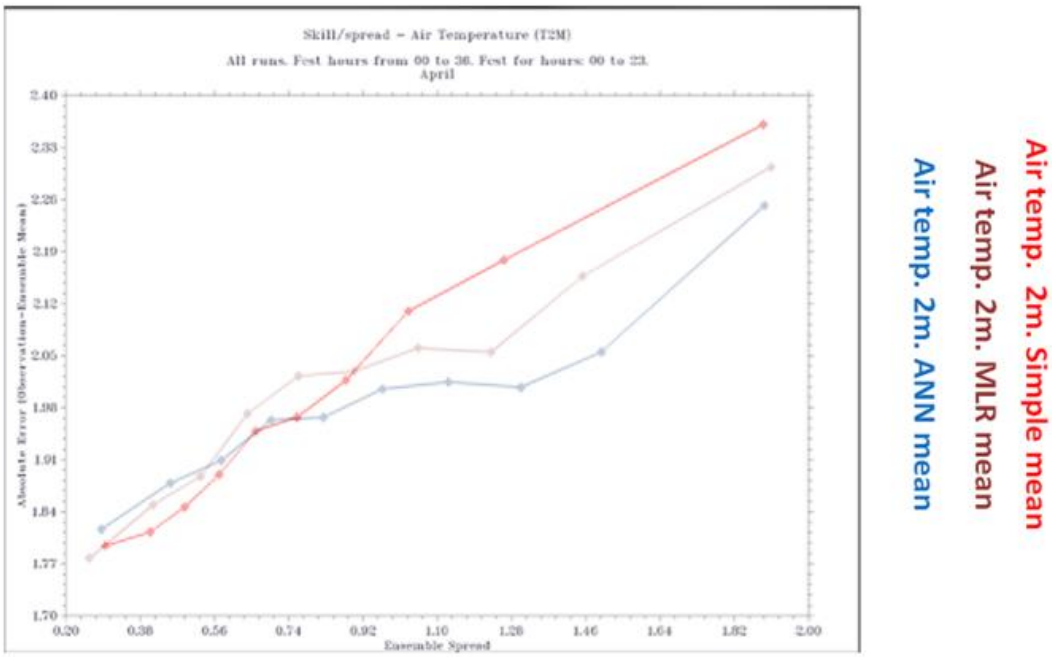

Figure 41: Skill-spread relation. Red - Simple Mean. Brown - MLR mean. Blue - ANN mean. Air temperature forecasts, average values for April 2018.

The general conclusions to be drawn from this study, was that significant improvement in forecasts (described in terms of EPS-mean vs. observations or forecast skill) can be seen. The longer learning period, the better forecasts are. Furthermore, the phrase "more predictors" - in general - means "better forecast", but also "longer calculations" - that is why some sort compromise should be established. ANN-based computation of EPS mean seems to be significantly better in comparison with Simple EPS Mean and with MLR mean, and that is why is has been chosen for further operational work.

6 Initial Conditions for the CP ensembles

The aim of this activity was to further study which methodology to follow to provide the ICs to the ensemble members. Experiments with ICs from KENDA compared with ICs from

cheaper options (downscaling) have been performed. It has also been performed a work on member selection from larger-scale ensembles.

6.1 Test of Initial Conditions from KENDA (DWD)

The KENDA-suite was running pre-operational providing initial perturbations for COSMO-DE-EPS. Two versions of BC perturbations are produced, with 20 members each (including physics perturbations): the known BCEPS multi-model approach and BCs from ICON-EPS (20 km grid size nest for Europe in a 40 km global EPS). Very preliminary results show an increase of spread together with a reduced RMSE of the ensemble mean for both 20 member setups. The resultingimproved spread-skill relation is still, but to a far less degree, underdispersive. The results have to be confirmed by longer verification periods and can be considered as first hints for improvement. The main results were an improvement in CRPS and partly RMSE of EPS mean for T_2M, gusts, and precipitation in summer and winter, particularly in the early forecast hours. An increase in spread for the variables lasts throughout the full forecast range of 27 hours. Improvements in thresholds-based BSS could be shown, where KENDA improved the resolution mainly. (Additionally, replacing BCEPS by ICON-EPS for the BCs improved mostly the reliability).

6.2 Test of Initial Conditions from KENDA (Arpae)

KENDA was tested for providing Initial Conditions to the deterministic and ensemble experimental chains with COSMO at 2.2 km over Italy. It is here shown the impact of the KENDA analyses as Initial Conditions to the members of the COSMO-IT-EPS ensemble for a period of May-June 2016 characterised by intense thunderstorms over different parts of Italy. The ensemble gets BCs from COSMO-ME-EPS and Parameter Perturbation is applied to the model. COSMO-IT-EPS with only parameter perturbations (PP experiment) and PP plus KENDA Initial Conditions (kendaIC_PP experiment) are compared in the following. An objective verification of the quality of the precipitation forecasted by the ensemble is carried out by comparing the forecasts with observations of precipitation estimated by radar and then adjusted with raingauge data. Both sets of data cover the entire Italian territory. Average and maximum over 0.2 deg boxes are considered.

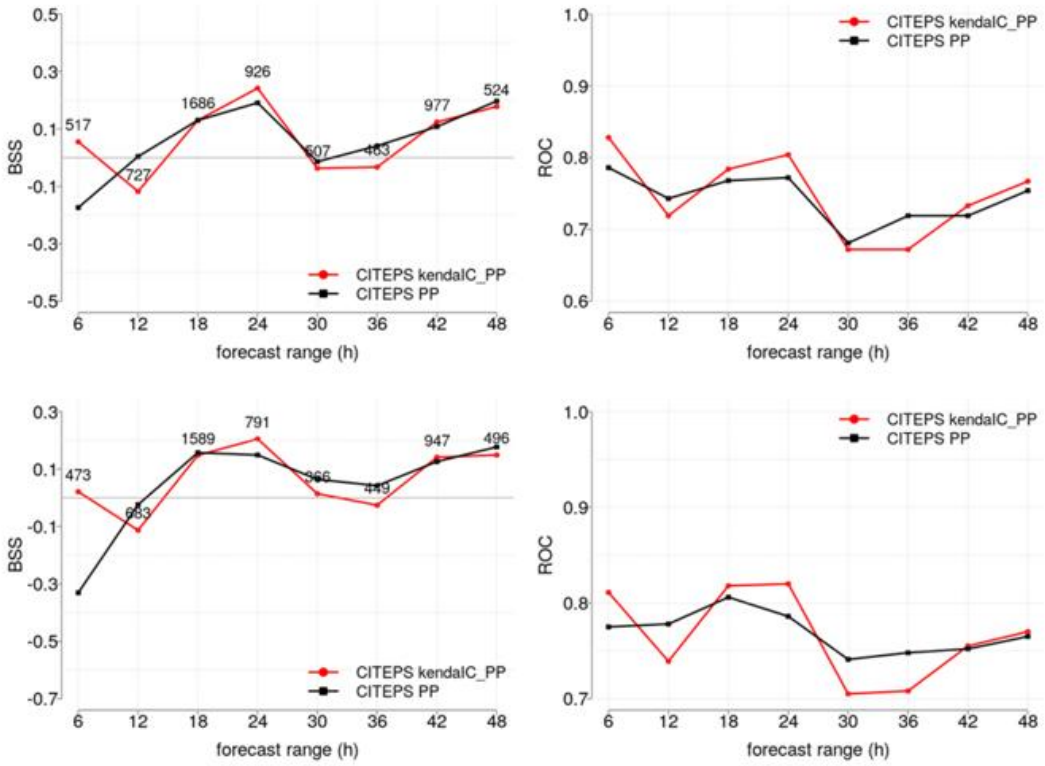

Figure 42: Brier Skill Score (left column) and the ROC area (right column) for average precipitation over each box exceeding 1 mm in 6 h (top row) and for maximum precipitation over each box exceeding 5 mm in 6 h (bottom row), computed against precipitation estimated from the Italian radar network, adjusted with raingauge values.

In all the plots of Fig. 42 is particularly evident the gain in skill in the first 6 hours of forecast determined by the use of Initial Conditions from the KENDA assimilation cycle. Generally, scores are not very high, showing the difficulty of forecasting thunderstorm events at high resolution (the verification boxes are of the order of 20 x 20 km). In order to show the quality of the ensemble members and how this is affected by the different initial conditions, a deterministic verification of the individual members is presented in Fig. 43.

The Frequency Bias (top rows, labelled Bias Score) indicates that the precipitation is generally underestimated by the ensembles, particularly for the lower threshold. It is interesting to notice that instead precipitation is overestimated for the first 6 hours for the 5 and 10 mm thresholds and that this bias is partly cured by the Initial Conditions from the KENDA analysis cycle. The other two scores do not vary much between the two ensemble configurations, with the exception of the first 6 hours as already noticed. In order to provide a clearer indication of what kind of events the 2.2 km ensemble is able to forecast in presence of thunderstorms, probability maps for selected cases are also shown.

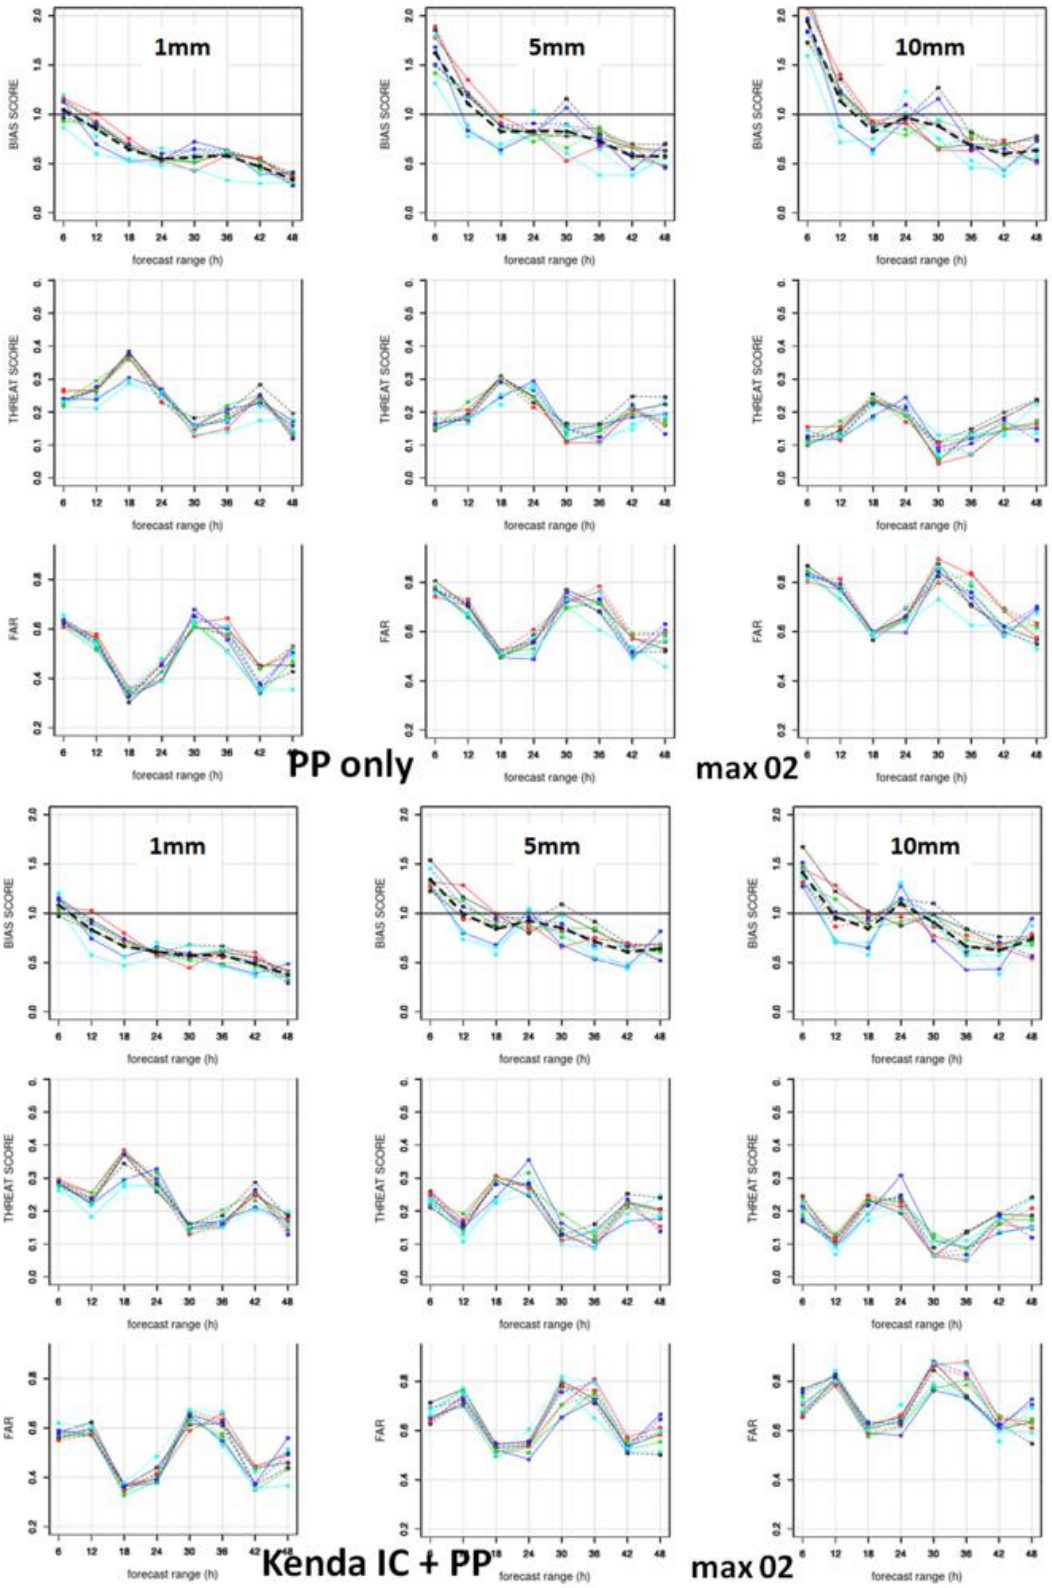

Figure 43: Frequency Bias (top row), Threat Score (middle row) and False Alarm Rate (bottom row) for the maxiumum precipitation over each box exceeding 1 mm in 6 h (left column), 5 mm in 6 h (central column) and 10 mm in 6 h (right row), computed against adjusted radar data for the PP (upper panels) and kendaIC_PP (lower panels) experiments.

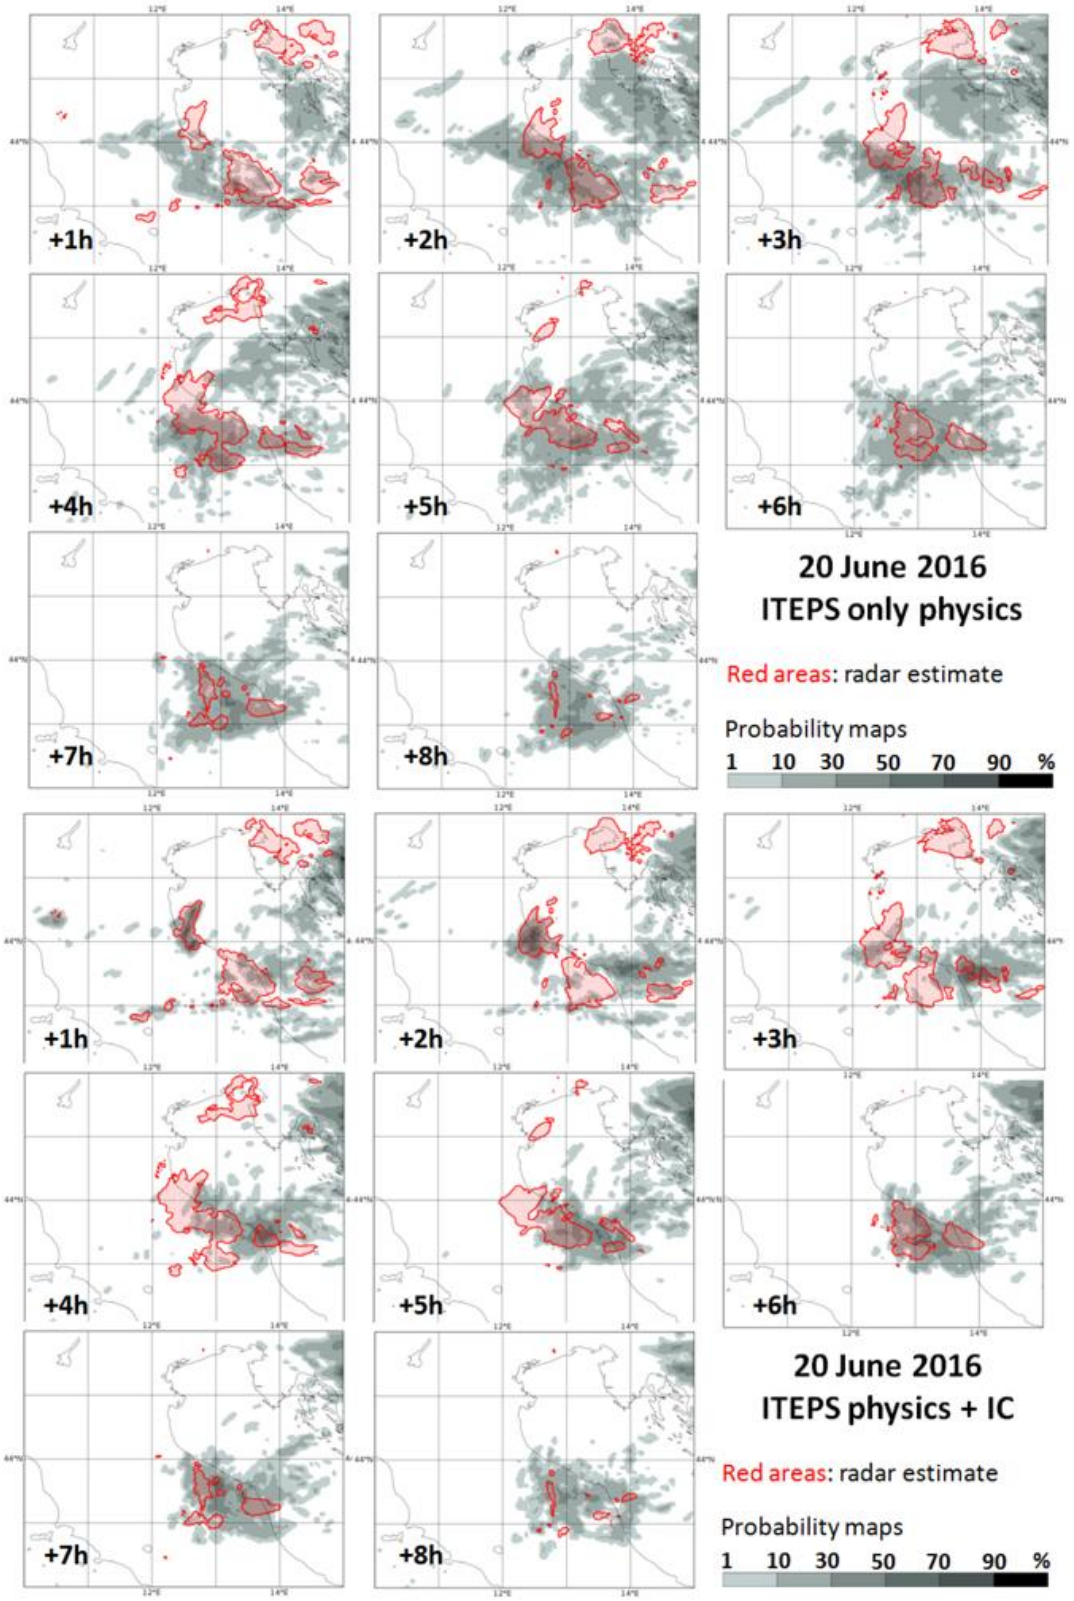

Figure 44: Probability maps (gray shaded) of precipitation exceeding 5 mm/1h generated by the ensemble, relative to the PP (upper panels) and kendalC_PP (lower panels) experiments, and filled contours (red areas) of precipitation estimated by radar exceeding 1mm/1h for the event of the 20th of June 2018, first 8 hours.

In Fig. 44, the probability of precipitation exceeding 5 mm in 1 hour as forecasted by the ensemble in the two different configurations (PP and kendaIC_PP) is plotted (as gray shaded) against the contour (red) relative to the precipitation exceeding 1mm in 1 hour as estimated by the radar network. It is possible to see that indeed the 2.2 km ensemble is generally able to indicated the probable occurrence of thunderstorms in the area where it was occurred. The level of spatial agreement between the forecast, issued in terms of probability and hence not really suitable for a one-to-one comparison with observations, is shown by the match or mismatch between the gray shaded areas and the red area. In this kind of evaluation, little can be said about the accuracy of the forecast of the precipitation amount, since the focus has been put on the capability of the ensemble to issue a forecast of thunderstorm at all, as a valuable tool to assist the forecasters in their daily task. On top, the level of spatial agreement or disagreement is what the forecaster should keep in mind for a profitable usage of the information provided by the ensemble. It is underlined that the different thresholds chosen for the probabilities and for the radar contouring are selected on purpose in order to take into account the tendency of the radar estimate to underestimate the precipitation amount (in analogy with what is done in a verification based on thresholds defined as percentiles instead of values). Considering the first 2-3 hours of forecast, it is evident that the data assimilation at 2.2 km with the KENDA cycle is able to provide initial conditions which greatly improve the position of the precipitation at the beginning of the forecast. This is believed to be partly due to the Latent Heat Nudging which is applied to each member of the KENDA ensemble, which had proven to increase the skill of the precipitation in the first few hours of the forecast. In this case, the forecast by the kendaIC_PP ensemble remains better than the PP one for the entire period shown.

6.3 Clustering of ensemble members for Lateral Boundary Conditions at MeteoSwiss

In the operational COSMO-E setup the perturbed members just use the first 20 members of KENDA and ECMWF ENS for the initial (ICs) and lateral boundary conditions (LBCs), respectively. Westerhuis (2016) investigated whether it is possible to enhance the COSMO-E forecast quality by using a smart selection. For COSMO-E it is found that:

- a sophisticated member selection like clustering for LBCs can improve COSMO-E forecasts significantly while a random member choice can result in significantly worse forecasts with bad luck;
- a clustering is able to decrease the outliers and increase the spread for near-surface variables which is probably the main reason for the better scores as show in Fig. 45;
- a sensitivity analysis of the clustering parameters demonstrates that the verification scores are very sensitive to the time steps used in the clustering analysis;
- the benefit of a better ICs selection is very limited due to the small spread.

Due to the positive results obtained with a member selection based on a clustering analysis, MeteoSwiss plans to implement such a member selection in the operational setup of COSMO-E.

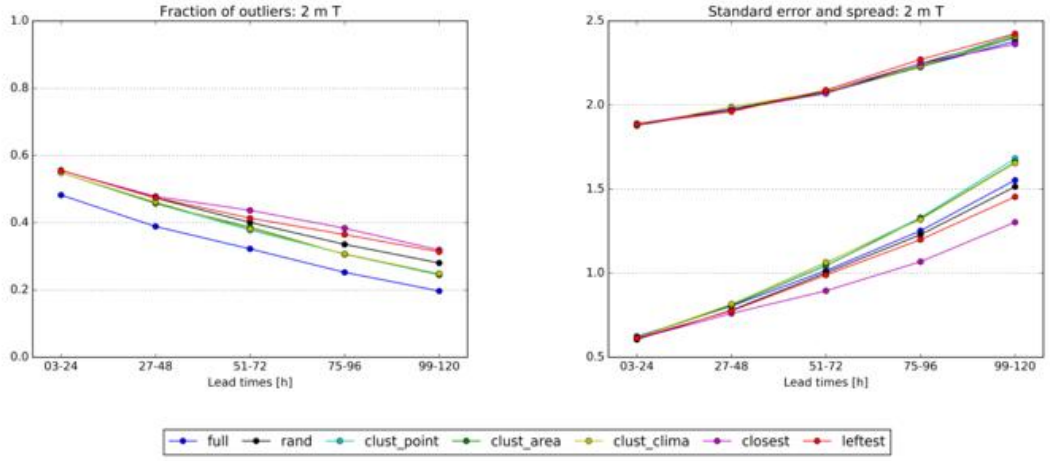

Figure 45: Fraction of outliers (left), standard deviation of error (upper lines in right panel) and ensemble spread (lower lines in right panel) for 2m temperature in COSMO-E forecasts from March 21 - April 8, 2015, for all stations in the model domain. The different lines show the scores obtained with different member selections methods: all 50 members (full), first 20 members (rand), clustering methods with different standardizations (clust), 20 members closest to ensemble mean (closest) and 20 driest members (leftest).

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Abstract

This project was aimed at consolidating the COSMO ensemble forecasting systems for the mesoscale. The operational ensemble COSMO-LEPS and the experimental COSMO-SREPS system, both running at 7 km horizontal mesh-size, have been designed for different forecast ranges (day 3-5 and 1-2, respectively) and with different perturbation strategies. The aim of the project was to propose a solution for a unique "multi-perturbation-strategy" COSMO ensemble system, benefiting of perturbations which can produce appropriate spread for the entire forecast range (i.e., day 1-5), including a set of model perturbations which should guarantee a good description of the COSMO model error. Both perturbations of the mode physics parameters and perturbation of the soil moisture field had been considered. Furthermore, a calibration strategy was developed and applied to the QPF issued by the COSMO-LEPS ensemble. The project lasted for 3 years.

2 Introduction

Since November 2002, COSMO is running a Consortium ensemble, COSMO-LEPS (Montani et al., 2003). In the present configuration, COSMO-LEPS is a 16 member ensemble based on the COSMO model with a 7 km horizontal mesh-size and 40 vertical levels. The system is running at ECMWF using the Billing Units provided by the COSMO Countries which are also ECMWF member states (Germany, Greece, Italy, and Switzerland) and it is developed an maintained by ARPA-SIMC. COSMO-LEPS is a dynamical downscaling of the ECMWF EPS, taking initial and boundary conditions from 16 selected members of the EPS. COSMO-LEPS is mainly designed for the early medium range (day 3-5) and the forecast range is 5.5 days. Some perturbations to the model are included, following the outcomes of the SREPS and CONSENS PPs. The soil moisture analysis provided by DWD for COSMO-EU is also used (COSMO-LEPS is currently using the same grid as COSMO-EU, but for a smaller domain). For more detail, the reader is referred to Montani et al., 2011. In September 2006, COSMO started the SREPS Priority Project, aiming at the development of an ensemble system targeted for the short-range, COSMO-SREPS (Marsigli et al., 2009). Two different kind of perturbations are applied: initial and boundary conditions benefit of a multi-model approach, being provided by 4 different operational global models and the COSMO model itself is perturbed by changing the values of a set of physics parameters. The SREPS project ended in September 2008, delivering an ensemble system for the short-range based on the COSMO model with a 10 km horizontal mesh-size and 40 levels in the vertical. Initial and boundary conditions to the 10 km COSMO-SREPS runs were provided by 4 COSMO run at 25km hor. res. nested on IFS, GME, GFS, UM, performed by AEMET as part of their SREPS system. Then, a new COSMO-SREPS suite was implemented in 2010, with direct nesting of COSMO at 7 km on the 4 global model. The system was running quasi-regularly at ECMWF, using the Billing Units provided by some COSMO Countries. COSMO-SREPS provided initial and boundary conditions to the convection-resolving ensemble for Germany under development at DWD (COSMO-DE-EPS) and it was used to compute a flow-dependent B-matrix for a test version of the 1d-Var assimilation of satellite data under development at ARPA-SIMC. In order to avoid duplications, COSMO aimed at a confluence of the two 7 km ensemble systems into a unique COSMO ensemble, covering both the short and the medium range and based on the most appropriate perturbation strategy for the entire forecast range. This implies the development of a "multi-perturbation-strategy" ensemble system, with perturbations more appropriate for the short range in the beginning (day 1-2), and with perturbations more appropriate for the medium range thereafter, or

a combination of both. It should be reminded that the importance of such an ensemble system resides both in its inherent value as assistant to the 7-km operational runs and in its capability of providing boundary conditions for the convection-permitting ensemble system under development in the COSMO countries. The issue of ensemble merging and of multi-perturbation strategy design has been dealt in the Project and results are presented in Section 4. A satisfactory representation of the uncertainty affecting the mesoscale was still lacking. The quantification of the errors which are made by the model in the description of the meteorological phenomena at this scale needs to be improved. The development of mesoscale ensemble should then include 1) the perturbation of the lower boundary forcing and 2) the perturbation of the parametrised physical processes. The importance of further perturbing the physics parameters has been underlined by the outcome of the SREPS PP. Within COSMO it has also been suggested that adding perturbations in the soil parameters can be crucial in order to get a better representation of the model error in terms of surface variables. The issue of model perturbation was also addressed in the Project, and results are presented in Section 3. Within this work on the consolidation of the COSMO ensemble systems, attention has also been paid to the post-processing. Calibration of ensemble forecasts in terms of precipitation and surface temperature has been studied and applied widely in recent years (e.g. Hamill and Whitaker, 2006; Hagedorn et al., 2008; Hamill et al., 2008; Santos-Muñoz et al., 2007). As for the COSMO-LEPS ensemble, it has been recognised that a calibration for 24 h precipitation would be desirable to improve the forecast skill (Marsigli et al., 2008). Last year, work on COSMO-LEPS calibration has been carried out at MeteoSwiss (Felix Fundel et al., 2008). Thirty year of re-forecast of one member of COSMO-LEPS have been computed and stored at ECMWF, and they have been used for calibrating the COSMO-LEPS output over Switzerland. This work has shown the potential of using re-forecast to improve the forecast skill. Therefore, calibration of QPF, especially aimed at hydrological applications, was also addressed in the Project, and results are shown in Section 5.

3 Model perturbations

3.1 Parameter perturbations

On the basis of the work carried out in the SREPS Priority Project (COSMO Technical Report n. 13, 2009), further investigations on the perturbation of model parameters had been carried out. In CONSENS, it was decided to start by evaluating a set of parameters, already tested in SREPS, over a different season, JJA (summer 2008, 92 days). For this purpose, an ad hoc test suite have been set-up at ECMWF, CSPERT, where 16 runs of COSMO are performed, with the same configuration of the COSMOSREPS/LEPS runs, but with IC and BCs provided by the IFS deterministic forecast. The model domain is shown in Figure 1. The 16 runs have 16 different set-up of the physics parameters, as described in Figure 2. An analysis has been carried out in terms of 2m temperature and dew-point temperature, for both northern Italy and Greece (see Figure 3 and Figure 4 respectively). Results confirm what has been found for the autumn 2007 season:

- qc0: no detectable impact
- tur_len: small impact for tur_len=150
- c_soil, c_lnd and pat_len parameters: marked impact, even suspicious for c_soil and c_land

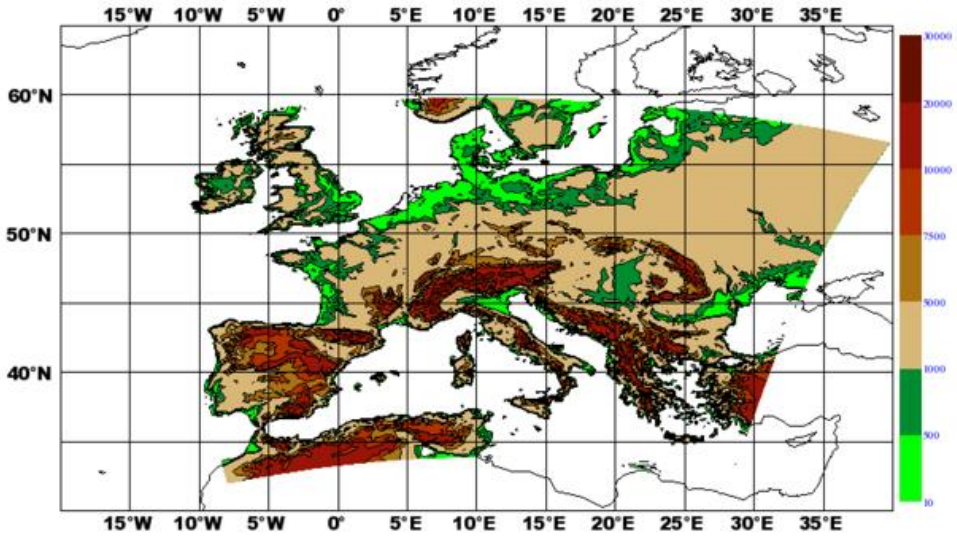

Figure 1: Orography of the model in the ensemble systems, showing the model domain.

- rlam_heat is an important parameter to perturb and it is sensitive to small changes, especially over Greece

On the basis of these results, and on the previous ones, it was decided to test other parameters or combinations of parameters in the CSPERT test suite (Figure 5). In this set up the new parameters considered are: cloud droplet number concentration (cloud), exponent of the raindrop size distribution (mu_rain) and switch on/off of the graupel scheme (gscp). These tests were run over MAM, JJA and SON 2009 and evaluation was performed in terms of precipitation over Northern Italy and Greece, then over Greece also for T, Td, and 10m wind. Some results of the evaluation are listed below:

- 2m temperature: patlen=10000 has strong detrimental effect over Greece ($\longrightarrow$ decision to switch to patlen=2000, also based on previous results); crsmin=200 has little positive impact
- 10 m wind: no strong effects (not expected, due to the perturbed parameters, at least for the horizontal wind)
- precipitation (very little precipitation in spring, though, especially over Greece):
  - crsmin=200 determines an increase the precipitation amount. Detrimental effect over Greece in terms of BSS
  - itype_gscp=3 determines a decrease of precipitation over Northern Italy
  - there is an impact of both perturbing cloud_num and mu_rain

In Figure 6 the scores in terms of 6h precipitation over Northern Italy are shown, for some parameter set-up for the spring 2009 season. The perturbation of the mu_rain parameter has an impact, increasing POD for intense precipitation and decreasing it for light precipitation,

Figure 2: Set up to the CSPERT suite for the 2007 and 2008 runs.

with almost no effect on the false alarm rate. Its association with the cloud_num perturbation gives detectable, though small, impact. The same scores are computed also for the autumn season (Figure 7), confirm that the impact of these 2 perturbations is detectable, especially for intense precipitation, and that they do not lead to a worsening of the forecast. On the basis of these results, a final set-up for the COSMO-SREPS perturbations (shown in Figure 8) has been implemented in 2011. The same perturbations have been adopted also in the COSMO-LEPS suite, but they can be combined differently.

3.2 Soil moisture perturbation

The interaction between the surface and the lower troposphere determines the development of fluxes close to the ground. Soil moisture is of primary importance in determining the partition of energy between surface heat fluxes, thus affecting surface temperature forecasts. The ensemble forecasts usually suffer of a lack of variability among the members, which is typically worse near the surface rather than higher in the troposphere. Therefore, the aim of this work is to ameliorate this deficiency by implementing a technique for perturbing soil moisture conditions and explore its impacts on the variability of the members for the different forecasted surface parameters (e.g. 2m air temperature, accumulative precipitation). The proposed technique is based on the method by Sutton and Hamill, 2004. The steps followed for its implementation are:

- use daily soil moisture data for a period with soil moisture variability for continuous years, in order to have a "climatology"
- calculate a 30-day running mean from this set of dataset
- subtract the running mean from the daily soil moisture data to calculate daily deviations
- apply an Empirical Orthogonal Function (EOF) analysis to calculate the perturbations in the variability categories appearing in the data

For the retrieval/archiving of soil moisture data, daily soil water content data were provided by DWD COSMO-EU surface analysis. The period selected for the dataset, is three months

Figure 8: Final set up to the COSMO-SREPS suite.

(April to June) for three years (2007-2009). This spring-to-summer period can provide the necessary soil moisture variability in the data. These data (water content for each soil layer kg/m^2) are extracted at 8 different levels in the soil, namely 1, 2, 6, 18, 54, 162, 486, and 1458 cm. In this way, 241 deviation data files (=3years*3months*30days-29days=241 days) have been created, each of them containing 436,905 lines (grid points). Then an EOF analysis was developed and implemented to the daily soil water content data. The EOF analysis was implemented to the first soil layer from the surface. The perturbations are created through the following equation suggested by Houtekamer, 1993:

$$\varepsilon_j = \sum_{i=1}^{N=244} d_i \lambda_i \sigma_i \tag{1}$$

where, ε_j is the j-th perturbation, d_i a standard normally distributed random number, λ_i the square root of the eigenvalues and σ_i the corresponding eigenvectors. In order to solve the above equation a method for creating random numbers was used based on Press et al., 1992. Routines calculating EOFs have been found and selected the one by Ziemke J.R. (http://acdb-ext.gsfc.nasa.gov/People/Ziemke/) who has based his code on Kutzbach, 1967. This routine has been built to work for matrices with moderate size. Therefore, the main problem encountered with the available data is that the routine could not handle the extremely large data matrices (436,905 lines x 436,905 rows) as they require a very large stack memory. For this reason it was necessary to find solutions to overcome this problem. An efficient method was proposed by von Storch and Hannoschock, 1984 and Legler, 1984. They proposed to inverse the matrices, i.e. if initially there are M lines (grid points) and N days, with N $\ll$ M, it is possible to invert the problem and instead of creating MxM matrices to end up with NxN matrices that would lead to much less computationally intensive problem. Then, the input to the EOF analysis has been changed to an NxM data matrix in which there are N rows (corresponding to the available days) and M columns (corresponding to the grid points). After this change, the EOF analysis can run without stack memory problems. Then work has been performed on:

- adding the calculated "perturbations" to the initial soil water content file
- calculating the resulting fractional soil moisture
- constraining it to between 3% and 100% and then
- get the final perturbed soil moisture fields

The perturbations are calculated from:

$$P = d\Lambda c = \begin{pmatrix} \sum_{i=1}^{M} d_i c_{1,i} \\ \sum_{i=1}^{M} d_i c_{2,i} \\ \vdots \\ \sum_{i=1}^{M} d_i c_{M,i} \end{pmatrix} \tag{2}$$

where "d" are the random numbers , "c" are the space eigenvectors and "lambdas" are the space eigenvalues. Each line corresponds to each point in space and the sum is over the 244 EOF categories (if all are kept). In order to solve the equation a method for creating random numbers was used, based on Box-Muller method for generating random deviates with normal distribution (Press et al., 1992).

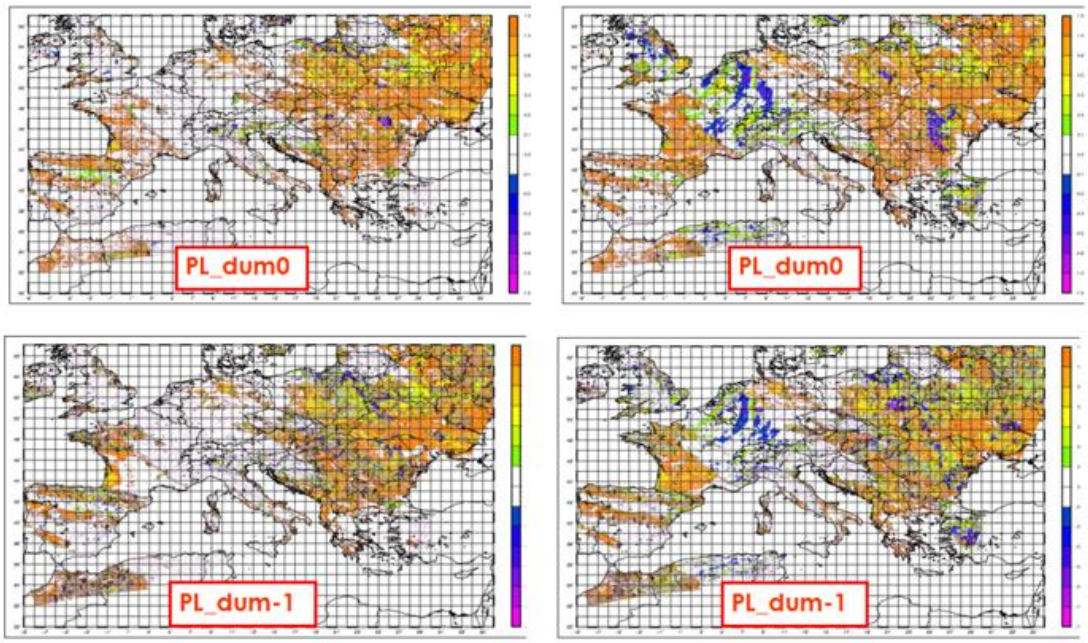

Figure 9: Differences of the soil moisture fields at the first level between perturbed runs (for different seeds, as indicated) and the control, at +24h (left) and +48h (right) forecast range.

Once the perturbed fields of soil moisture (on 7 levels) has been obtained, they have been tested in COSMO runs (Figure 9 and Figure 10). Different random seeds were used. The perturbations obtained (one set per each soil level) are added (the perturbations can be positive or negative) to the initial (original) soil moisture fields. A constraint is imposed: the perturbed value should not be more than 50% of the original value. Perturbations of the soil moisture is performed at all the soil levels (except the climatological level). COSMO was run on one case (9th June 2011) in the COSMO-SREPS configuration with perturbed soil moisture fields, for each perturbation set (no random number, seed=-1, seed=-5), at +48-hour. COSMO was also run with unperturbed soil moisture, for comparison (control run). Results have been presented at the COSMO GM 2011 (WG7 parallel session). As for the soil moisture difference, it is highlighted that positive values correspond to wetter soil layer for the CTRL run. The areas with positive values seem to be more than those with negative values at t+24h. For the particular date it seems that the method leads mostly to differences over East and some parts of West Europe although there are also differences in smaller areas elsewhere. At t+48h, the differences with the CTRL are greater and appear generally over the whole domain. There are also some changes among the results from the tests with various random numbers used (which could lead to different members of an ensemble). The control run is more wet in eastern Europe. Then, the control has more LHF than the perturbed, which is coherent with the fact that the control is wetter. For the SHF, this depends very much from the hour of the day. During the night (as it is at +24h, since the run starts at 00) it should be more from the ground towards the atmosphere, which means negative. Hence, since the difference it is positive, this may indicate that the SHF of the perturbed is stronger than that of the control, which is in agreement with the fact that in the perturbed the LHF is reduced, so the two are complementary. As for 2mT, the control is colder than the perturbed (and wetter in the soil and with more LHF and less SHF). The differences (positive or negative) between the CTRL run and the new runs in precipitation are larger at +48h, and they interest larger areas of the domain (Figure 11). This technique has not been implemented yet in an ensemble configuration for testing. Its applicability will be further investigated in the future.

4 Ensemble merging

4.1 Clustering applied to a multi-ensemble

In the framework of the TIGGE-LAM coordination, it is proposed to analyse the possible benefit of a multi- ensemble for driving the limited area ensemble. More specifically, it is studied if a downscaling of a combination of more than one global ensemble can bring benefit with respect to downscaling a unique global ensemble. In this study, the member selection technique which is used to select the EPS members driving COSMO-LEPS (Molteni et al., 2001, Marsigli et al., 2001) is used to select members in the multi-ensemble made ECMWF EPS and the global MOGREPS ensemble of UKMO. The following global ensemble are considered:

- EPS (50+1): 51 members
- MOGREPS (23+1): 24 members
- MINI-MIX (EPS24 +MOGREPS24): 48 members
- MEGA-MIX (EPS51 +MOGREPS24): 75 members

For each of the above-mentioned ensembles, a 16-member cluster analysis and representative-member identification is performed. Then, 10-member global ensembles (EPS_REDU, MOGREPS_REDU, MINI_REDU, MEGA_REDU) are thus generated and the properties of the "REDU" ensembles are studied. It is worth pointing out that ECMWF EPS control run was always included in ECMWF24. More specifically, the following questions will be addressed:

- how many times do the 2 ensembles mix ?
- where do the best (and the worst) elements of "REDU" ensembles come from? How to they score depending on their "origin" ?
- how do "REDU" ensembles rank with respect to EPS, MOGEREPS, MINI-MIX and MEGA-MIX ?

The investigation was carried out over the period March to May 2009 (MAM09) for a total of 184 cases, considering both 00 and 12UTC runs of the two systems, as archived in TIGGE database. Z500 at fc+96h was used as clustering variable. As verifying analysis (at 00 and 12 UTC), a "consensus analysis" (average of UKMO and ECMWF high-resolution analyses) was taken. The performance of the MINIMIX48 ensemble was assessed in terms of root-mean-square error (RMSE) and anomaly correlation coefficient (ACC) of the geopotential height at 4-day forecast time (fc+96h), averaged over a domain covering Central and Southern Europe (30-60N, 10W-30E). The skill of MINIMIX24 is compared to that of UKMO24 and ECMWF24, using the common "consensus analysis". Figure 12 shows the time-series of the RMSE for the 3 ensembles means: a marked day-to-day variability is evident, with peaks of high (low) values of the score, indicative of particularly inaccurate (accurate) forecasts. It can also be noticed that ECMWF24 tends to outperform UKMO24, with lower values of RMSE for most of the days under investigation. As expected, the RMSE of the MINIMIX ensemble mean tends to stay somewhat in between the RMSE of the two other ensembles. It is worth pointing out that the use of MINIMIX turns out to be particularly useful in the days of failure of the more skilful ECMWF24. If we consider all 184 cases, the average RMSE of

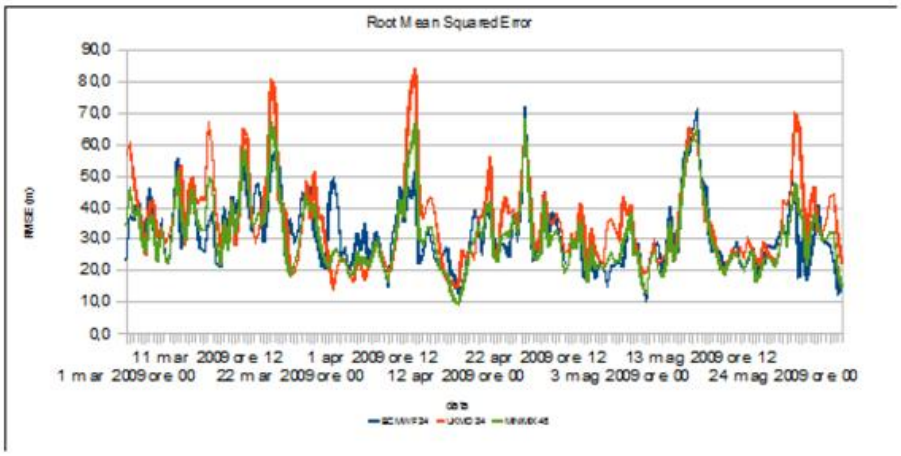

Figure 12: Time-series of the rmse (in metres) of the ensemble means for UKMO24 (red), ECMWF24 (blue) and MINIMIX48 (green) in terms of geopotential height at 500 hPa at fc+96h, averaged over the domain 30-60N, 10E-30W.

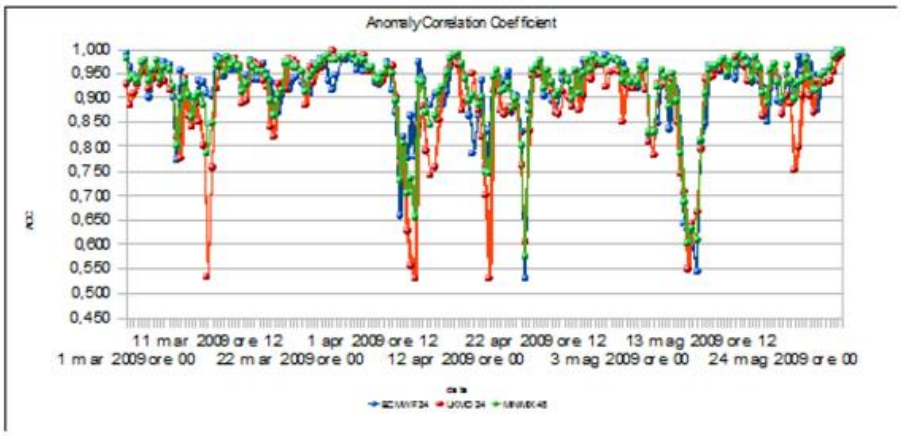

Figure 13: The same as Fig. 9, but for the anomaly correlation coefficient.

MINIMIX is slightly lower than ECMWF24, indicating the added value of multi-model even a low-population version of a very skilful global ensemble is used to generate a multi-model system.

Similar conclusions can be drawn if the ACC is considered (Figure 13). This score is sensitive to how the climate is computed. In fact, the ACC measures the correlation between the forecast and analysed deviations from climate. As an estimate of the climate, we used the three years of analyses present in TIGGE database and only the MAM season was considered. Also the ACC coefficient varies a lot from day to day and, as before, ECMWF24 tends to have better scores than UKMO 24, as shown by the higher values in ACC. It is again shown that the ACC of MINIMIX ensemble mean is, on average, slightly higher than that of ECMWF24, while UKMO24 has generally lower correlation coefficient. As a measure of the ensemble properties, we also considered the ensemble standard deviation (usually referred to as "spread") around the ensemble mean for the 3 ensembles. Figure 14 shows the time-series evolution of the spread for ECMWF24, UKMO24 and MINIMIX48. This quantity, rather than a pure verification score like RMSE and ACC, reflects the properties of the ensembles, more precisely the extent to which the different ensemble members get more and more differentiated as the forecast step increases. It is immediately evident that, at least for this

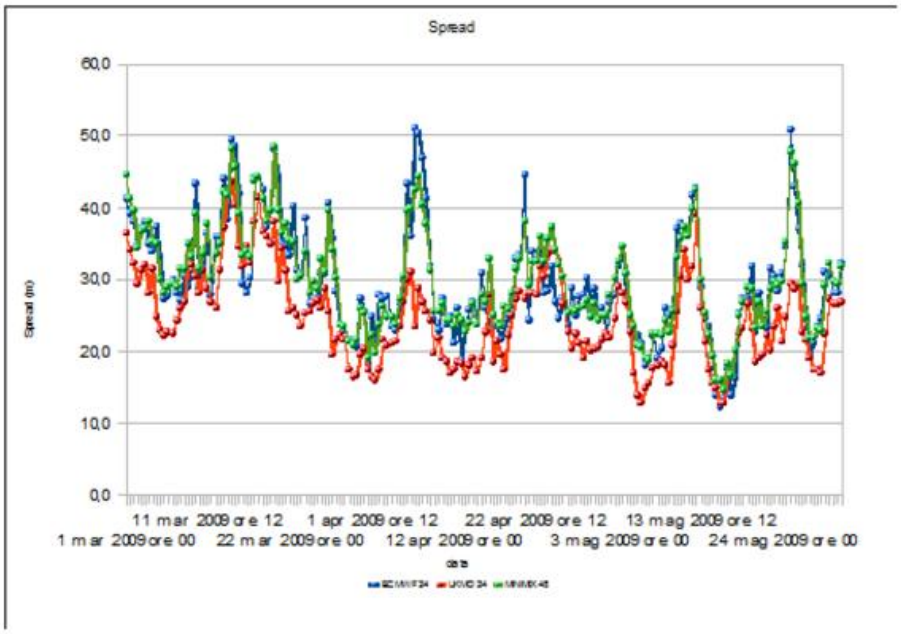

Figure 14: The same as Fig.9, but for the ensemble standard deviation (spread) among the members of the ensembles.

Figure 15: Synthesis of the performance for single-model and multi-model systems in terms of Z500 rmse and spread.

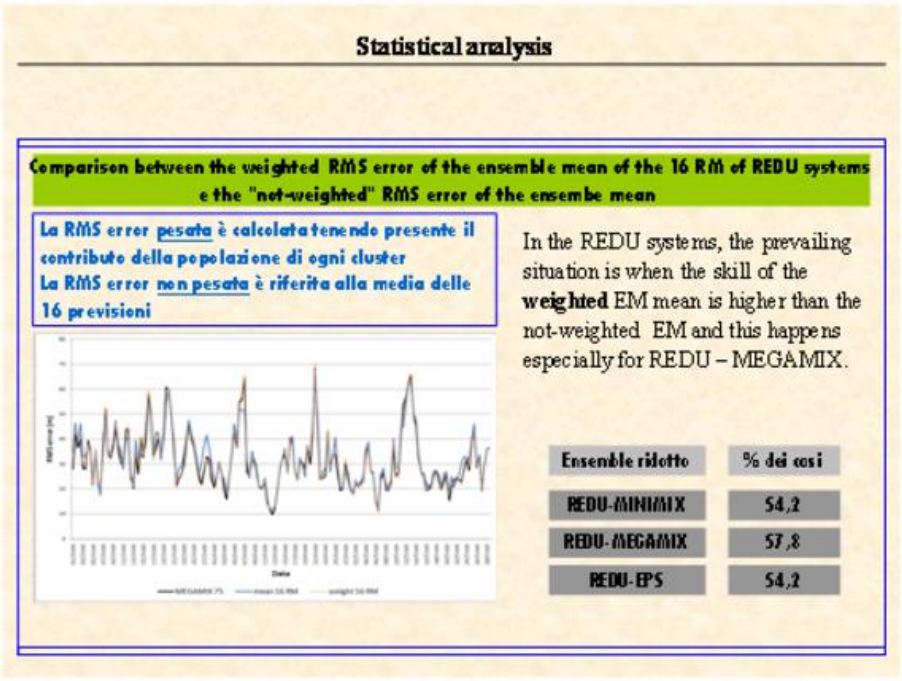

Figure 16: Synthesis of the performance for the REDU-ensembles.

forecast range, ECMWF24 has systematically larger spread than UKMO24. This is possibly related to the different strategies followed to generate the initial perturbations in the two ensembles (Singular Vectors for ECMWF24 versus Ensemble Transform Kalman Filter for UKMO24), although other interpretations are being put forward. As a further comment, it can be noticed that the MINIMIX48 ensemble has a spread very close to that of ECMWF24. In some cases, the MINIMIX48 spread is the largest one, suggesting that the use of a multi-model system allows the exploration of a wider region of the phase space of the atmosphere. If also the performances of EC-EPS51 (the full ECMWF-EPS system), MOGREPS24 (the full UKMO system) and MEGAMIX75 are considered, then the results indicate that the latter system outperforms all the others and that MINIMIX48 performs better than EC-EPS51 in terms of RMSE of the ensemble mean (see also Figure 15). As for the evaluation of the skill of the 16-member REDU ensembles, the attention is focus on the performance of the ensemble mean of these systems, calculated in the different ways: EM_w is the ensemble mean obtained weighting each member with the population of the cluster, while EM_now is the ensemble mean computed in the "classical way", that is without any weight. The attention is focussed of REDU-MINIMIX, REDU-MEGAMIX and REDU-EPS and results are summarised in Figure 16, which indicates a higher skill for the REDU systems where the ensemble mean is weighted according to the cluster population. This happens especially for the "best" system: REDU-MEGAMIX. Results can be summarized as follows:

- MINIMIX (48 members) performs better than EPS51 in terms of z500 RMSE of the ensemble means
- REDU-MEGAMIX outperforms the others ensembles in terms of "RMSE of the best element"
- REDU-MINIMIX performs slightly better than EPS51 in terms of "RMSE of the best element"
- for each of the 16-member ensembles, the weighted ensemble mean gives better score

than the non-weighted one

4.2 Multi-model vs single-model approach for IC and BC to ensemble

The Consortium was running two mesoscale ensemble system, COSMO-LEPS, up to 6 days, mainly targeted for the early medium range, and COSMO-SREPS, which was developed for the aim of short-range forecasting (up to 48 h) in the last years (SREPS PP). One task of CONSENS was dedicated to decide what to do out of these two systems: - how is performing COSMO-SREPS for short-range forecasting, with respect to the already available COSMO-LEPS system? This also considering that recently the ECMWF EPS, on which COSMO-LEPS is based, has improved its spread-skill relation in the short-range, due to the introduction of the EDA.

- is it worth to run two separate systems at the same spatial scale, one for short-range only ?
- is it feasible to merge the two systems ? And if yes, how ?

The set-up of COSMO-SREPS is presented in Figure 17. An intercomparison of COSMO-LEPS and COSMO-SREPS in terms of short-range precipitation forecasting has been carried out, including also two combinations of the systems:

- a 20-member ensemble made up of the 16 COSMO-LEPS runs + 4 runs selected from COSMO-SREPS (mix20)
- a 16-member ensemble made up by the first 12 COSMO-LEPS runs + 4 runs selected from COSMO-SREPS (mix16)

The 4 runs selected from COSMO-SREPS are members 1 (nested on IFS), 6 (nested on GME), 11 (nested on GFS), 16 (control run). Verification is performed in terms of Probabilistic Quantitative Precipitation Forecast (PQPF), 6-hourly accumulated, over Northern Italy (more than 400 stations) for the winter 2010-2011 (20 Nov 2010 - 28 Feb 2011). The verification method is DIST (Marsigli et al., 2008), a distributional method. Some parameters

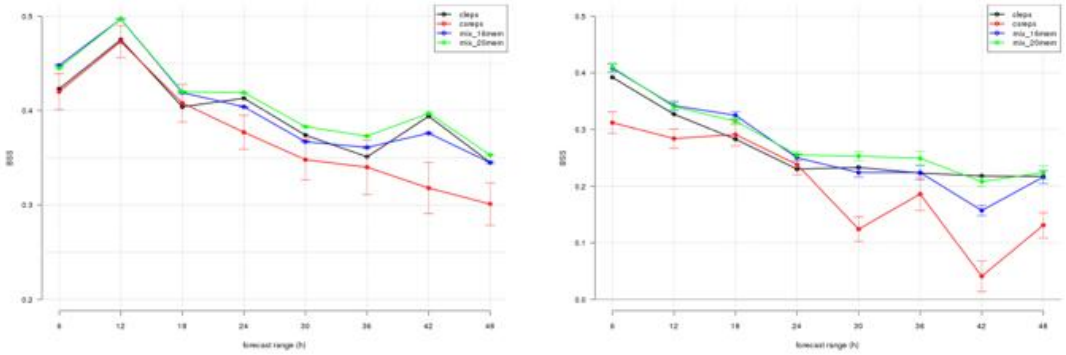

Figure 18: BSS as a function of the forecast range relative to the 4 ensemble systems for the event average precipitation exceeding 1 (left) and 5 (right) mm/6h.

of the distribution of both observed and forecasted precipitation are computed over boxes of 0.5 x 0.5 degrees size, then are compared. Results show that COSMO-LEPS performs better than COSMO-SREPS for almost all the forecast ranges, with some overlapping in the forecast range 18-24h (Figure 18). The mix16 ensemble outperforms COSMO-LEPS for the first 18 h in terms of BSS, while is comparable in terms of ROC area (not shown). For the higher threshold, mix16 performs better than COSMO-LEPS for the first 24. The mix20 ensemble performs better than COSMO-LEPS for almost the whole forecast range, especially for the higher precipitation threshold. Results are confirmed for different parameters of the precipitation distribution (not shown) and for a different season (spring 2011). It is shown that, for COSMO-SREPS, with only 3 global models providing initial and boundary conditions, the scores increase after 8 members is very limited (Figure 19). Therefore, it is not suggested to run an ensemble with more than 5-8 members with only 3 different perturbed initial and boundary conditions. Furthermore, the scores of both ensembles saturates around ensemble size 13-14. This implies that with a 16-member downscaling of the EPS we are already at the maximum skill attainable in the short-range, while there is some indication of room for improvement in the medium range. In summary, results (analysis of 6h precipitation over northern Italy for winter 2010/2011) indicates that:

- generally COSMO-LEPS outperforms COSMO-SREPS in terms of probabilistic indices
- the multi-model approach for i.c. and b.c. proves valuable even if model with different qualities are used
- comparing a 5-member COSMO-LEPS with a 5-member COSMO-SREPS (where all the 3 different i.c. and b.c. sets are included + 2 extra IFS-driven members), the two performs similarly
- comparing a 3-member COSMO-LEPS with a 3-member COSMO-SREPS (where the 3 members have the 3 different i.c. and b.c. sets), the reverse happens: COSMO-SREPS outperforms COSMO-LEPS
- hence, for the multi-model approach to be effective in providing i.c. and b.c., several models are needed to get a performance similar (or better) to a downscaling from a well constructed ensemble (like EPS)
- combining the 16 COSMO-LEPS members with 4 COSMO-SREPS members (taking 3 members with the 3 different i.c. and b.c. sets + the control), this 20-member ensemble outperforms both systems

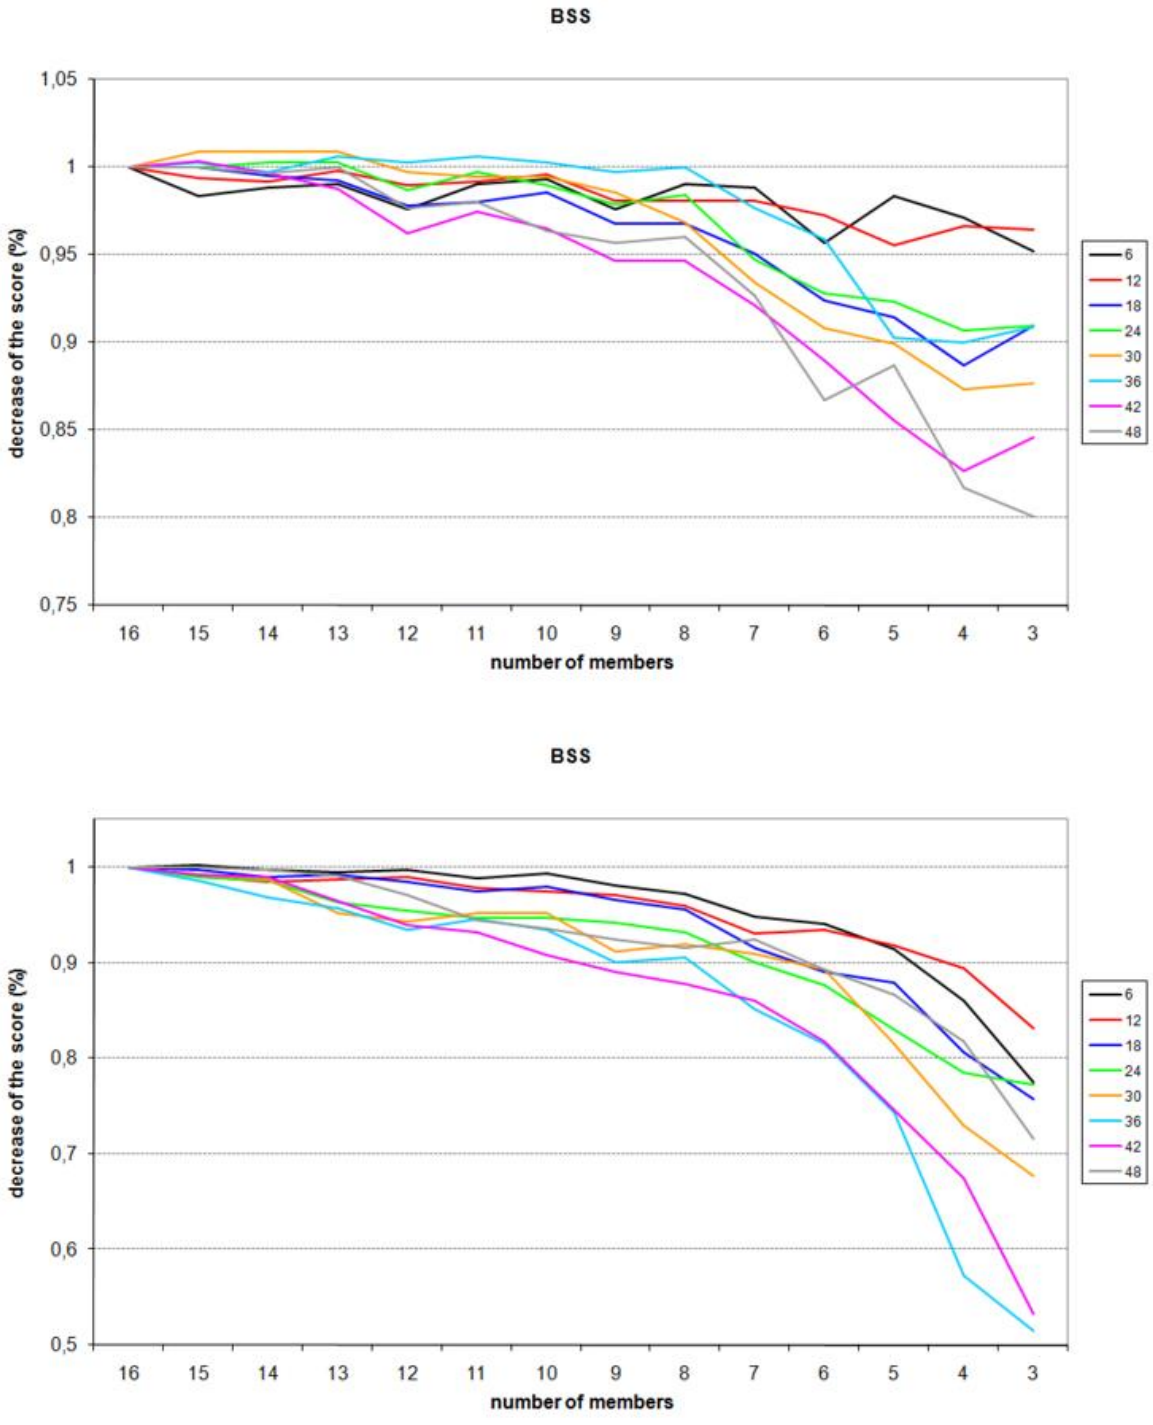

Figure 19: Dependence of the ensemble size of the BSS for COSMO-SREPS (top) and COSMO-LEPS (bottom).

- combining 12 COSMO-LEPS members with 4 COSMO-SREPS members (taking 3 members with the 3 different i.c. and b.c. sets + the control), this 16-member ensemble outperforms COSMO-LEPS for the first day (from 18 to 30 h)

A more comprehensive evaluation is described in Marsigli et al., 2013. On the basis of these results, it was decided to stop running the extra COSMO-SREPS members (nested on the same sets of IC and BC but with different physics), and to Keep only the COSMO-SREPS members which receive IC and BC by different global models, but prolonging the runs up to +132h, as COSMO-LEPS. Then, a new ensemble system has been created, COSMO-HYBEPS, by merging the 16 COSMO-LEPS runs with the 4 BC-EPS runs, creating an additional product which is currently under evaluation in a test suite.

5 Calibration

Three different calibration methods have been implemented and tested on 24h accumulated precipitation forecast issued by COSMO-LEPS. These techniques provide corrections based on: the cumulative distribution function (quantile-to-quantile mapping, hereafter, CDF), the linear regression (hereafter, LR) and analogs. The basic implementations of the CDF and LR methods were developed by generating a seasonal correction function for each model grid point. Each function was defined by using the historical data which were forecasted and observed for the considered grid point during each season. This approach generates correction functions that are location (i.e. grid point) specific. The analogs search was performed in terms of the similarity of the forecasted 24-h precipitation fields over the area under investigation (i.e. ER). The calibration strategy was based on historical forecast and observed rainfall data which were available over the area under investigation. Thirty years of reforecast of one member of COSMO-LEPS were run by MeteoSwiss. One reforecast run with a 90-h lead time was available every three days from 1971 to 2000. This model climatology is used to calibrate forecasts of all lead times, although forecasts of longer lead times might require a longer lead time reforecast data set. According to the model climatology, the climatological observed precipitation data were collected over the period 1971-2000 for ER and Switzerland; unfortunately, the observed data over Germany were available only for the period 1989-2000. Finally, the impact of the calibration process was also verified by performing the coupling of the ensemble QPFs with an hydrological model. This experiment was carried out only for a medium-sized catchment located in Emilia-Romagna, as other implementations of the meteo-hydrological coupled system were not available over the study areas under investigation.

5.1 Comparison of the calibration methodologies in terms of precipitation forecast

The impact of the calibration process on the 24-h QPFs operationally provided by COSMO-LEPS was verified for the years 2003-2007. Three study areas (Figure 20) have been analysed: the total area of Germany (about 357000 km^2), Switzerland (about 41000 km^2) and Emilia-Romagna (about 22000 km^2). Four different lead times were considered, ranging from day-2 to day-5.

According to the 24-h time window over which the observed rainfall amounts were available for each study area, these lead times correspond to, respectively, the 18-42, 42-66, 66-90 and 90-114 forecast hours for Germany and Switzerland and the 20-44, 44-68, 68-92 and 92-116

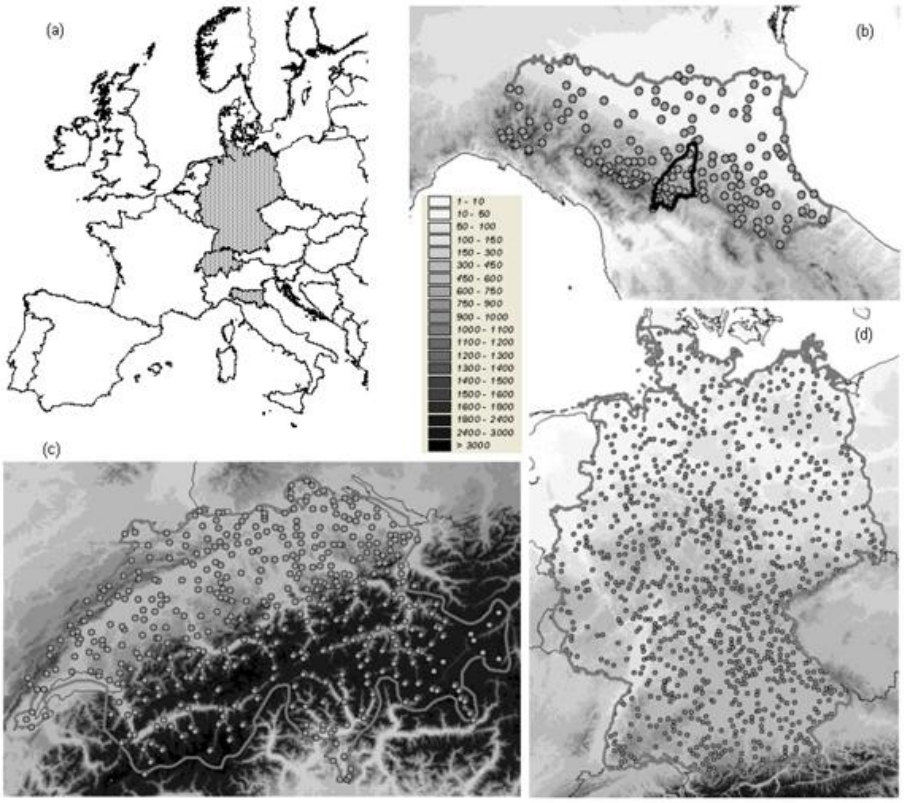

Figure 20: The three study areas localised in western Europe (a). Rain gauge locations (dots) of observed climatology and verification datasets for (b) Emilia-Romagna, northern Italy (in evidence the Reno river basin); (c) Switzerland and (d) Germany. The legend of the digital elevation model (in meters above sea) is common for the latter three panels.

forecast hours for Emilia-Romagna. The verification methods used here were the attributes diagram and the Brier Skill Score (BSS). The thresholds for the verified events were defined as percentiles of the climatological distribution of observed 24-h precipitation, different for each grid point. The use of percentiles of climatological distribution as thresholds guarantees that the sample points share the same climatological frequency of the event. This approach enables to avoid that chosen metrics might report unexpectedly large skill in some points due to the variation of the climatological event frequencies within the verification area. In the following of this Section, results are analysed for each study area separately. The forecast verification measures were first computed independently for each model grid point and were then averaged over the area under investigation. Attributes diagrams are shown for each season only at the day-2 lead time, considering the 80-th and the 95-th percentiles of 24-h climatological rainfall amount as verification thresholds. For brevity, we have chosen not to show attributes diagrams at other thresholds and lead times, as results do not depend strongly on the forecast range (forecasts show a slightly better reliability for the shorter lead times than for the longer lead times) and approximately shows a blend of the hereafter discussed diagrams, giving a little additional information only. Inset histograms for the frequency of usage were plotted on a log-10 scale, in order to provide a better visualization of the distribution in the tails. Results in terms of BSS are shown for each season, considering different forecast ranges (from day-2 up to day-5) and verification thresholds (the 80-th and 95-th percentiles of 24-h climatological rainfall amount). The observed climatology was used as the reference forecast for the computation of the BSS.

a Germany

1 ATTRIBUTES DIAGRAM
The raw ensemble provides poor performance at forecast probabilities lower than 60% in all the seasons; only forecasts of higher probabilities show reliability lines which lie above the no skill line, except for summer (Figure 21). The un-calibrated forecasts provided in autumn are better than forecasts provided in the remaining seasons. Generally, the calibration increases the forecast reliability at all the probabilities; the LR method is particularly effective in spring and summer. The best performances resulting from the forecast calibration are obtained in spring and winter. The improvement of the calibrated forecasts is somewhat less salient in summer, especially for probabilities greater than 60%. The calibrated forecasts show more reliability at lower probabilities for all the seasons. Generally, the raw and calibrated forecasts are overconfident; except for the forecast calibrated by the LR method which results underconfident at the lower probabilities of the higher threshold, especially in spring

2 BSS
The BSS values are always improved by calibrating the COSMO-LEPS system with the CDF method, for all the seasons and both the thresholds (Figure 22). The ANL and LR methods provide a less significant improvement, especially for the spring and summer seasons. The greatest amount of skill improvement is obtained in winter. Forecasts of lower precipitation events are slightly skilful than forecasts of higher precipitation events. Both the raw and calibrated forecasts show a remarkable decay of performance with lead time

b Switzerland

1 ATTRIBUTES DIAGRAM
The raw ensemble shows low reliability; un-calibrated forecasts for winter are particularly worse than forecasts for the other seasons (Figure 23), due to the

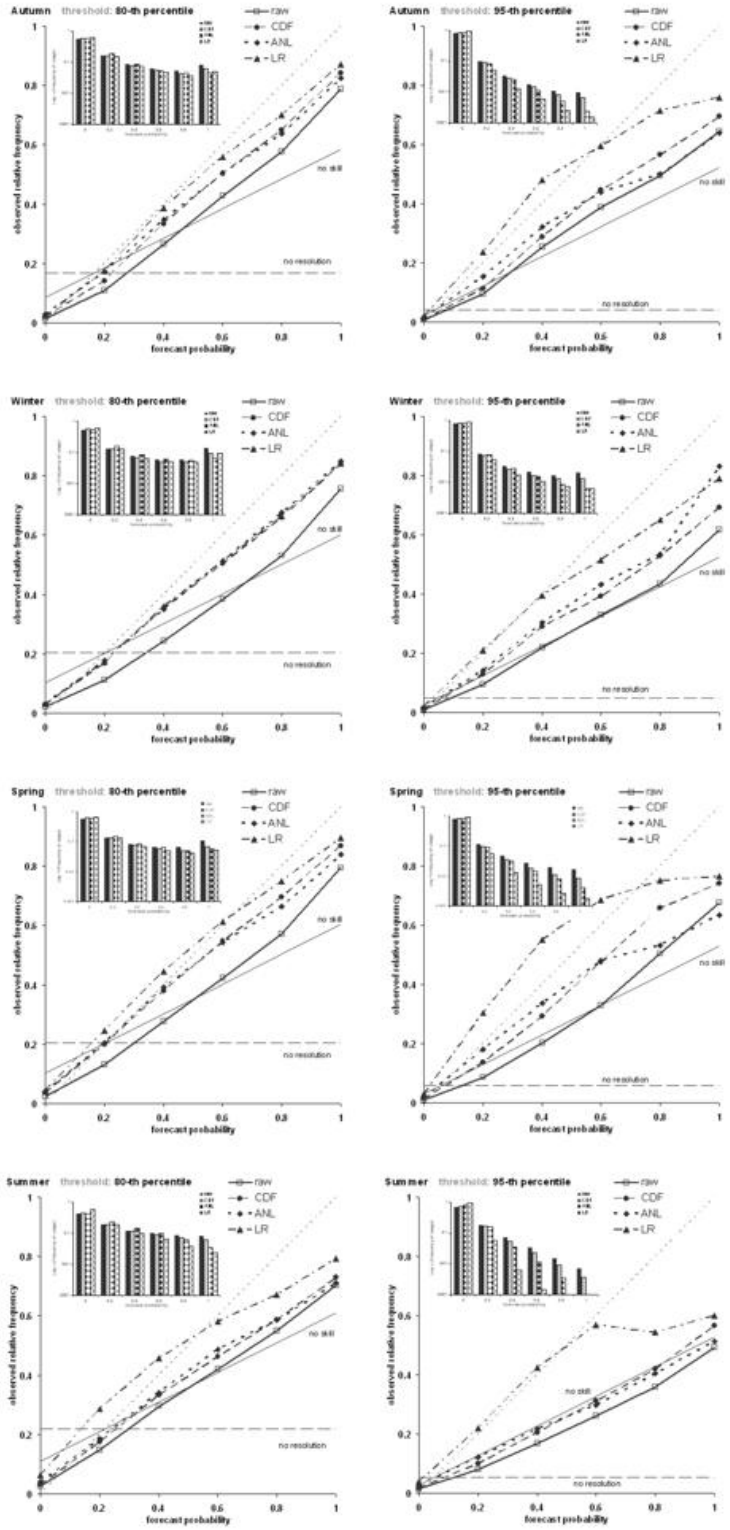

Figure 21: Attributes diagrams of the calibrated and raw forecasts over Germany at day2 lead time for the (left panels) 80-th and (right panels) 95-th percentile thresholds. The diagrams refer to (first row) autumn, (second row) winter, (third row) spring, (fourth row) summer. The inset histograms denote frequency of forecast usage of each probability bin.

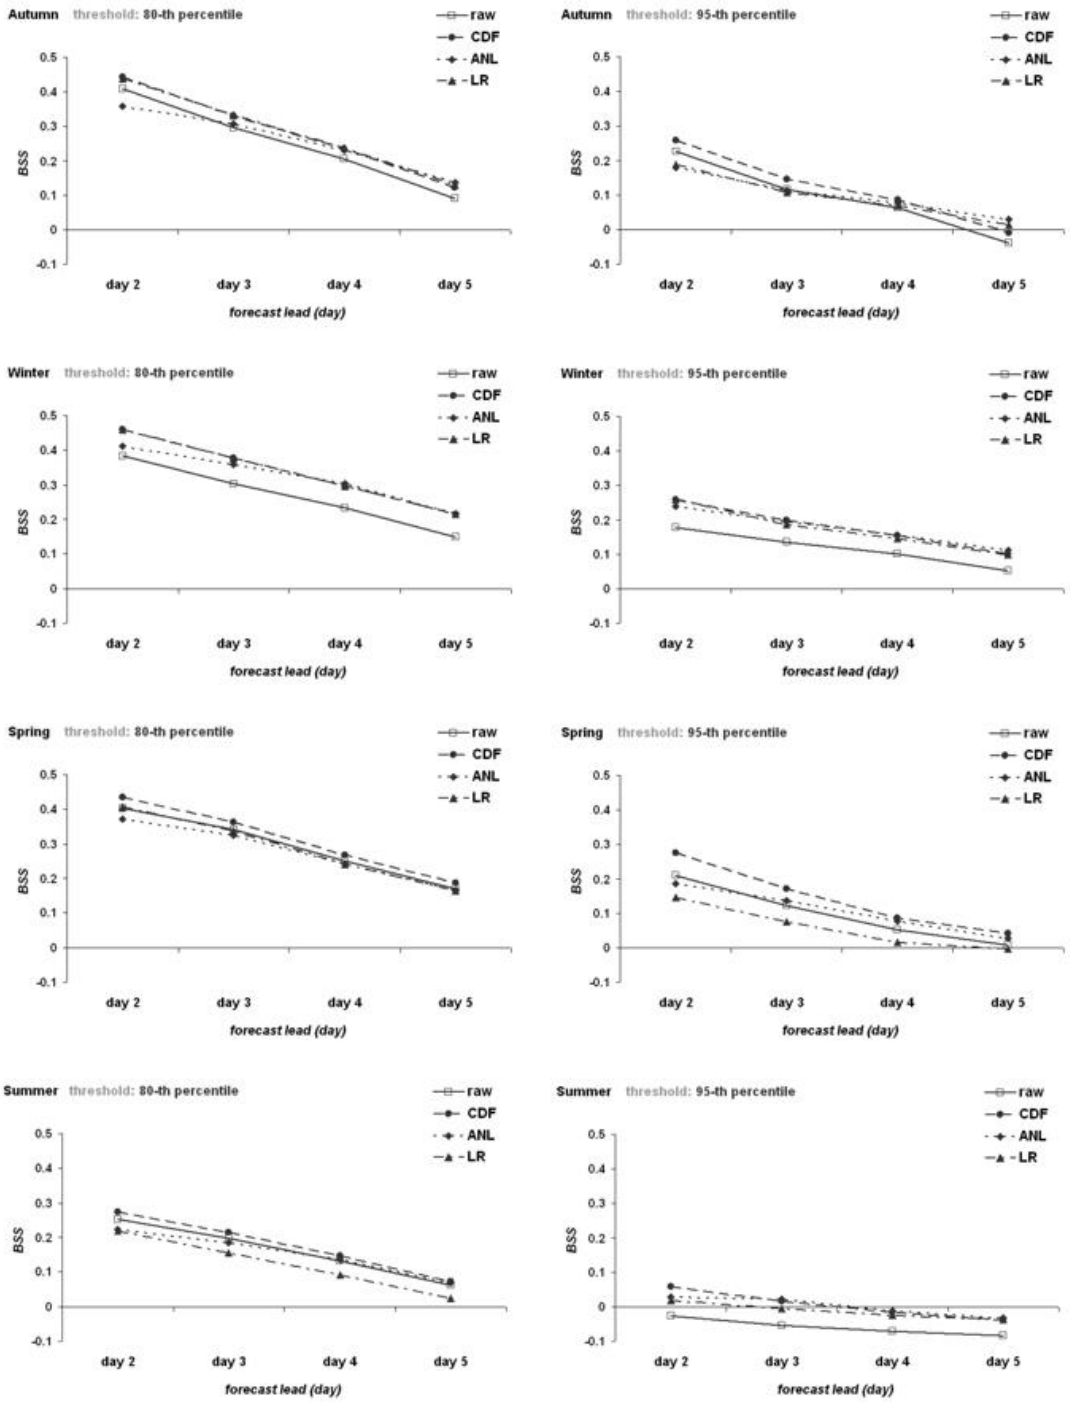

Figure 22: BSS at (left panels) 80-th and (right panels) 95-th percentile thresholds for the raw and calibrated ensembles over Germany in (first row) autumn, (second row) winter, (third row) spring, (fourth row) summer. The results refer to different forecast ranges, up to day5 lead time.

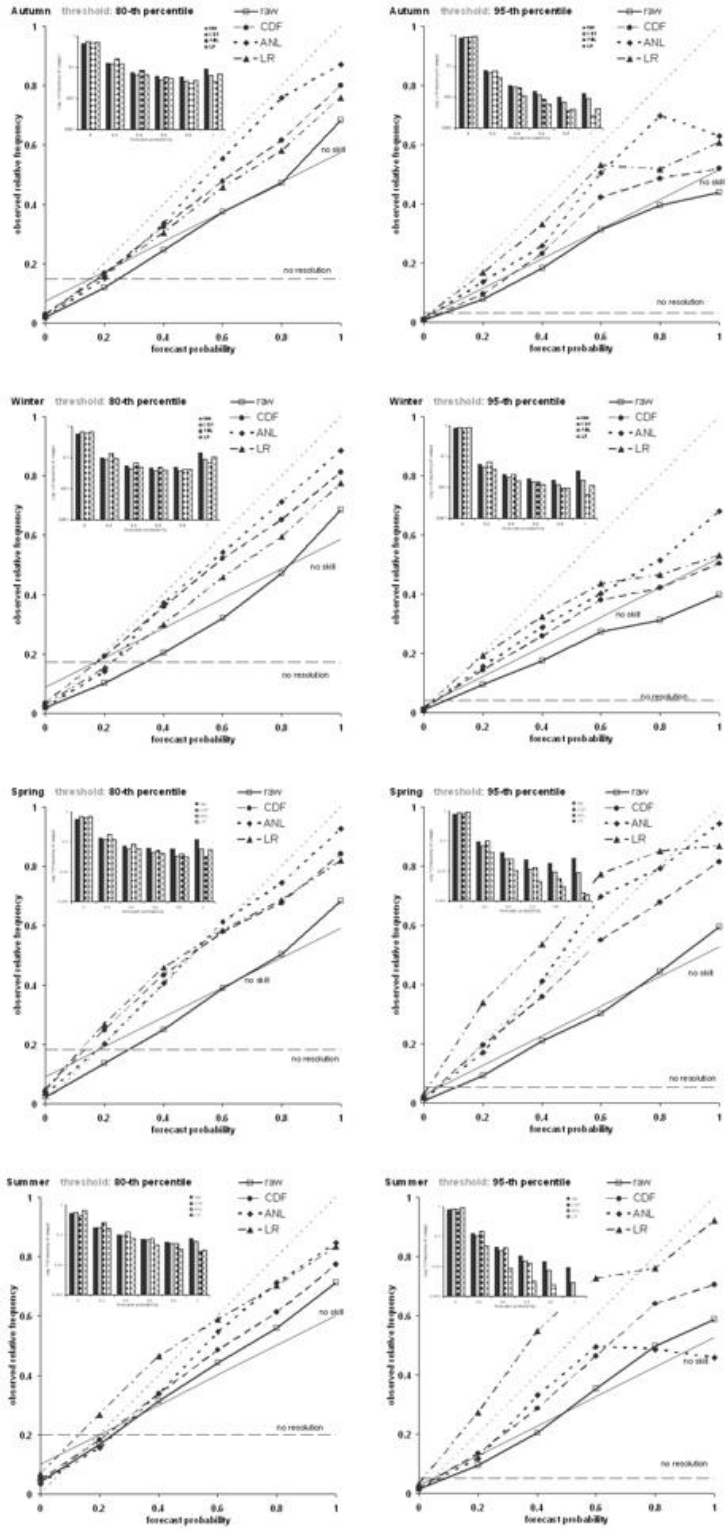

Figure 23: Same as Figure 21, but results refer to Switzerland.

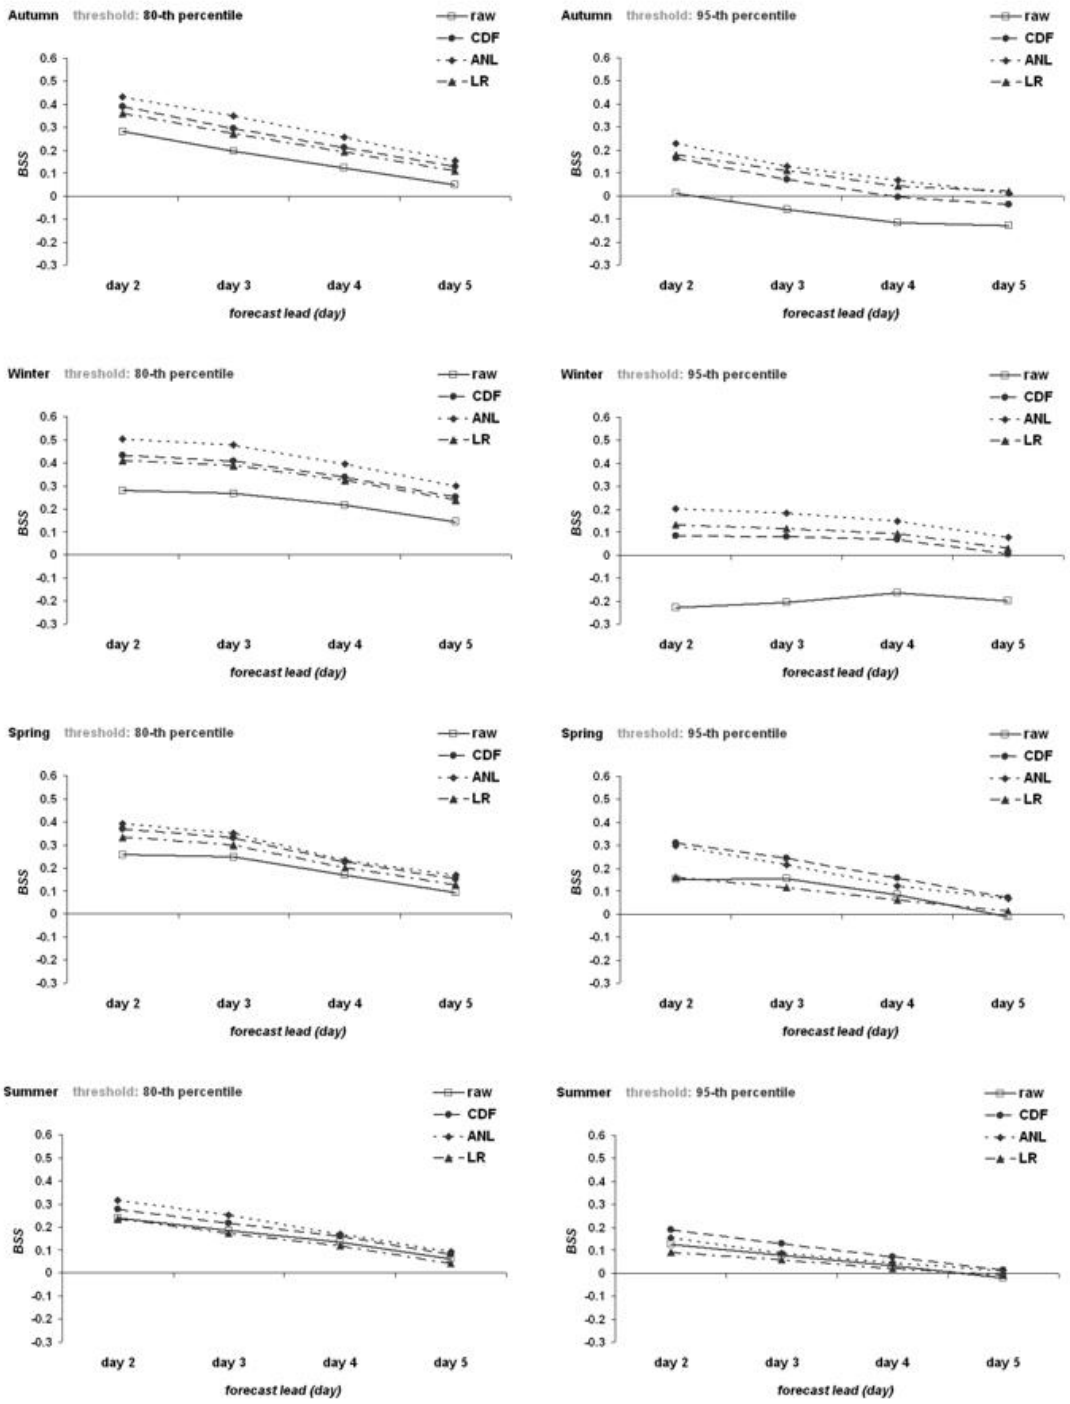

Figure 24: Same as Figure 22, but results refer to Switzerland.

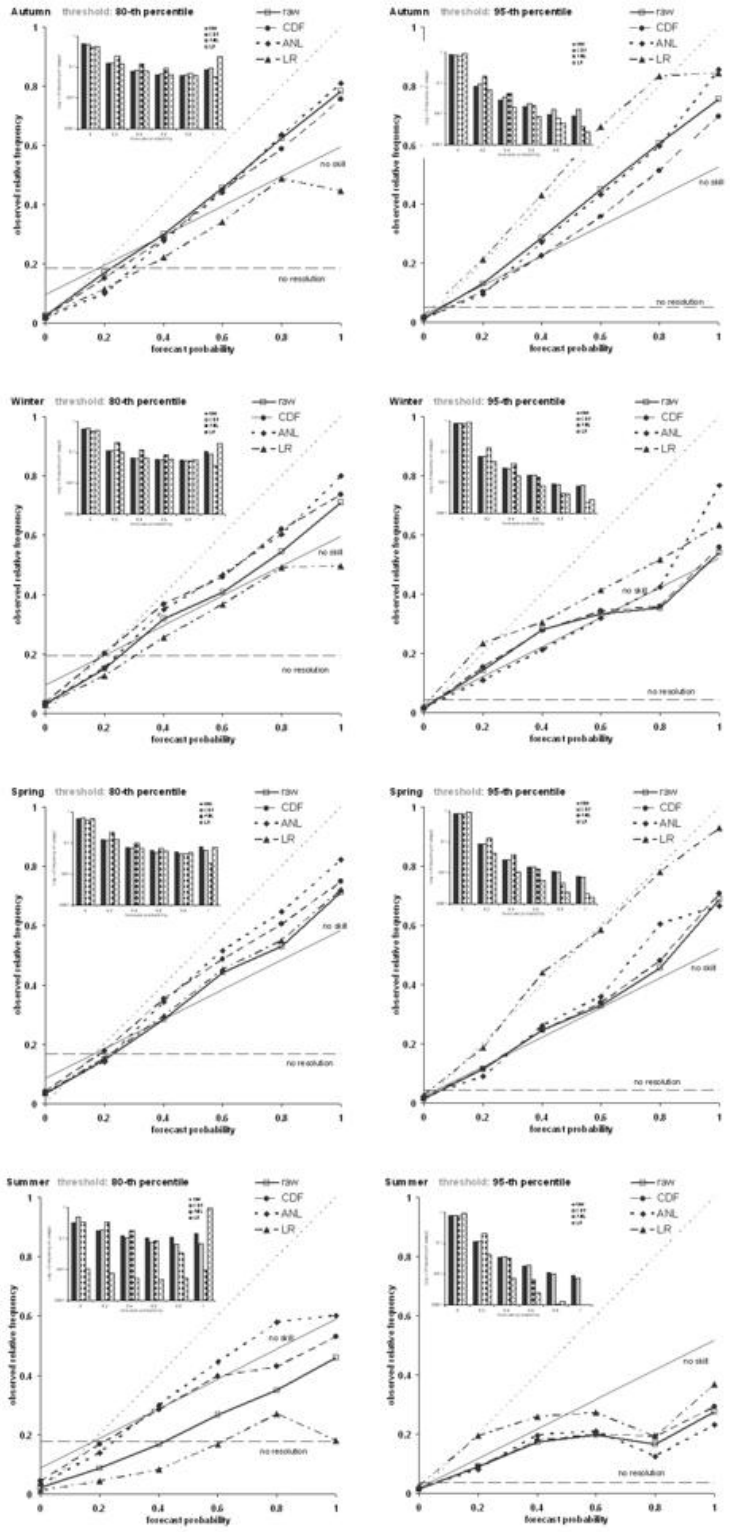

Figure 25: Same as Figure 21, but results refer to Emilia-Romagna.

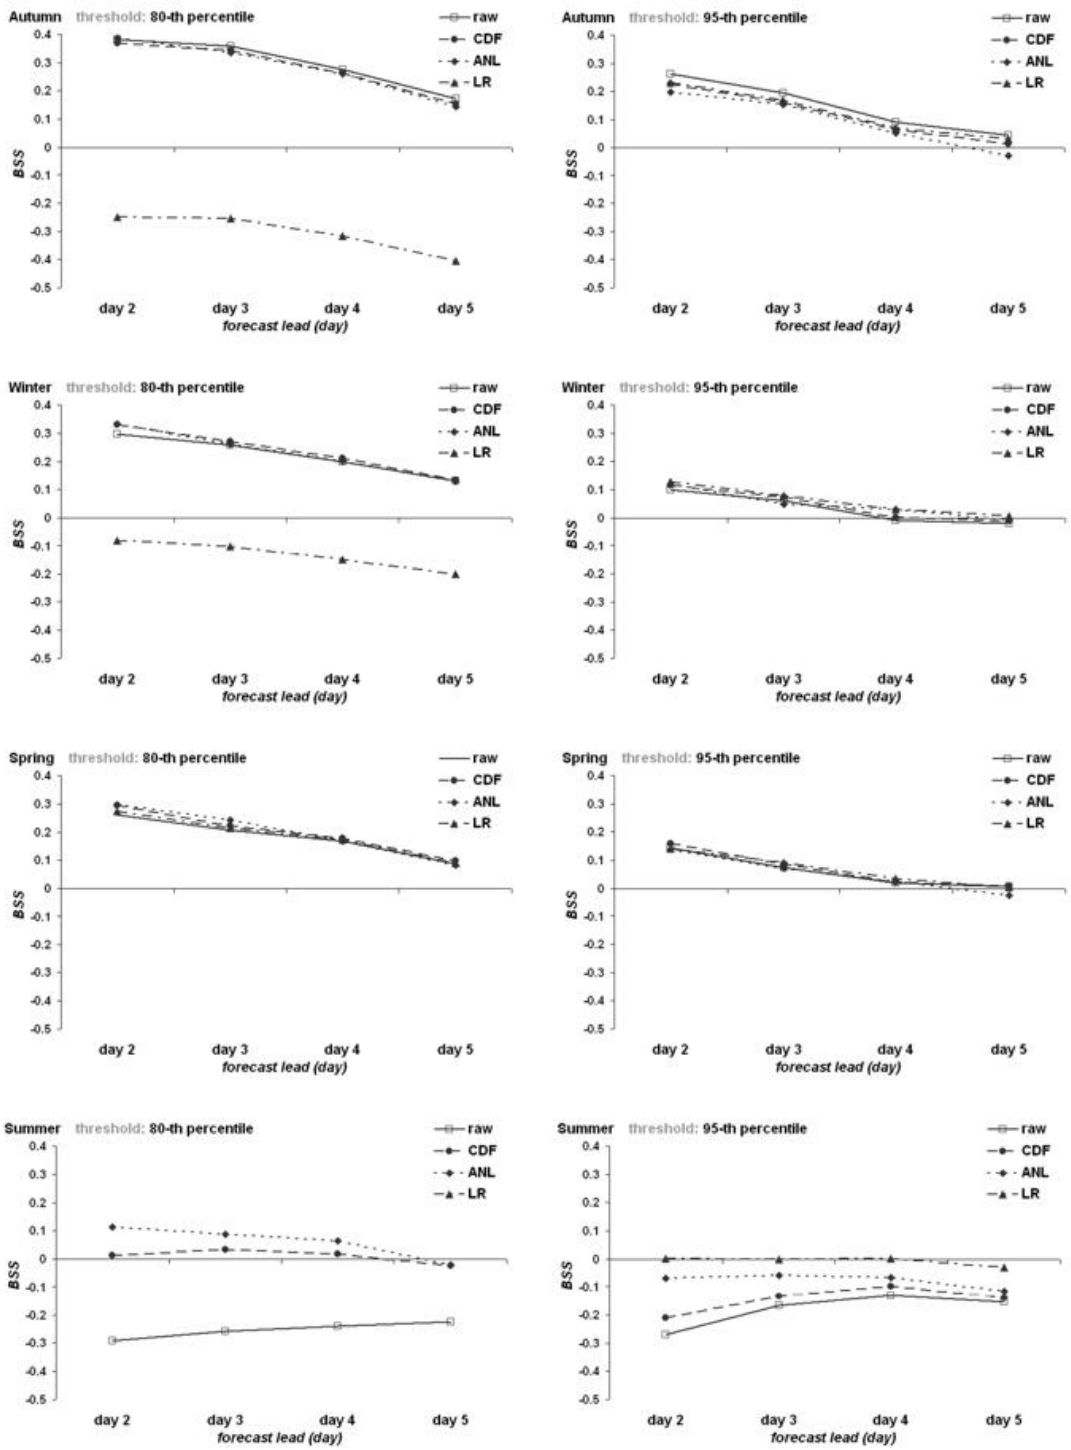

Figure 26: Same as Figure 22, but results refer to Emilia-Romagna.

larger systematic error which results in this season (Fundel et al. 2010). The calibration process enables to increase the reliability in all the seasons; generally, the ANL method performs better than the other methods (except for summer). Calibration is particularly effective in spring. The improvement of the calibrated forecasts is somewhat less salient in summer, as the raw forecasts have a relatively higher reliability. For all the seasons, the calibrated forecasts show more reliability at probabilities lower than 60%. Generally, both the raw and calibrated forecasts are overconfident in all the seasons, except for the forecasts calibrated by the LR method which result as underconfident in spring and summer at the lower probabilities

2 BSS
Generally, for all the seasons and both the thresholds, the BSS values are always improved by calibrating the COSMO-LEPS system with the CDF and ANL methods (Figure 24). The LR method proved to produce a less significant improvement, especially in spring and summer. A large amount of skill improvement is obtained in autumn and winter. Even, with respect to the higher threshold, unskilful raw forecasts for autumn and winter can be turned into skilful forecasts. The amount of skill improvement is smaller in spring and the smallest in summer. As explained in Fundel et al., 2010, the latter result can be due to the more convective and localized nature of precipitation events which occur in summer over Switzerland. During this season, systematic errors in the forecast system might be less important than spatial errors that cannot be corrected for with the proposed calibration methods. Forecasts of lower precipitation events are more skilful than forecasts of higher precipitation events. The decay of performance with lead time is quite evident for the raw and calibrated forecasts, especially for the lower threshold, and with a greater extent in autumn and spring

c Emilia-Romagna

1 ATTRIBUTES DIAGRAM
Generally, the raw and calibrated forecasts are overconfident in all the seasons (Figure 25). The raw ensemble has no good reliability; the un-calibrated forecasts provided in autumn are better than forecasts provided in the remaining seasons. This outcome can be ascribed to the higher predictability of precipitation in autumn, when precipitation events are more frequent and driven by large scale forcing. Raw forecasts for spring and winter show reliability lines which lie quite close to or under the no skill line; the higher threshold worsening this outcome. Even, raw forecasts for summer show reliability lines which lie quite under the no skill line. The results obtained by the forecast calibration process show high variability with respect to the season and the methods. The calibration does not substantially improve reliability in autumn, except for the LR technique at the higher threshold. However, a slight improvement is provided by the ANL method at the lower threshold for probabilities greater than 50%. Improvements are detectable in the winter and spring seasons at the lower threshold when the CDF or ANL calibration techniques are applied. At the higher threshold, only LR enables an increase of reliability, especially for spring. A little gain in reliability is obtained at the lower threshold for summer with the CDF and ANL methods, but results are still quite poor. As the performance of the calibration methods provide only slight improvements in such cases with respect to the raw forecast, a procedure based on a 1000-member block bootstrap sample was used, following Hamill, 1999, to test whether the possible benefits were statistically significant. Generally, the error bars showed a small magnitude, not overlapping to the raw

forecast line (not shown), revealing that the improvements can be evaluated as statistically significant, at a 95% level

2 BSS
The calibration process does not provide a clear beneficial impact on the ensemble QPFs (Figure 26), except for summer. For the autumn season, the values of BSS associated to the calibrated ensembles are lower than the BSS of the raw ensemble for all the lead times. For the winter and spring seasons, the BSSs associated to the calibrated ensembles are quite similar, sometimes slightly higher, with respect to the BSS of the raw ensemble. A clear improvement is obtained in summer, but the raw ensemble is quite unskilful and the calibrated ensembles perform similar to climatology. Generally, at the higher threshold, the calibration methods provide quite similar performances. Rather, at the lower threshold, the LR method provides very bad corrections with respect to the CDF and ANL methods (except for spring); even, very low negative BSS values (out of scale in the graph) result in summer. This outcome can be ascribed to the correction typical of the LR function. In particular, the value of the intercept strongly influences the calibrated value for lower QPF, providing a systematic increase of the raw forecast. Therefore, this aspect strongly penalizes the BSS when computed with respect to low QPF values as verification threshold, such as the 80-th percentile of observed climatology of Emilia-Romagna. Actually, this value is lower than 2.5 mm over the large part of Emilia-Romagna, especially in the plain areas. The scores for forecasts of lower precipitation events are slightly better than the scores of forecasts of higher precipitation events. The decay of performance with lead time is significant, except in summer

5.2 Verification of the calibration process by coupling QPFS with an hydrological model

The hydrological model used to generate simulated discharges is TOPKAPI (TOPographic Kine-matic Approximation and Integration), a physically-based distributed rainfall-runoff model. A detailed description of the model can be found in Liu and Todini, 2002. The performance of the meteo-hydrological coupled system has been evaluated over the Reno river basin (for a more detailed description of the basin refer to Diomede et al. 2008); in particular, the stream flow forecasts were evaluated at Casalecchio Chiusa, the closure section of its mountainous part which dimension is about 1000 km^2 (Figure 20 panel b). The stream flow forecast experiments covered the autumn and spring seasons in the period 2003-2008. Each hydrological run driven by COSMO-LEPS QPFs is 120-h long, starting at 1200 UTC on each day. Every hydrological forecast was run starting with basin initial conditions which were generated by running TOPKAPI in a continuous mode for the whole period 2003-2008 driven by observed precipitation and temperature data. Both QPF and rain gauge observations were downscaled to the hydrological model grid resolution (i.e., 500 x 500 m) by assigning to each cell, respectively, the QPF and the observed value provided on the nearest COSMO-LEPS grid point.

As the hydrological model runs with an hourly time step, hourly calibrated QPFs were used. For each grid point and 24-h lead time, the hourly calibrated QPFs were obtained from the hourly raw QPFs by using a scaling factor defined as the ratio of the calibrated and raw 24-h precipitation amounts. The hydrological simulations generated using rainfall observations were used as the reference measure, in order to assess the skill of the meteorological forecasts. Results of the meteo-hydrological coupling were investigated by statistical analyses. The analysis has firstly been carried out in terms of root-mean-square error (hereafter, RMSE). A

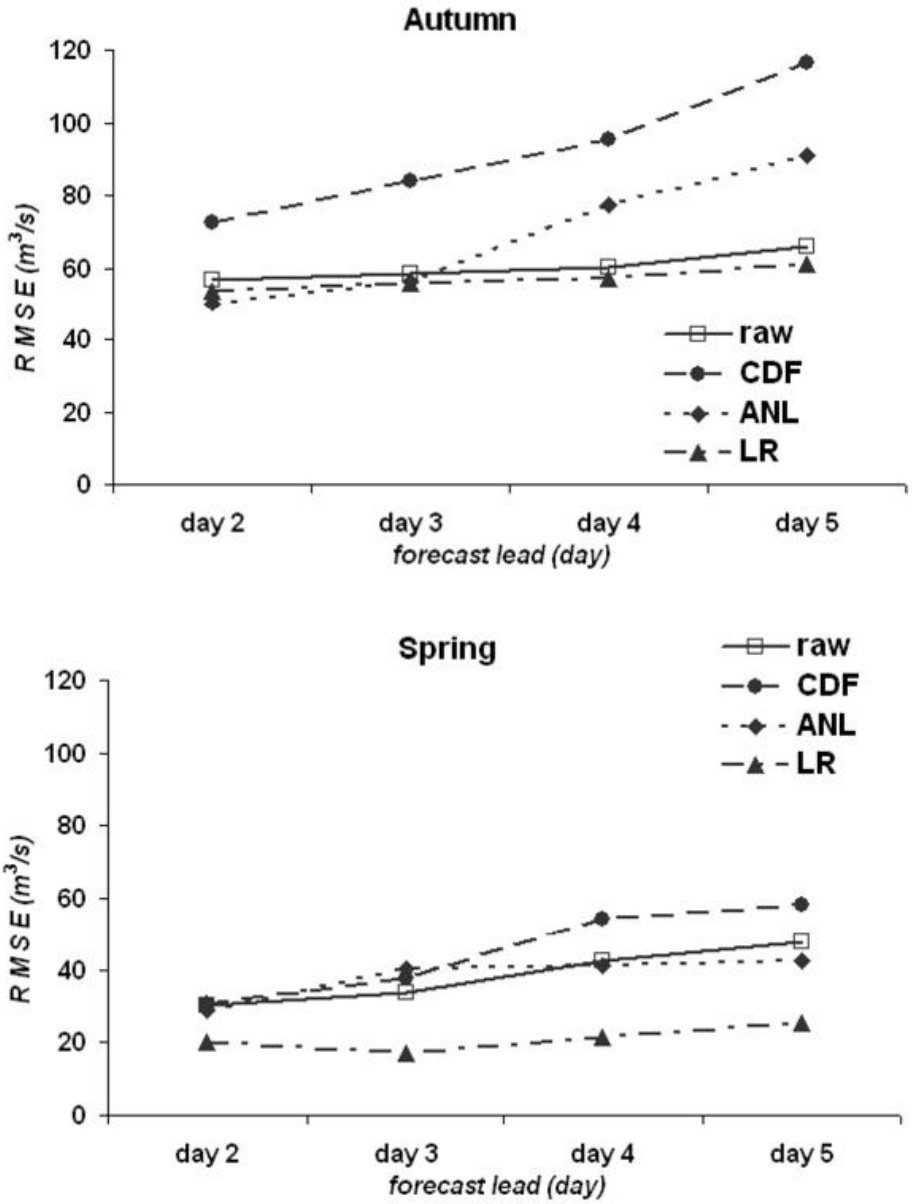

Figure 27: Root-mean-square error for the 95-th percentile of the ensemble of discharge forecasts provided at Casalecchio Chiusa in the autumn (panel a) and spring (panel b) seasons of the years 2003-2008. The discharge forecasts were driven by the QPFs provided by the raw ensemble (black line) and the ensemble calibrated by the CDF (dashed line with circles), ANL (dotted line with diamonds) and LR (dotted-dashed line with triangles) methods. The statistics are displayed as a function of the lead time of the forecast.

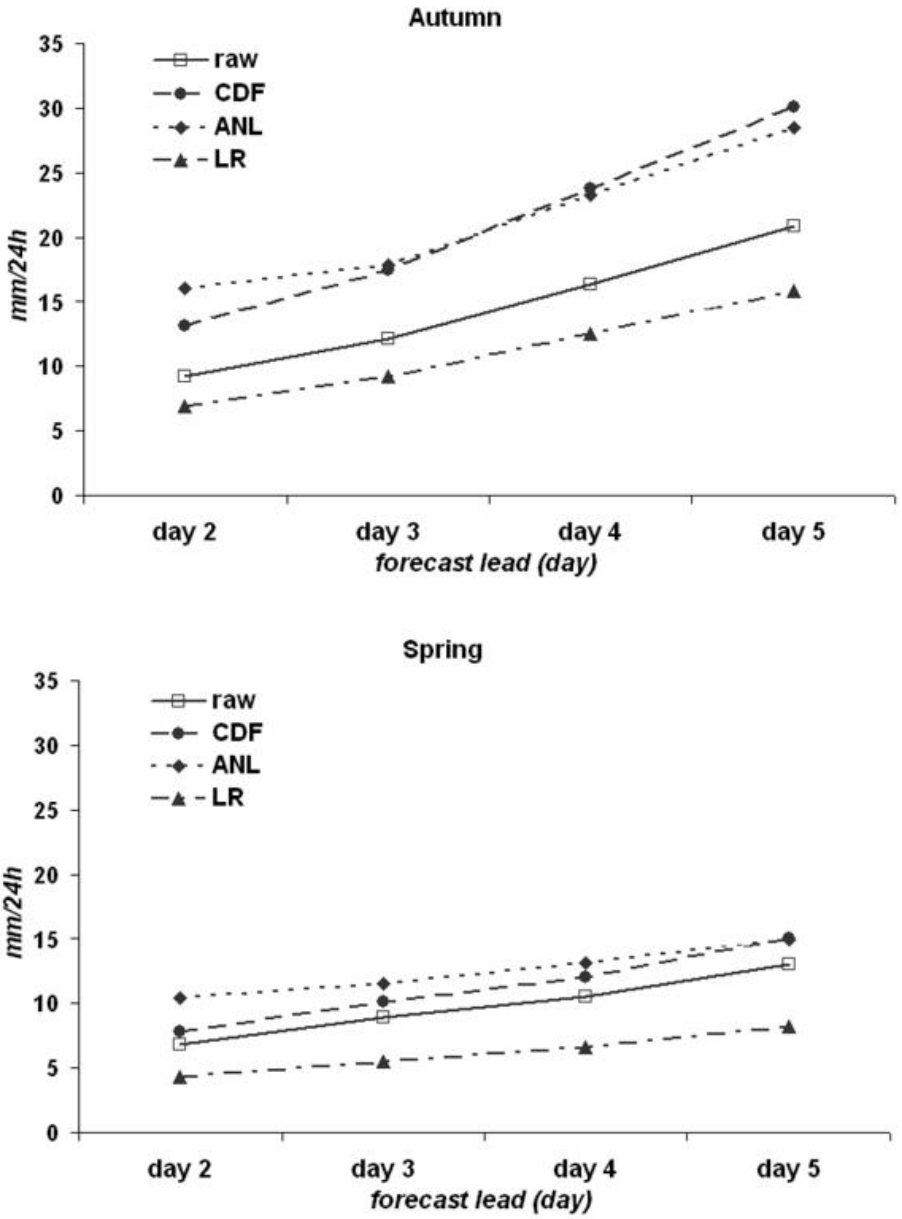

Figure 28: Spread of 24-h rainfall amount for the raw and calibrated ensembles, as a function of the lead time of the forecast. Results are shown for the autumn (panel a) and spring (panel b) seasons of the years 2003-2008.

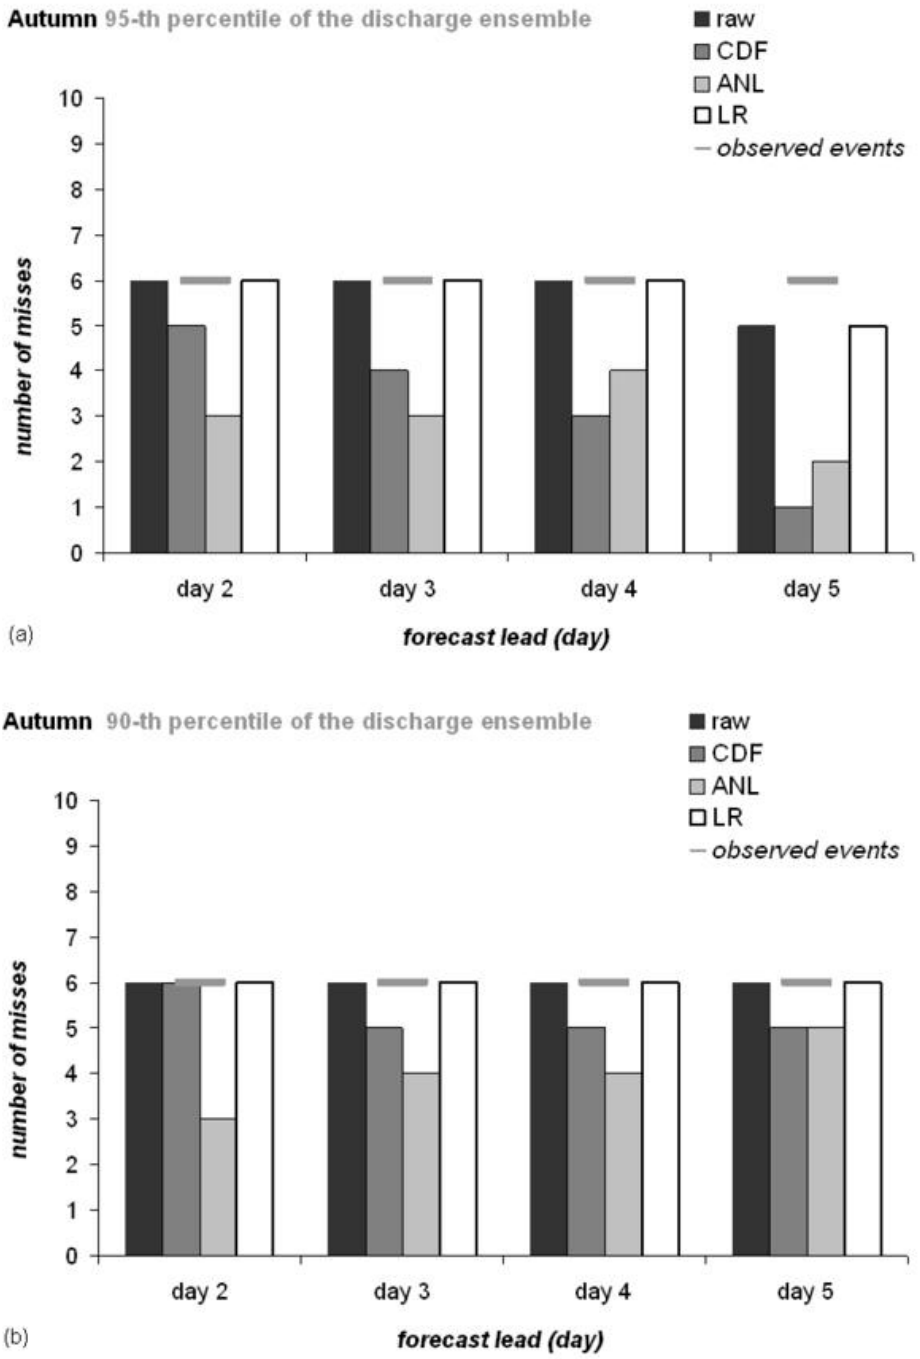

Figure 29: Number of missed events provided by the discharge forecasts driven by the raw and calibrated QPF ensembles for the autumn seasons in the years 2003-2008, as a function of the lead time. The statistics refer to the (panel a) 95-th and (panel b) 90-th percentiles of each discharge ensemble, with respect to the exceeding of the warning threshold at the Casalecchio Chiusa river section. The number of observed events (six) is displayed by the horizontal thick grey line.

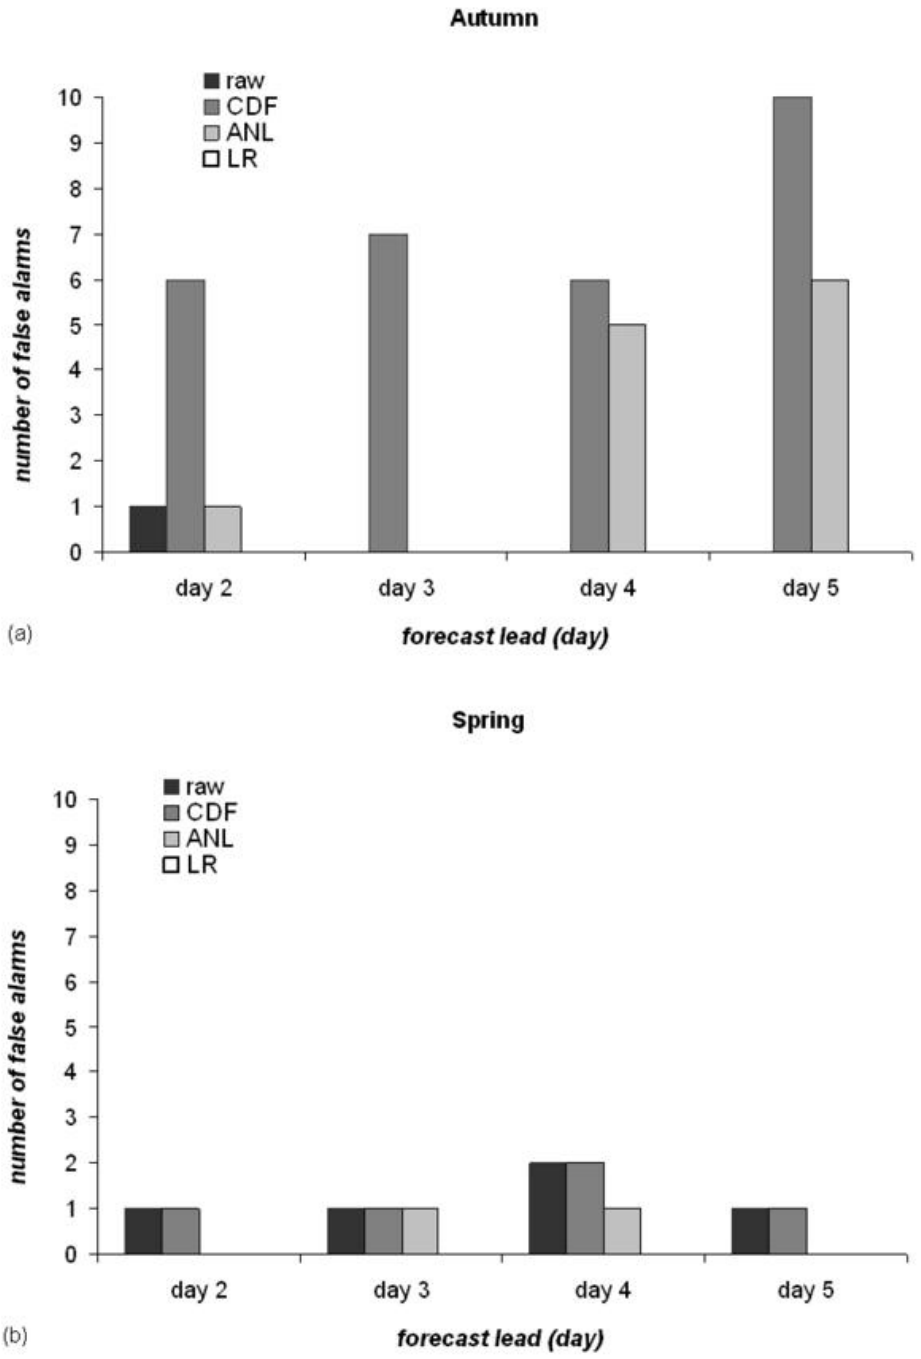

Figure 30: Number of false alarms provided by the discharge forecasts driven by the raw and calibrated QPF ensembles for the autumn (panel a) and spring (panel b) seasons in the years 2003-2008, as a function of the lead time. The statistics refer to the 95-th percentile of each discharge ensemble, with respect to the exceeding of the warning threshold at the Casalecchio Chiusa river section.

noteworthy outcome stands out by the calibration when the 95-th percentile of the discharge ensemble is considered. With respect to the raw ensemble, the CDF and ANL methods provided an increase of RMSE, especially in autumn for longer lead times; instead, the LR method provided a decrease of RMSE, more evident in spring (Figure 27). At the same time, for both autumn and spring, the RMSE values of the discharge ensemble mean driven by the raw and calibrated QPFs are quite similar (not shown). By the light of these outcomes, it seems that the CDF and ANL methods tend to increase the spread of the discharge ensemble. An additional investigation for the period 2003-2008 was then performed on the 24-h rainfall fields forecasted over the sub-area of Emilia-Romagna which includes the Reno river basin, in order to deeper investigate the impact of the calibration methodologies on the spread of the ensemble. This analysis confirms that the ANL and CDF methods tend to increase the spread of the ensemble (evaluated as the difference between the minimum and the maximum values of QPF provided by the ensemble members), especially in autumn (Figure 28). The increased spread associated to the ANL method can be due to the lower quality of analogs, namely very different situations which are not related to the current forecast are selected as analogs. Such a tendency to degrade the calibrated ensemble towards the climatology can also characterise the CDF method, which by construction does not correct for spread deficiencies (Hamill and Whitaker, 2006) and neglects the conditional relationship between observations and forecasts (Hopson and Webster, 2010). Instead, the reduced spread of the ensemble calibrated by the LR method could be explained by considering that in case of forecasts and observations are uncorrelated, this method is not able to remove the error systematically, providing a correction which could adjust all member forecasts to very close values (probably the climatological mean), regardless of their initial value (Hamill and Whitaker, 2006). Then, the impact of the calibration approach focussed on the verification of warning messages which would have been issued on the basis of the discharge scenarios driven by COSMO-LEPS. In particular, missed events and false alarms for the autumn and spring seasons in the years 2003-2008 have been investigated with respect to the exceeding of the warning threshold (i.e., the second level out of three levels of alert defined for the aims of civil protection) at Casalecchio Chiusa within each 24-h forecast period, up to day-5. Noteworthy outcomes were provided by the higher percentiles of the discharge ensemble. Considering the 95-th percentile, the impact of the calibration process in terms of reduction of misses for the autumn season is remarkable for the CDF and ANL methods (Figure 29, panel a). Actually, the discharge forecasts driven by the raw QPFs missed the six observed events totally for the lead times up to day-4; at day-5, five out of six events were missed. Rather, the discharge forecasts driven by the QPFs calibrated by the CDF and ANL methods reduced the missed events. In particular, the ANL method performs better up to day-3 (the number of misses is reduced by half), whereas the CDF method provides the best performance for longer lead times (one missed event only out of six cases at day-5). The LR method does not enable a reduction of misses with respect to the raw forecast. The positive impact provided by the CDF and ANL methods in terms of decrease of misses is reduced when the 90-th percentile of the discharge ensemble is considered (Figure 29, panel b). Nonetheless, the performance of the ANL method is quite similar up to day-4 for both the percentiles of the ensemble. No events occurred in the spring season in the period 2003-2008, thus no missed events result.

In terms of false alarms, when the 95-th percentile of the ensemble is considered, the discharge forecasts driven by QPFs calibrated by the CDF and ANL methods provide an increase of false alarms in the autumn season, with respect to the raw forecast (Figure 30, panel a). However, the worsening for the ANL method is evident only from day-4. The LR method does not provide any false alarm. When the 90-th percentile of the discharge ensemble is considered (not shown), only the CDF method still provides some (e.g., no more than four) false alarms. The number of false alarms provided by the 95-th percentile of the discharge ensemble is quite reduced (no more than two false alarms) in the spring season (Figure

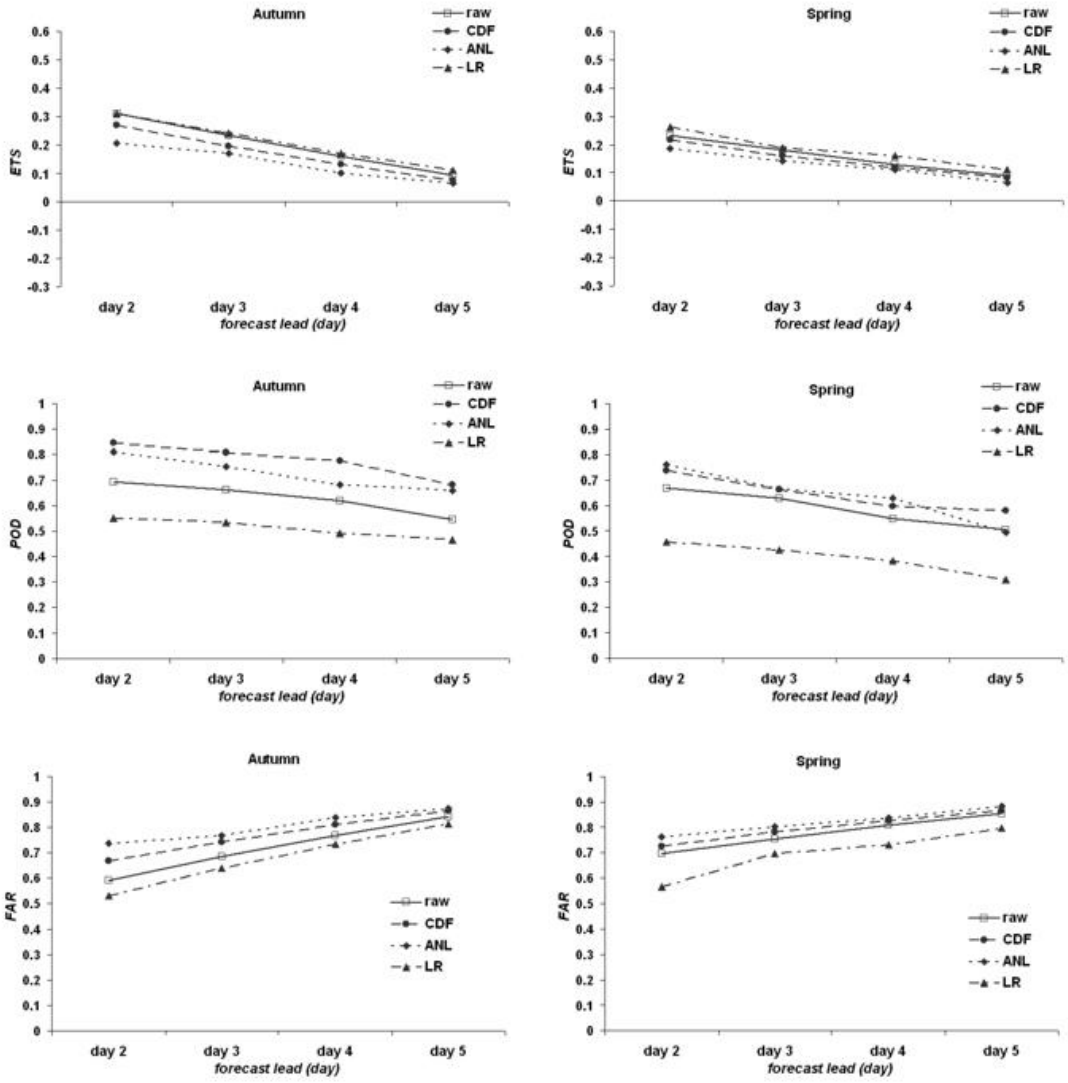

Figure 31: Equitable Threat Score, Probability Of Detection and False Alarm Rate at the 95-th percentile threshold of rainfall climatology for the 95-th percentile of QPFs of the raw and calibrated ensembles over the sub-area of Emilia-Romagna which includes the Reno river basin. The results refer to different forecast ranges, up to day 5 lead time, for the autumn (left panels) and spring (right panels) seasons in the years 2003-2008.

30, panel b). In particular, the discharge ensembles driven by QPFs calibrated with the CDF and ANL methods does not provide an increase of false alarms with respect to stream flow forecasts driven by the raw QPFs; even, the ANL method enables a reduction of false alarms. The LR method does not provide any false alarm. Similar results are obtained when the 90-th percentile of the discharge ensemble is considered (not shown). Summarising, the investigation over the Reno river basin shows that the calibration performed with the ANL and CDF methods enables to decrease the number of missed events, at the expenses of an increase of false alarms. Decision-makers have to evaluate (for instance, on the strength of a cost-loss analysis) which percentile of the discharge ensemble should be more suitable for supporting their activities. The noteworthy outcomes provided by the meteo-hydrological coupling suggested to perform an additional statistical analysis in terms of QPFs for the sub-area which includes the Reno river catchment, in order to investigate the ability of the calibrated ensembles to discriminate precipitation events. Actually, the calibration did not show a remarkable beneficial impact in terms of reliability and BSS on 24-h QPFs, especially in autumn . The attributes diagrams and the BSSs relative to the sub-area of the Reno river basin (not shown) provide results which are similar to those of the total area of Emilia-Romagna (shown in Figure 25 and Figure 26 respectively). The Equitable Threat Score (ETS), Probability Of Detection (POD) and False Alarm Rate (FAR) were thus computed for the autumn and spring seasons in the years 2003-2008. Figure 31 shows the forecast skills in terms of ETS, POD and FAR for the 95-th percentile of raw and calibrated ensembles, with respect to the 95-th percentile of rainfall climatology as verification threshold. The increase of POD and FAR for the ensembles calibrated by CDF and ANL with respect to the raw ensemble confirms the outcomes of the meteo-hydrological coupling. On the one hand, the improved QPF performance in terms of POD for the ensembles calibrated by CDF and ANL constitutes a real issue for the beneficial impact of calibration, as end-users are usually more concerned about missed events than by false alarms. On the other hand, these calibrated forecasts are characterised by an increase of FAR, even though not at a preoccupying rate. The ETS does not change significantly, due to the balance between the increases of both hits (influencing positively the ETS) and false alarms (influencing negatively the ETS).

5.3 Comments and conclusions

The direct model output of COSMO-LEPS is biased and shows deficiencies concerning both reliability and sharpness. Consequently, there is a need for calibration and post-processing techniques that address these issues and provide to the forecasters more reliable products for operational use. Here, the calibration approach utilized a 30-yr reforecast dataset produced by MeteoSwiss. In the recent past, several studies showed that reforecasts turn out to be useful for additional forecast improvement and diagnostic capability, making worth the extra computational resources required to produce them. In this work, the impact of the calibration approach was not so beneficial with respect to it had been reported in some comparable studies, in particular in terms of increase of reliability and skill. This can be due to the fact that in this study high resolution precipitation forecasts is dealt with. The paper investigated three methods for postprocessing the ensemble precipitation forecasts: quantile-to-quantile mapping, linear regression and analogs. The accuracy of calibrated QPFs was verified, with a particular focus on the use of such fields in hydrological applications. There appeared to be no single best forecast method for all applications and study areas, among the three tested. This study demonstrated that it is possible to improve raw ensemble forecasts of precipitation, but the improvements vary strongly from to site to site. It is reasonable to assume that this was more related to the non systematic model error than to the lack of capability of these methods to extract predictive information. The statistical analyses over Switzerland and

Germany revealed a positive impact of the calibration process. The calibrated ensembles increased the forecast reliability in all the seasons. The best performance over Switzerland was generally obtained with the ANL method, except for summer. Rather, the LR and CDF methods provided the best performances over Germany. No significant improvements resulted over Emilia-Romagna by the statistical analysis on the calibrated QPFs. But, the quality of these forecasts proved to be as improved for hydrological applications. Actually, the output of the hydrological model TOPKAPI driven by the calibrated QPFs revealed a beneficial impact of calibration for the discharge predictions over a medium-size catchment (i.e., the Reno river basin) selected as case study. In particular, the investigation on the hydrological runs covering the autumn and spring seasons of the years 2003-2008 showed that the calibration performed with the ANL and CDF methods enabled to obtain a decrease of missed events. But, an increase of false alarms resulted by the application of these two calibration methods, even though this trend was evident for the ANL method for longer lead times only. Decision-makers, who are usually more concerned by missed events than false alarms, have to evaluate which percentile of the discharge ensemble should be more suitable for supporting their activities. It seems clear that objective post-processing of ensemble forecasts will remain a critical component of the forecast process. The difficulty of accurately forecasting the intensity, location and timing of intense precipitation events at the spatial scale typical of small/medium-size catchments limits the ability of COSMO-LEPS to confidently and reliably capture observed intense peak discharges. Therefore, although calibrated forecasts do convey added-value in comparison to raw ones, precipitation forecasts need to be further improved to guarantee sufficiently reliable flood predictions over small/ medium-size catchments. The promising results of this study indicate that further research is merited. Whatever the case, there is definitely room for improvement in the calibration of ensemble systems. Reduction of errors that vary by weather element and flow configuration from ensemble precipitation forecasts is considered a necessary step to improving forecast quality and benefiting end users (Gneiting and Raftery, 2005; Yuan et al., 2007). There is a multitude of techniques that could be applied to regime-based calibration approach. Considering the techniques which were applied in the present study, a future improvement for the analog search could be obtained by a multi-variable approach, in order to find a better matching of the space-time evolution of the synoptic pattern. With respect to the CDF and LR methods, a solution could be the division of the training sample size according to some criteria which would allow to pool data which have similar model errors with respect to a certain meteorological situation.

6 Conclusions

The CONSENS PP has ended in 2011 and the work carried out within the Project has provided useful indications about the update and/or modification of the ensemble suites, together with suggestions about future works. The main outcomes are:

- the work on parameter perturbation has lead to the choice of a definite set of parameters and values which have been implemented in both the COSMO-SREPS and COSMO-LEPS ensembles. In the latter, though, perturbations can have different combinations with respect to those here analysed, since the combination is randomly selected day by days
- the soil moisture analysis perturbation technique has been developed and implemented, and it is available for further testing. This technique has not been implemented yet in an ensemble configuration for testing, but its applicability will be further investigated

in the future

- the work on multi-clustering has confirmed that the ensemble reduction methodology is able to retain a good fraction of the information contained in the original ensemble and that there is a relationship between cluster size and skill of the corresponding representative member of the large scale ensemble (for upper air variables). Therefore, the clustering methodology will be further developed and updated, aiming at improving also the short-range performances
- on the basis of the results of the COSMO-LEPS/COSMO-SREPS comparison, it was decided to stop running the extra COSMO-SREPS members (nested on the same sets of IC and BC but with different physics), and to keep only the COSMO-SREPS members which receive IC and BC by different global models, but prolonging the runs up to +132h, as COSMO-LEPS. These four extra runs (one nested on IFS with Tiedkte convection, one nested on IFS with Kain-Fritsch convection, one nested on GME and one nested on GFS) are now run as part of an experimental suite, which in combination with COSMO-LEPS constitutes the COSMO-HYBEPS 20 member ensemble, currently under evaluation
- an additional product of COSMO-LEPS has been made available, the 24h QPF calibrated with the CDF methodology over the 3 domains which have been considered in the study here presented

These results have lead to an effective consolidation of the mesoscale ensemble system of the Consortium and have provided useful indications about possible further improvements. Furthermore, the experience gained in the field of model perturbation techniques is useful for the development of the convection-permitting ensembles which is on-going in several COSMO Countries and which will be addressed in a forthcoming PP.

7 Acknowledgments

This project was carried out in the framework of the COSMO Consortium, therefore the authors would like to thank the COSMO colleagues for fruitful discussions and useful suggestions. We are also grateful for their help to Davide Cesari, Paolo Patruno and Fabrizio Nerozzi (ARPA-SIMC). The COSMO-LEPS and COSMO-SREPS ensembles have been run at ECMWF thanks to the Billing Units provided by the COSMO Countries which are also ECMWF members (Germany, Italy, Switzerland, Greece). The Italian institutions which provided observed data for the verification are also acknowledged.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction

Atmospheric processes such as the development of the boundary layer, low level cloudiness, and the onset and intensity of convection are significantly influenced by the evolution of the lower boundary conditions. Consequently, an accurate representation of exchange processes between the soil and the atmosphere is essential to produce high quality NWP forecasts. At the time of the definition of the project, many activities concerning the lower boundary of the COSMO model had been undertaken, but most of these activities lacked some final efforts to bring them into operations and to make them accessible to the whole COSMO community. In 2008, the COSMO steering committee (STC) established a new Priority Project named Consolidation of Lower Boundary Conditions (COLOBOC), to finalize these developments and to incorporate them into well tested and documented software packages. The project was structured in 8 tasks, namely:

- Facilitate the access and usage of soil and surface observations (task 0)
- Consolidate an externalized TERRA module (task 1)
- Consolidate the software used to generate the external parameters (task 2)
- Consolidate and extend the external parameters database (task 3)
- Find and validate an optimal configuration of TERRA with its associated external parameters and look-up tables (task 4)
- Revise the snow model and the snow analysis (task 5)
- Deploy an urban module developed at EPFL/Switzerland (task 6)
- Consolidate the parameterization of land surface heterogeneity (task 7)

The project spanned the period 09.2008 to 09.2011; during these 3 years, about 8.5 FTE have been invested, with resources coming from 6 different institutions. Many discussions with colleagues of the CLM community took place during this project, resulting in the organization of regular COSMO / CLM meeting around this topic. Although not all tasks were successful (see chapter 3 for details), most of the developments done during this project have resulted in follow-up activities in the COSMO working group dedicated to soil and surface activities (see http://www.cosmo-model.org/content/tasks/workGroups/wg3b/default.htm).

2 State of the modelling system at the start of the project

The soil vegetation atmosphere transfer (SVAT) scheme TERRA and the associated external parameters provide the terrestrial lower boundary conditions for the atmospheric component of the COSMO model. TERRA is a multilayer model with a direct solution of the heat conduction equation and considers moisture transport due to hydraulic processes within the soil and the effects of transpiration by plants. Phase change processes of soil water (freezing/thawing of soil water/ice) are incorporated in the scheme both for their thermodynamic effect and for their impact on the hydraulic properties of the soil. In addition, the COSMO model employs a single layer snow module considering melting of a snow pack with prognostic snow density and time dependent snow albedo. Many uncertainties in the description and simulation of surface characteristics are partly caused by well-known problems. A critical

issue is the limited knowledge of the physical properties of the surface in the form of the so-called external parameters (e.g. soil type, root depth). These parameters play a vital role, e.g. in the simulation of the hydrological state, but both the quality of the raw databases and the methods used to derive the required model properties from these databases are not optimal. Moreover, the increase in horizontal resolution of current NWP models implies that some surface types previously neglected, such as lake and urban regions, are becoming more important. The simulation of the evolution of the soil is also hampered by inadequate knowledge of the initial state. Unrealistic drifts in soil moisture are ubiquitous in most NWP models, due to both incorrect representation of soil processes and the accumulation of precipitation errors (Scipal and Drusch, 2007). As demonstrated for the global model GME, an improvement may be achieved through a change in the root density distribution together with the introduction of seasonal vegetation parameters (Ritter, 2007). Due to the non-linear relations between surface parameters and fluxes, neglecting subgrid-scale land-surface heterogeneities by using average external parameters, may result in erroneous flux estimates. Studies have shown that, even with a grid spacing of only a few kilometres, considerable aggregation effects may indeed occur and must be corrected for. This can be tackled by introducing one of the so-called tile or mosaic approaches: the surface within a coarse scale atmospheric grid box is subdivided into patches with assumed homogeneous surface characteristics, fluxes are computed for each patch separately and then averaged. The current representation of the snow does not allow liquid water to stay within the snow pack, which is a severe limitation in spring when the freezing of trapped water during the night slows down the melting of the snow pack. Furthermore, many local effects such as snow transport by wind and influence of slope orientation make a correct representation of the snow cover particularly difficult.

3 Tasks and achievements

A summary of the different project tasks and of the achieved results are presented in this chapter. More details on some of these developments can be found in the following chapters.

Task 0: Facilitate the access and usage of soil and surface observations.

Goals: convenient access to recent operational high quality observations, representative for different climate and different type of soils.

Achievements: an action started in October 2009 with an official letter sent to a selection of NMS directors. Soil and surface data from 9 European observatories is now available on-line, in a common ASCII format (see http://www.cosmo-model.org/srnwp/content/default.htm). Time series starts in 2006; recent data is added each year, with 6 months time lag. The DWD has agreed to support this action in the future (C.Heret, F.Beyrich). This action is also supported by the C-SRNWP Programme of EUMETNET.

Open issues: only 5 sites are regularly updated (Cabauw, Lindenberg, Payerne, SP Capofiume, Sodankyla). Users community is small.

Task 1: Consolidate an externalized TERRA module.

TERRA standalone is the isolated terrestrial surface module of COSMO driven by external atmospheric fields, taken either from observations or from model runs. This tool provides a computationally efficient way to generate balanced soil conditions for the whole integration domain by computing multi-years TERRA integrations; it is also a useful tool to experiment with the soil model and the external parameters. It has been originally developed by F. Ament.

Goals: clean-up and consolidate the TERRA standalone code.

Achievements: a consolidated package, based on COSMO release 4.13, including documentation, is available on the COSMO web site (see http://www.cosmo-model.org/content/support/software/default.htm).

Open issues: the code is not compliant with the COSMO standard. The TERRA standalone code is not integrated in the COSMO software, making the synchronization with the model development difficult. No COSMO resource is available to further support this code, in particular to coordinate multiple developments taking place in the CLM community (the situation has changed at the time of writing of this report, IMS being interested taking over this duty).

Task 2: Consolidate the software used to generate the external parameters for the COSMO model.

Goals: the software infrastructure should be flexible and modular in order to support various raw datasets and to allow for experimentation with new aggregation algorithms or different look-up tables. It should be easily extensible to support future external parameters. It should support the needs of COSMO, COSMO-CLM, ICON, and GME.

Achievements: a software, called EXTPAR, fulfilling the stated goals and well documented, has been developed (see the Extpar user and implementation manual at http://www.cosmo-model.org/content/model/modules). At the time of writing of this report, this software is an official COSMO software, kept on a centralized repository at CSCS, with D. Lüthi as source code administrator; EXTPAR can now be activated through a web interface hosted on the CLM web site (http://www.clm-community.eu/index.php?menuid=221).

Open issues: none.

Task 3: Consolidate and extend the external parameters database.

Goals: a survey of external parameter fields and raw data sources used within the COSMO and the COSMO-CLM community will be performed. Where appropriate, replace older data sets by newer ones. Adapt work done for the GME. Consolidate external parameters required for new extensions of TERRA.

Achievements: the databases used for the external parameters have been updated according to the stated goals (see http://www.cosmo-model.org/content/model/modules/externalParams/default.htm).

In particular, a total of 15 new external parameters have been added: (vegetation characteristics) NDVI, NDVI_MX, NDVI_RATIO, RSMIN, (surface characteristics) EMISS_RAD, (deep soil) T2M_CL, (topo corrected radiation) SLOPE_ASP, SLOPE_ANG, HORIZON, SKYVIEW, (urban fraction) URBAN, (lake model) FR_LAKE, DEPTH_LK, (aerosols) AER_BC, AER_DUST, AER_SO4, AER_SS.

Open issues: the need to update the external parameters will always be present, e.g. for higher resolution applications or when new parameters are required for newly developed model parameterizations.

Task 4: Find and validate an optimal configuration of TERRA with its associated external parameters and look-up tables.

Goals: (1) gather and integrate tested developments of TERRA in official COSMO code, (2) define a consolidated set of look-up tables, (3) find and validate an optimal reference configuration of TERRA, using the external parameters and the consolidated look-up tables

developed within task 3.

Achievements: many experiments have been done to evaluate the impact of improved parameterizations, new external parameters and updated look-up tables. A new unified consolidated configuration, based on COSMO release 4.11, used both for the global scale in GME and for the regional scale in COSMO, has been defined. Experiments at MeteoSwiss and at DWD with this consolidated configuration showed mixed, neutral impact on verification scores; however, this consolidated configuration provides a physically sound basis for further developments. More details are available in chapter 4 of this report.

Open issues: compensating errors in different parts of the model hinders the development of TERRA.

Task 5: Revise the snow model and the snow analysis.

Goals: (1) Finalize and deploy a new multi-layer snow model supporting change of phases within the snow pack, (2) combine and improve a snow analysis approach based on in-situ observations and MSG derived snow mask.

Achievements: a detailed analysis of the performance of COSMO-RU has shown very large T2m errors in spring, up to 12 deg, at the boundary of the snow pack; these errors could be related to inadequate values of the snow water equivalent provided by the global snow analysis cycle. Different approaches have been proposed by our Russian colleagues to circumvent this issue (new parameterization of the snow density, observation driven 1D snow model). The work on the snow model has resulted in a revised parameterization of the snow albedo (incl. ageing), in a revised parameterization of the partial snow cover (height instead of snow water equivalent based), and in an experimental implementation of the multi-layers snow model in release 4.11 of COSMO (see chapter 5 for a description of this new snow model). The snow analysis software used at DWD (sfcana) has been adapted to support the use of the MSG derived snow mask.

Open issues: the multi-layers snow model has still some stability issues, in particular for very shallow snow layers, and needs more testing (at the time of writing of this report, the development of the multi-layers snow model has been transferred in ICON but is still not finalized). More generally, snow analysis and modelling still requires more work, in particular in complex terrain, during the snow melting period, or when going to finer resolution.

Task 6: Deploy an urban module developed at EPFL/Switzerland.

Goals: Consolidate and transfer an urban model developed at EPFL/Switzerland, based on the Buildings Effects Parametrization (BEP), into the latest COSMO release.

Achievements: an implementation of BEP, including some documentation, is available in a COSMO private release at MeteoSwiss (based on COSMO release 4.7). The description of the BEP implementation in COSMO, and of its impact, is available in chapter 6 of this report.

Open issues: no code responsible has been found. Furthermore, due to the complexity of this urban model, possibly not suited for general NWP applications, the decision to take it in the official COSMO release is pending (at the time of writing of this report, the choice of a simpler urban parameterization for the official COSMO release has been made).

Task 7: Consolidate the parameterization of land surface heterogeneity.

Goals: Finalize and deploy an implementation of the tile/mosaic approach, using the developments of Ament, 2006, implemented in a COSMO private release at MeteoSwiss.

Achievements: these developments have been consolidated and transferred in COSMO release 4.16. Dynamic snow tile has been introduced. Sensitivity studies have been performed, without conclusive results about the impact of this parameterization.

Open issues: code implementation is still experimental and has not been validated by COSMO Source Code Administrator (at the time of writing of this report, the COLOBOC implementation has been discarded and a new tile parameterization has been fully re-implemented in the ICON model).

4 Experiments towards an unified soil-vegetation atmosphere transfer scheme TERRA for global and limited-area numerical weather prediction (J. Helmert, G. Vogel, H. Asensio, J. M. Bettems, M. Lange, F. Brenner, B. Ritter)

4.1 Introduction

One of the critical issues in the description and simulation of surface characteristics in atmospheric models is due to physical surface properties in the form of the so-called external parameters (e.g. soil type, vegetation state, root depth, plant physiological parameters). These parameters play a crucial role, e.g. in the simulation of the hydrological state, but both, the variable quality of the raw databases and the used methods to retrieve the required model properties from these databases contribute to uncertainties in NWP model forecasts.

Together with the external parameters the soil vegetation atmosphere transfer (SVAT) scheme TERRA provides the terrestrial lower boundary conditions for the atmospheric component of the global GME model and the limited-area COSMO model. Driven by radiation fluxes, the evolution of the lower boundary conditions influence the exchange of heat, moisture, and momentum between the surface and the atmosphere and has a large impact on the simulation of screen level variables and atmospheric processes, such as the development of the boundary layer, low level cloudiness, and the onset and intensity of convection.

The SVAT model TERRA is a multilayer model with a direct solution of the heat conduction equation and considers moisture transport due to hydraulic processes within the soil and the effects of transpiration by plants. Phase change processes of soil water (freezing/thawing of soil water/ice) are incorporated in the scheme both for their thermodynamic effect and for their impact on the hydraulic properties of the soil. A snow module (single or multilayer) is employed considering melting of a snow pack with prognostic snow density and time dependent snow albedo. However, there is a need to employ also a canopy layer for vegetation in TERRA to improve the surface energy budget in COSMO.

Although the global GME and the limited-are COSMO model share the SVAT model TERRA in large parts it is reasonable to test new developments first on the global scale. Therefore a number of changes in external parameters and modifications of TERRA are used in operational GME, that are still experimental in COSMO. To fill this gap in the SVAT model between GME and COSMO a unified configuration for TERRA that further improves the lower boundary condition of NWP models at global and regional scale is proposed. For soil moisture analysis (SMA), employed to minimize the difference between diagnosed 2m-temperature and observations this unification between COSMO and GME is now achieved (Lange, 2011).

The report starts with the operational and experimental configuration of GME and COSMO-EU, both models with SMA, then show a case study at 10th April 2011 to illustrate the sensitivity of the results on the applied configuration. Long-term simulations of GME and COSMO-EU are evaluated from soil-moisture analyis monitoring and objective verification followed by a summary and an outlook. The appendix contains figures that refers to changes in external parameters.

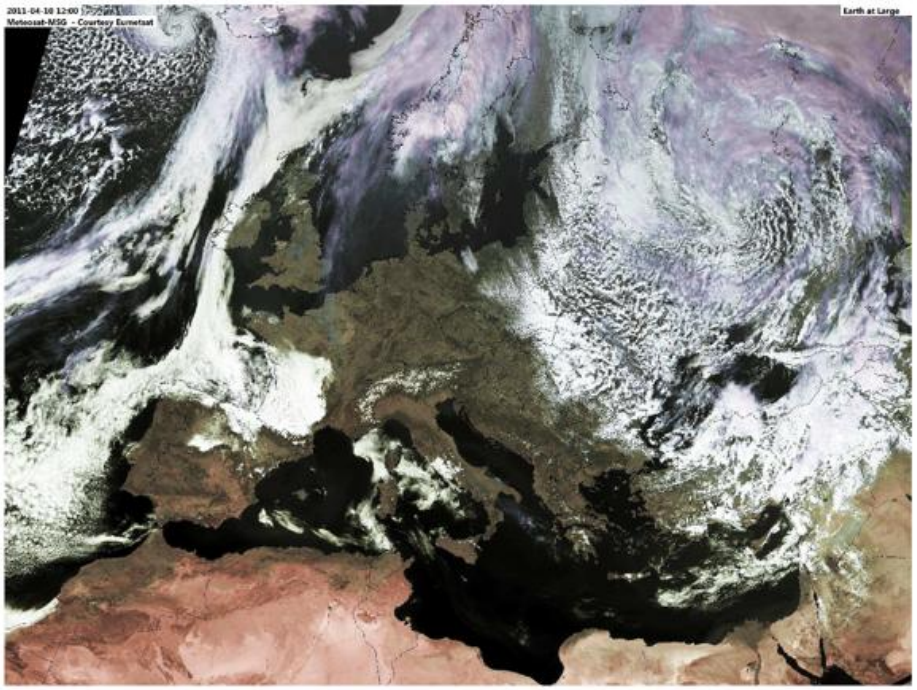

Figure 1: Meteosat VIS image of Europe on 10th April 2011 12 UTC

4.2 Model configuration

The differences in model configuration with impact on the energy budget at surface between GME and COSMO include the aerosol distribution, surface emissivity, vegetation albedo, vegetation climatology, root density profile, and minimum stomatal resistance (Tab. 1).

The radiation budget at Earth surface forces the energy fluxes into the atmosphere and to the ground. The magnitude of these fluxes depends on the amount of incoming global radiation, which is altered primarily by clouds and aerosols. While the global model GME uses a aerosol climatology from Tegen et al. (1997), the COSMO model employs a constant distribution of aerosols according to Tanre et al. (1984) with a known overestimation of desert dust aerosol in Europe (e.g. Hohenegger et al., 2005). In order to obtain a similar surface radiation budget in COSMO in comparison with GME, the aerosol climatology from Tegen et al. (1997) was applied in the COSMO experiment that used similar to the GME the land-use dependent surface emissivity.

In addition to the incoming radiation, the surface radiation budget of vegetation covered areas depends also on the vegetation albedo. The approach of a constant vegetation albedo of 15 % is enhanced in the numerical experiments of GME and COSMO, following e.g. Moody et al. (2008) by taking into account the land-use by distinction of evergreen (10 %), deciduous (15 %) , and non-forest (20 %). Given the radiation budget at surface, the partition of energy fluxes is influenced by the evapotranspiration depending on plant physiological parameters. The prescribed annual cycle of vegetation parameters (e.g leaf-area index (LAI) and vegetation fraction) in the outer-tropics depending on latitude and height (Doms et al., 2005) was modified in the GME and the COSMO experiments by employing an annual cycle from the climatology (1998-2003) of the normalized differential vegetation index (NDVI).

The partition of energy fluxes at the surface depends also on a large extent on the soil moisture (Balsamo et al., 2009), that has therefore a large impact on the Bowen ratio.

	GME	COSMO-EU	GME EXP	COSMO-EU EXP
Model status	operational	operational	109/1009	8474
Aerosol distribution	climatology	fixed	climatology	climatology
Emissivity	land-use	const	land-use	land-use
Vegetation albedo	const	const	land-use	land-use
Vegetation climatology	NDVI	analytical	NDVI	NDVI
Root density profile	exponential	uniform	exponential	exponential
Min. stomatal resistance	GLC2000	const	ECOCLIMAP	ECOCLIMAP

Table 1: Configuration of GME and COSMO routine and numerical experiments.

However, the simulation of the evolution of the soil is hampered by inadequate knowledge of the initial state. Unrealistic drifts in soil moisture are ubiquitous in most NWP models, due to both incorrect representation of soil processes and the accumulation of precipitation errors (Scipal and Drusch, 2008). As already demonstrated for the global model GME, an improvement may be achieved through the introduction of the NDVI-based annual cycle of vegetation together with a change in the root density distribution (Ritter, 2007). The exponential root density profile used in GME was employed also in the COSMO model and applied in the limited-area experiments.

The maximum possible evapotranspiration of plants is connected with a minimum stomatal resistance r_{min}. The constant value of this parameter of 150 sm^{-}1 in the COSMO model was replaced by a land-use dependent formulation from GME. However it was found in GME that large uncertainties in the value of r_{min} for individual land-use classes exist that leads to a domain averaged overestimation of r_{min}. In connection with the soil-moisture analysis (SMA) that was adapted from COSMO to the GME to minimize the difference between diagnosed 2m-temperature and observations (Lange, 2011), an overestimation of r_{min} results in an accumulation of soil moisture. To further improve the SMA in GME and COSMO the relationship between land-use classes and r_{min} was adapted from ECOCLIMAP Masson et al. (2003) and applied in numerical experiments of GME and COSMO. From the observed reduction of domain averaged r_{min}, a more realistic annual cycle of soil moisture with reduced SMA increments was expected.

4.3 Numerical experiments - Case study 10th April 2011

The soil-moisture analysis was introduced in the operational GME at 9th March 2011 for the 00 UTC analysis. The accompanying numerical GME experiment (experiment code 109/1009) was initialized at 12th March 2011 00 UTC, which applies the land-use based vegetation albedo and minimal stomatal resistance from land-use classes of ECOCLIMAP. In order to allow for a spin-up of the GME experiment the numerical COSMO experiment (experiment code 8474) was initialized at 1st April 2011 00 UTC. This spin-up is considered as sufficient for atmospheric processes and processes of the upper soil. It used the boundary conditions from 109/1009 and shares the configuration of the external parameters and the SVAT scheme with the global model experiment.

As a case study the sensitivity of the COSMO-EU 36 hour forecast on the used configuration was investigated for a clear-sky situation in central Europe on the 10th April 2011 12 UTC. Figure 1 shows the visible satellite image on this date with a large cloud-free area in central

Europe.

As shown in Tab. 1, the GME experiment 109/1009 uses the same configuration setup as the COSMO experiment 8474. Therefore, the following figures show the absolute values for the GME experiment and the difference between operational COSMO-EU and the COSMO experiment 8474 assuming a much smaller difference between GME experiment 109/1009 and the COSMO experiment 8474. The 36 hour forecast of the averaged net radiation budget at surface from the GME experiment (Fig. 2 top) shows small values in North-Scandinavia due to the snow pack with high albedo compared to the snow free regions in central Europe. The difference of the averaged net radiation budget at surface between operational COSMO-EU and COSMO-EU experiment 8474 reveals the changes in aerosol optical depth, vegetation albedo, and surface emissivity. The dominant effect of the reduced desert dust aerosol optical depth leads to the expected increase of the averaged net radiation budget at surface in the domain mean.

The surface albedo (Fig. 14 top) is dominated by snow in northern Europe and the mountains but the difference in the snow free regions refers to the changes in annual cycle of vegetation and formulation of the vegetation albedo (Fig. 14, bottom). The modified albedo of evergreen forest (set to 10 % in the experiment) is visible for the low-mountain range of central Europe. An additional contribution to the difference in vegetation albedo comes from the vegetation coverage (Fig. 15, top). Replacing the analytical function by a NDVI-based climatology leads to a significant higher vegetation coverage in south-west and central Europe and a decrease north-east after the first third of April (Fig. 15, bottom) .

As expected this is also the case for the leaf ara index LAI (Fig. 16). The GME experiment (Fig. 16, top) refers the LAI to the NDVI climatology and shows therefore realistic maximum values in south-western Europe. The comparison to the operational COSMO-EU (Fig. 16, bottom) shows that the difference to the empirical relationship in this region is increased.

For the plant evapotranspiration, in addition to the LAI, the minimum stomatal resistance r_{min} is one important vegetation parameter (Fig. 17, top) . The impact of the relationship of the land-use classes to r_{min} based on ECOCLIMAP is large, exceeding 30 sm^{-1} in domain average (Fig. 17, bottom). Only for the low-mountain range and Scandinavia the difference is below 15 sm^{-1}.

In the average over the forecast time, a sensitivity of the heat fluxes on the differences in external parameters and SVAT model is expected. Figure 3 (top) shows the averaged sensible heat flux (positive downward) those difference for COSMO is a result of changes in surface radiation budget (Fig. 2) and differences in partition of energy at the surface. Positive values of the sensible heat flux averaged over forecast time reveals the cooling over the snow (Fig. 3, top) but the mean value over the domain increased by about 8 Wm^{-2} for the COSMO-EU experiment that is larger than the increase in averaged latent heat flux (Fig. 4) of below 4 Wm^{-2}. However, even regions in western and central Europe and northern Africa with different vegetation properties (higher vegetation coverage, LAI, smaller minimum stomatal resistance, different root density profile) in the COSMO-EU experiment compared to the operational COSMO-EU exceeds this value clearly. Considering the change in the Bowen ratio based on sensible and latent heat flux averaged over the forecast time, Fig. 5 supports this result since regions in western Europe with positive Bowen ratio below one, i.e. less sensitive heat flux than latent heat flux with same sign, show a positive difference to the operational COSMO-EU. It could be expected that the increased latent heat flux in the COSMO-EU experiment is correlated with a decrease in soil moisture and Fig. 6 confirms this assumption. Due to the exponential root density profile in the experiment the impact of the upper soil levels on the evapotranspiration is increased that leads to 10 % dryer upper soil in parts of western Europe and northern Africa (Fig. 6, top). Here, the correlation of

this pattern to the changes in vegetation parameters is obvious. The modified root water uptake leads as expected to a soil moisture increase in the soil layers 54 cm and 162 cm (Fig. 6, center). However due to the large time scales in the deeper soil after 10 days of the numerical experiment the change in this case study is just small and below 5 %. This is also the case for considering all six hydraulic active layers in TERRA (Fig. 6, bottom), where the soil moisture increase for the experiment in domain average is 0.15 %.

Although feedback effects of changes in the SVAT scheme on precipitation could be assumed, their identification within one case study is difficult. This is confirmed by considering the accumulated precipitation fractions over 36 hours forecast time (Fig. 7). In this situation the increase in domain average is 0.05 kgm^{-2} for grid-scale and for convective precipitation with a small increase of the convective fraction on total precipitation in the COSMO-EU experiment.

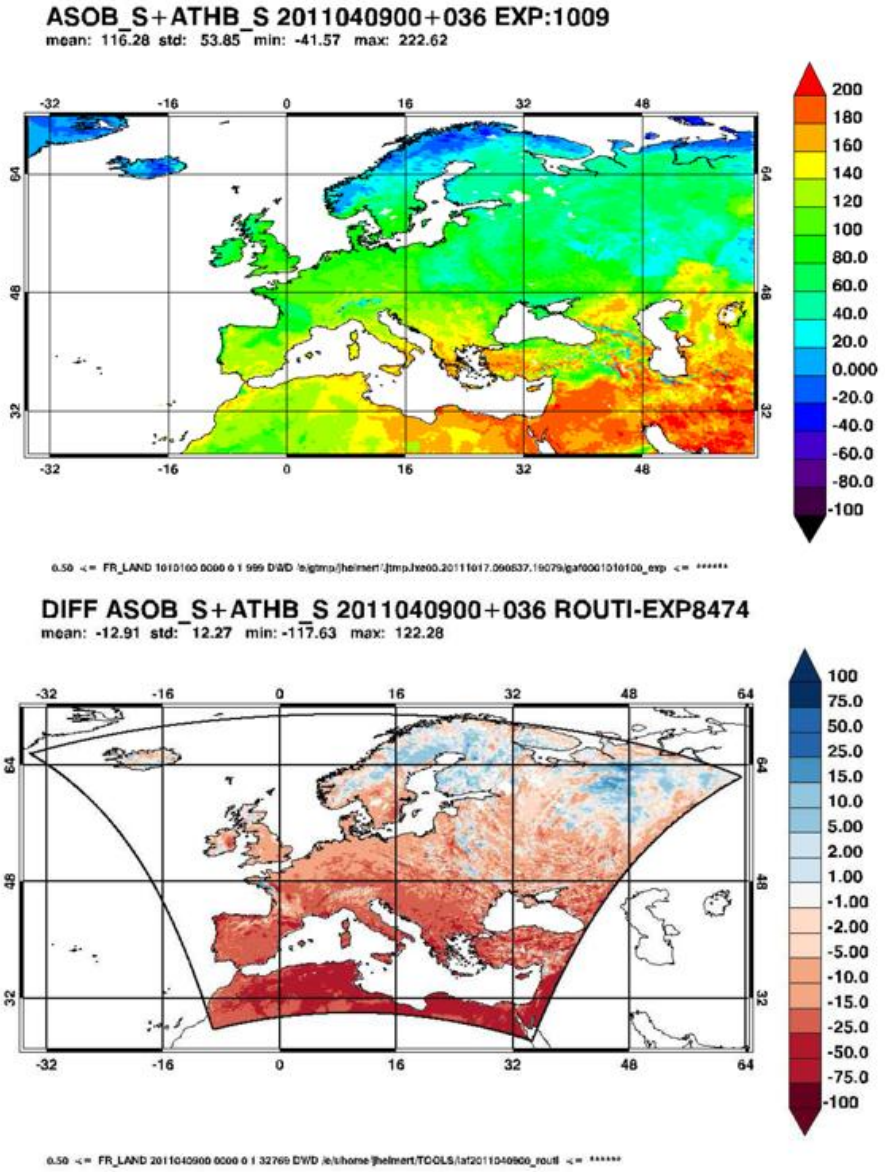

Figure 2: Averaged fluxes of solar and thermal radiation at surface (W/m^{-2}) at 10th April 2011 12 UTC for 36 hours forecast of the GME experiment 109/1009 (top) and difference between COSMO-EU routine and experiment 8474 (bottom)

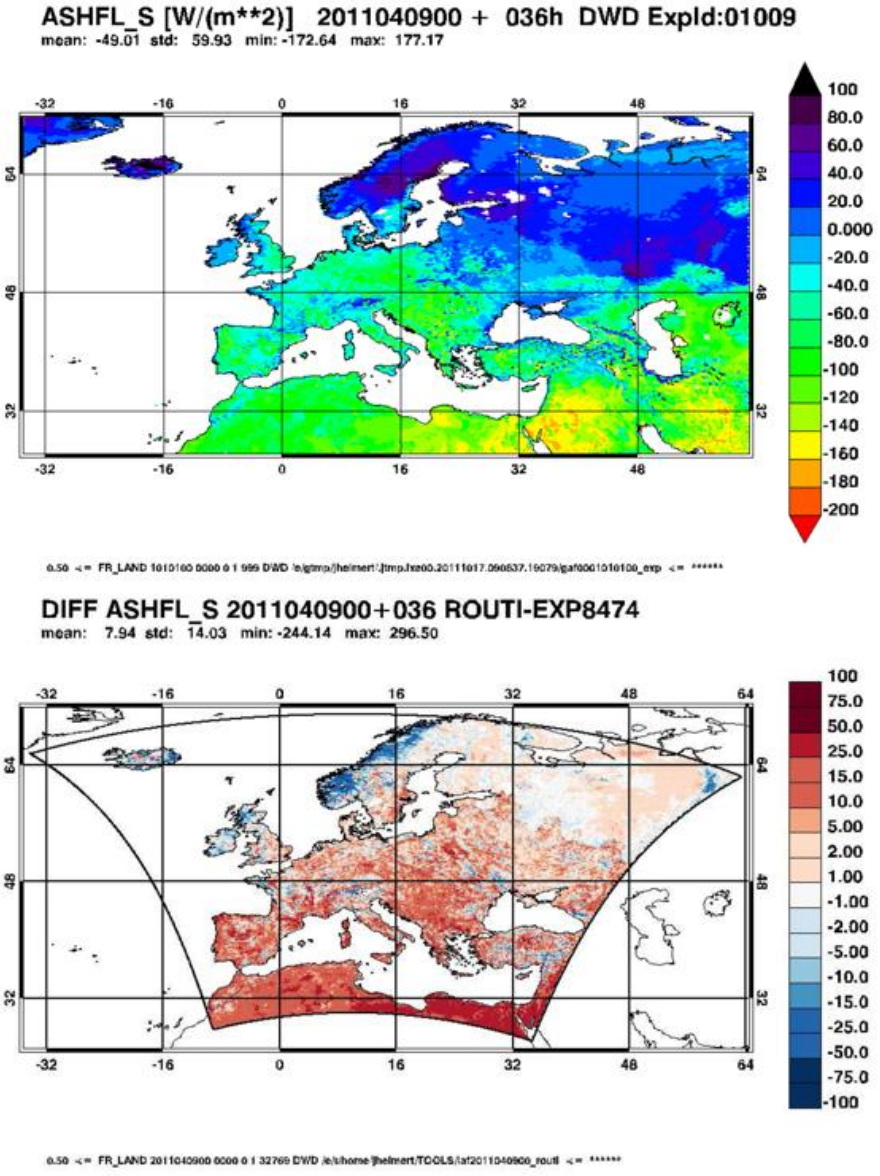

Figure 3: Flux of sensible heat (Wm^{-2}) averaged over 36 hours forecast time at 10th April 2011 12 UTC of the GME experiment 109/1009 (top) and difference between COSMO-EU routine and experiment 8474 (bottom).

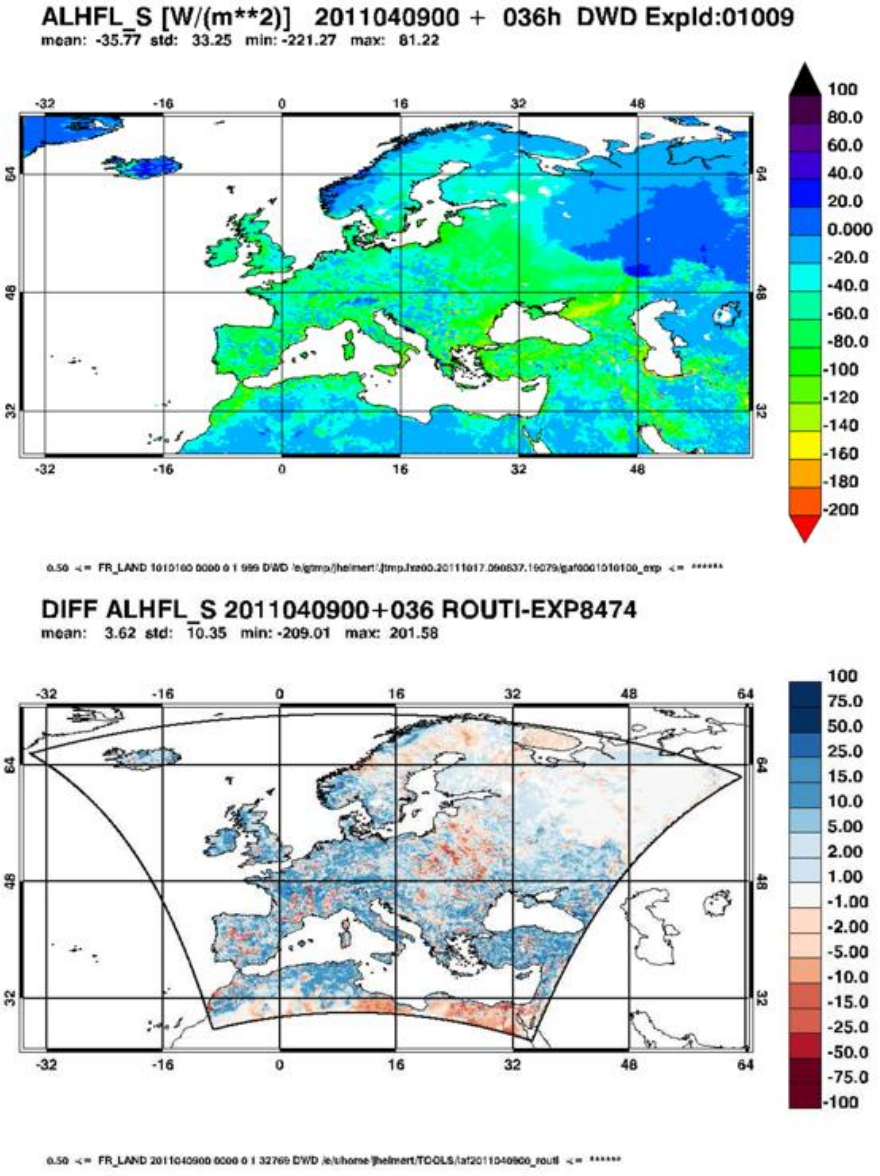

Figure 4: Flux of latent heat (Wm^{-2}) averaged over 36 hours forecast time at 10th April 2011 12 UTC of the GME experiment 109/1009 (top) and difference between COSMO-EU routine and experiment 8474 (bottom).

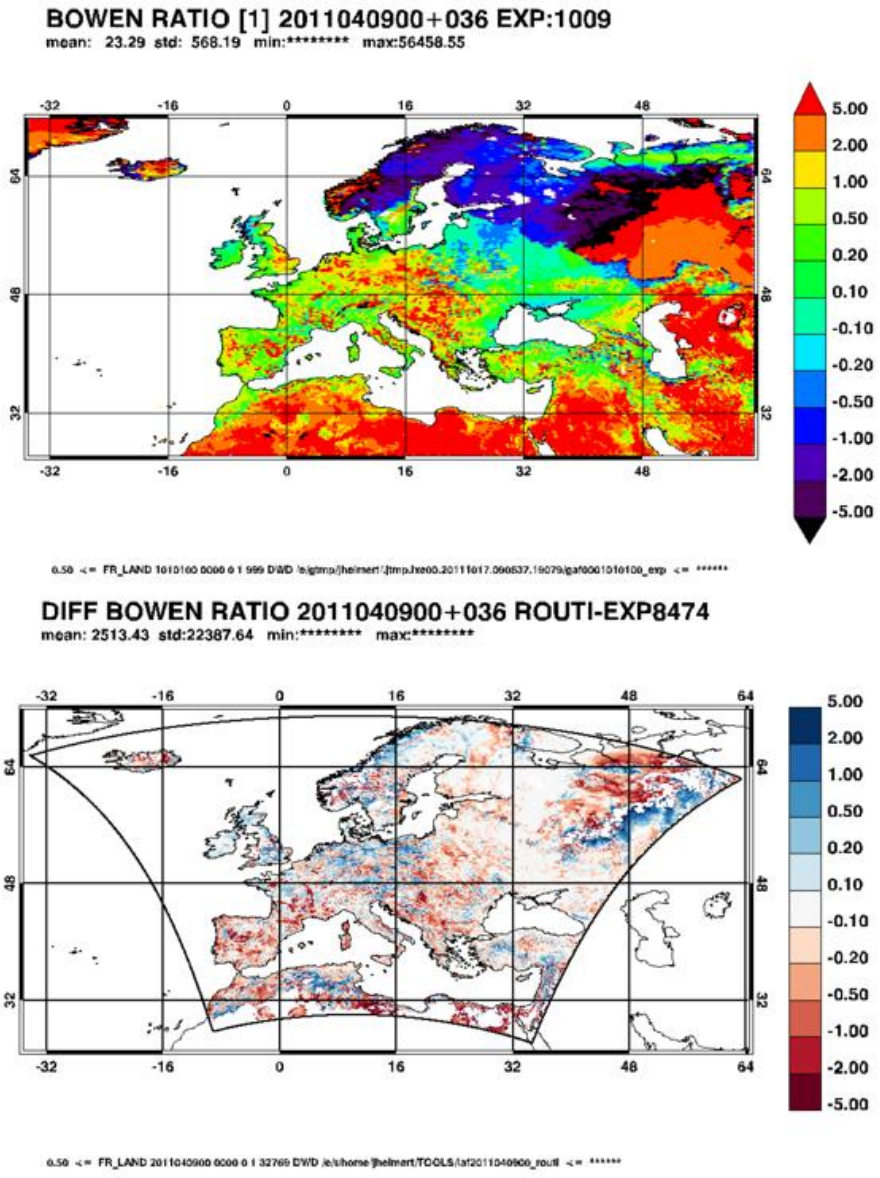

Figure 5: Bowen ratio based on flux of sensible and latent heat averaged over 36 hours forecast time at 10th April 2011 12 UTC of the GME experiment 109/1009 (top) and difference between COSMO-EU routine and experiment 8474 (bottom).

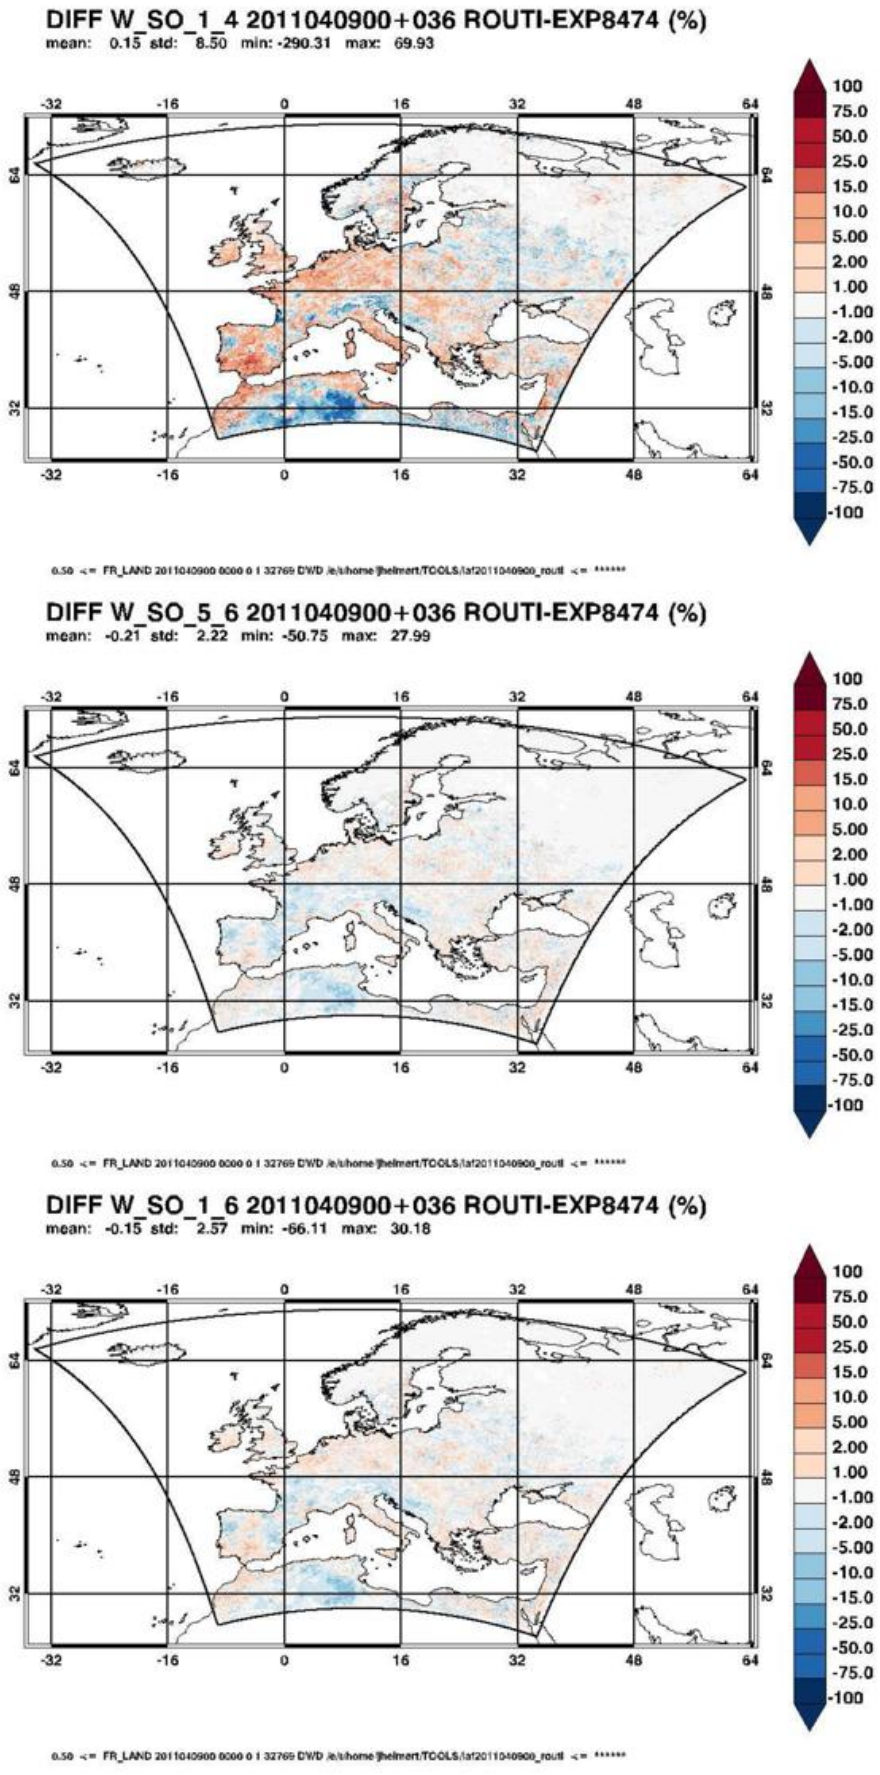

Figure 6: Difference between COSMO-EU routine and experiment 8474 for soil moisture including upper soil levels 1,2,6,18 cm (a), deeper soil levels 54 cm and 162 cm (b), and soil levels 1,2,6,18,54, and 162 cm (c). Shown is the deviation (%) in comparison to the COSMO-EU routine.

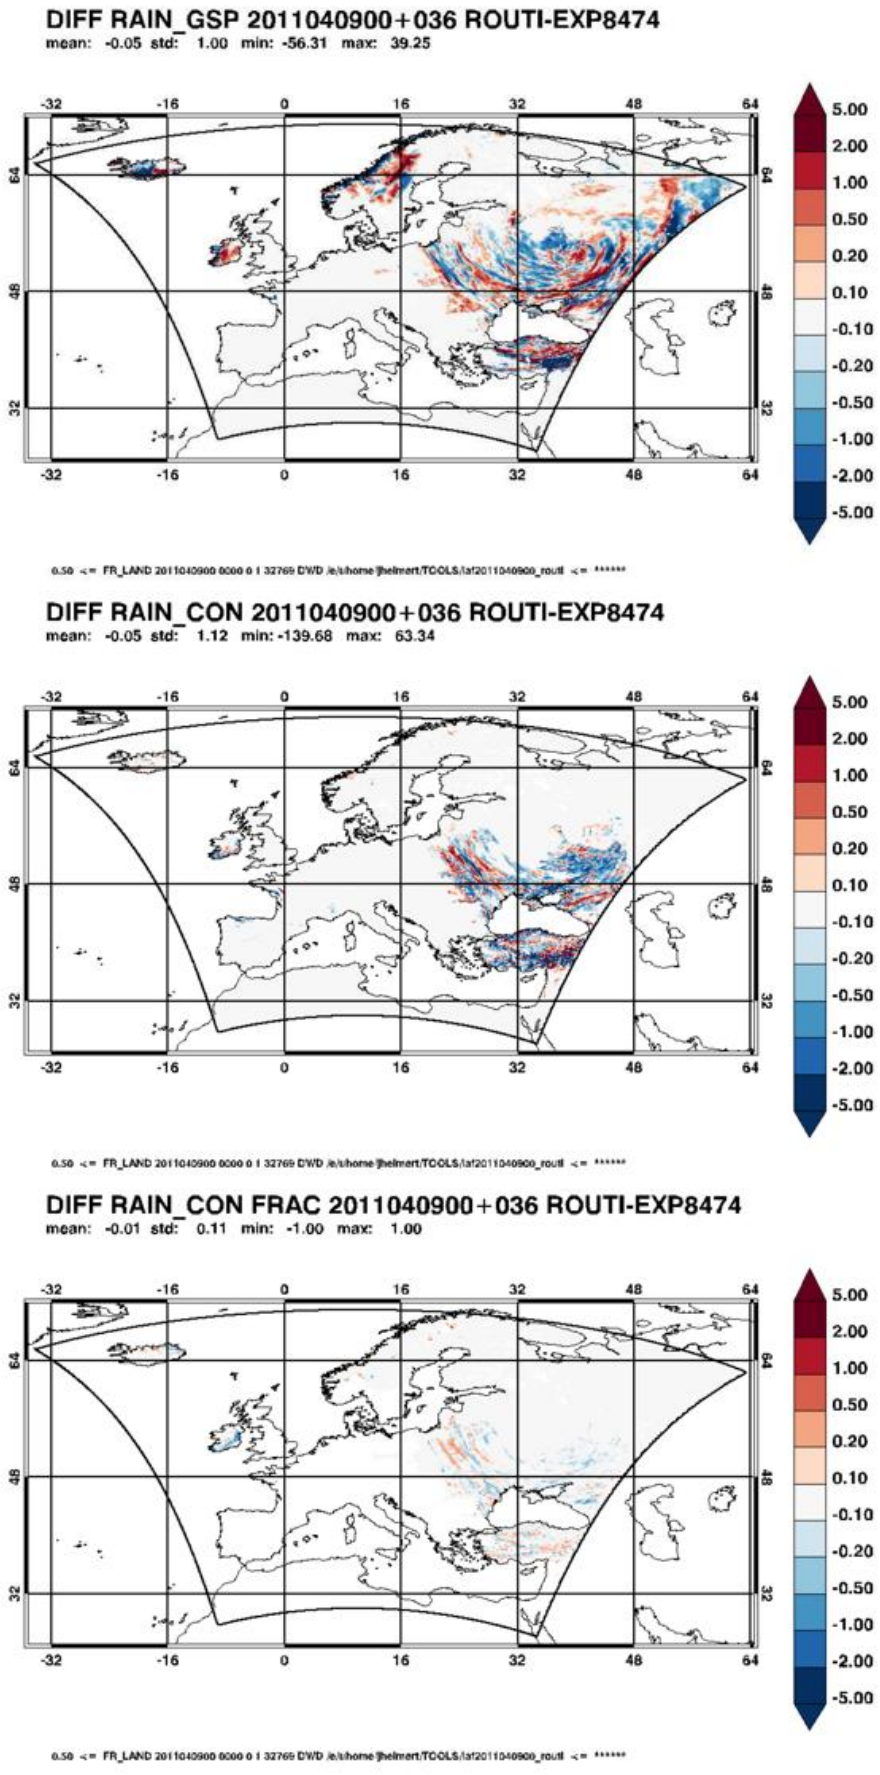

Figure 7: Difference between COSMO-EU routine and experiment 8474 for accumulated precipitation (kgm^{-2}) of grid-scale component (top), convective component (center), and fraction of convective component on total precipitation (grid-scale + convective) (bottom).

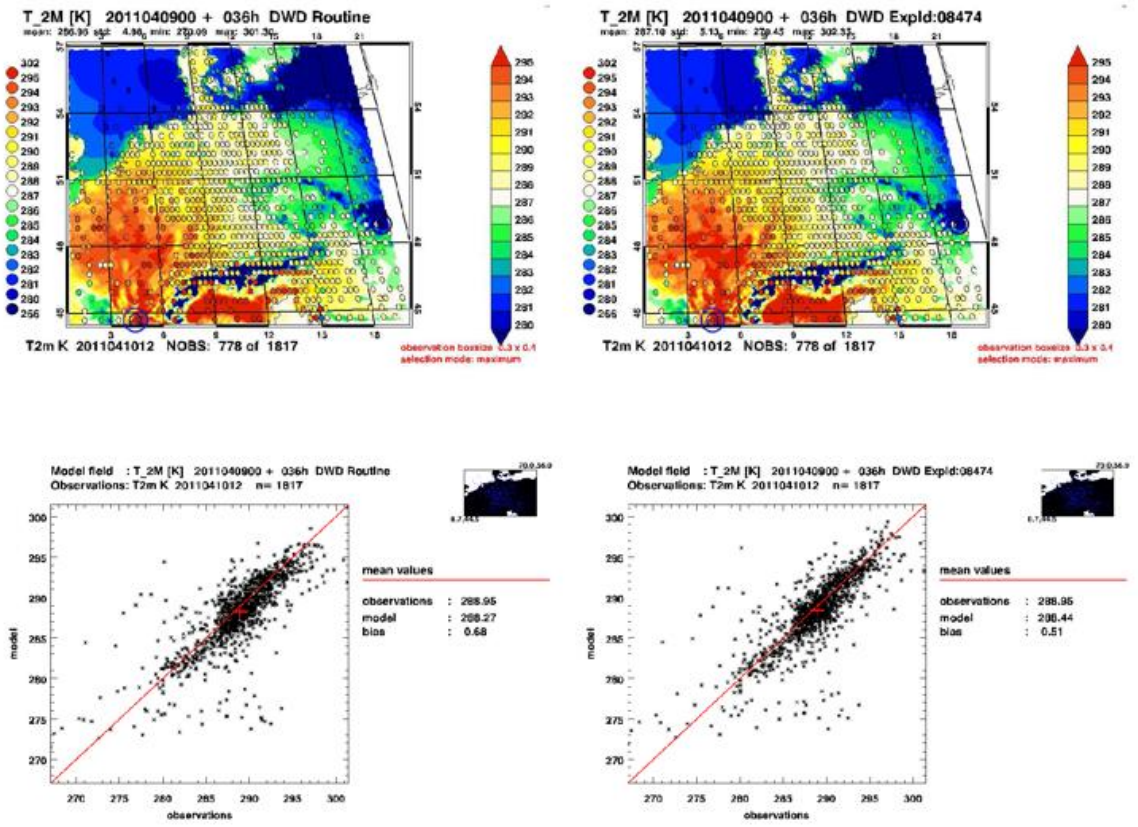

Figure 8: Comparison of 2m-temperature observations at 2011041012 and 36 hours forecast from 2011040900 of COSMO-EU routine (a) and experiment 8474 (b).

To exclude the impact of different cloud conditions in observation and model simulation, the clear sky region in central Europe was used for a validation of the COSMO-EU results with measurements at SYNOP stations. Figure 8 (top) shows that the difference in 2 m-temperature between operational COSMO and COSMO experiment is small, below 0.2 K in the area mean, but some measurements in northern Italy and France are in better agreement with the experiment. The statistical analysis (Fig. 8, bottom) confirms that considering 1817 observations the cold bias of 2 m-temperature of 0.68 K in the operational COSMO decreased in the experiment by 0.17 K that is mainly due to a better representation of 2 m-temperatures above 290 K in the experiment. This behaviour can be related to the impact of the aerosol climatology from Tegen et al. (1997).

Due to the changes in external parameters and in the SVAT scheme a feedback on the 2 m-dew point temperature can be assumed. Figure 9 (top) reveals that in area mean the difference in 2 m-dew point temperature of more than 0.4 K between operational COSMO-EU and experiment exceeds the difference in 2 m-temperature and by eye a better agreement with observations in the western region of the selected area can be found. For the 1869 observations the operational COSMO model bias of 2 m-dew point temperature was decreased from 3.10 K by 0.86 K in the experiment. The comparison of the model field with observations (Fig. 9, bottom) shows that a better capture of 2 m-dew point temperature in the range of 270 K to 280 K in the experiment is responsible for this improvement.

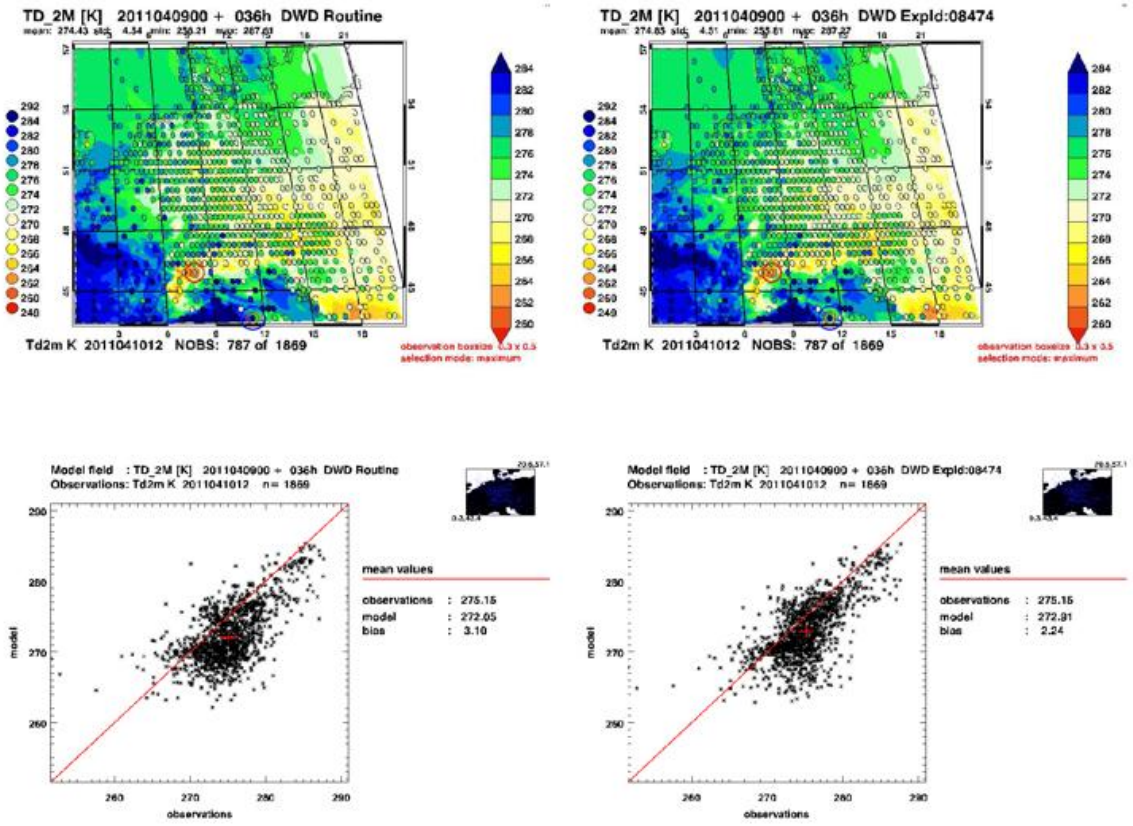

Figure 9: Comparison of 2m-dew point temperature observations at 2011041012 and 36 hours forecast from 2011040900 of COSMO-EU routine (a) and experiment 8474 (b).

4.4 Long-term results

A long-term comparison of the behavior of TERRA in the operational setup and with the new configuration in the soil-moisture analysis environment is available for the global model GME. Based on 24 hours forecasts Fig. 10 shows that the 2 m-temperature bias of GME in Europe (operational and experiment) changes its sign during April to the warm side for summer. Whereas the GME experiment 109/1009 shows similar RMSE values of 2 m-temperature as the operational simulations, the temperature bias in summer, when evapotranspiration of plants is most active in Europe is significantly reduced. Since the SMA diminishes their activity for the experiment by reduced soil water increments in top and bottom SMA layers it could be assumed that this is due to a more realistic behavior of TERRA in the experimental configuration. This assumption is further supported by the comparison of the soil moisture evolution in operational GME and experiment. The unrealistic nearly constant soil moisture in bottom SMA layer is improved by the experiment, which shows a decrease of soil moisture during summer that is confirmed by observations.

For the COSMO simulations an objective verification of the forecasts up to 72 hours against SYNOP stations in the COSMO-EU domain between 1st April 2011 and 30th June 2011 (Fig. 11 and 12) shows as expected largest changes in model bias of 2 m-temperature (TT) and 2 m-dew point temperature difference (TD) and surface pressure (P). However, verification shows a mixed picture. The bias and RMSE of 2 m-temperature and 2 m-dew point temperature difference increased but for surface pressure and 2-m minimum temperature (Tmin) an improvement was observed. In the global skill the experimental setup of COSMO-EU increased by 0.55 % compared to the operational setup.

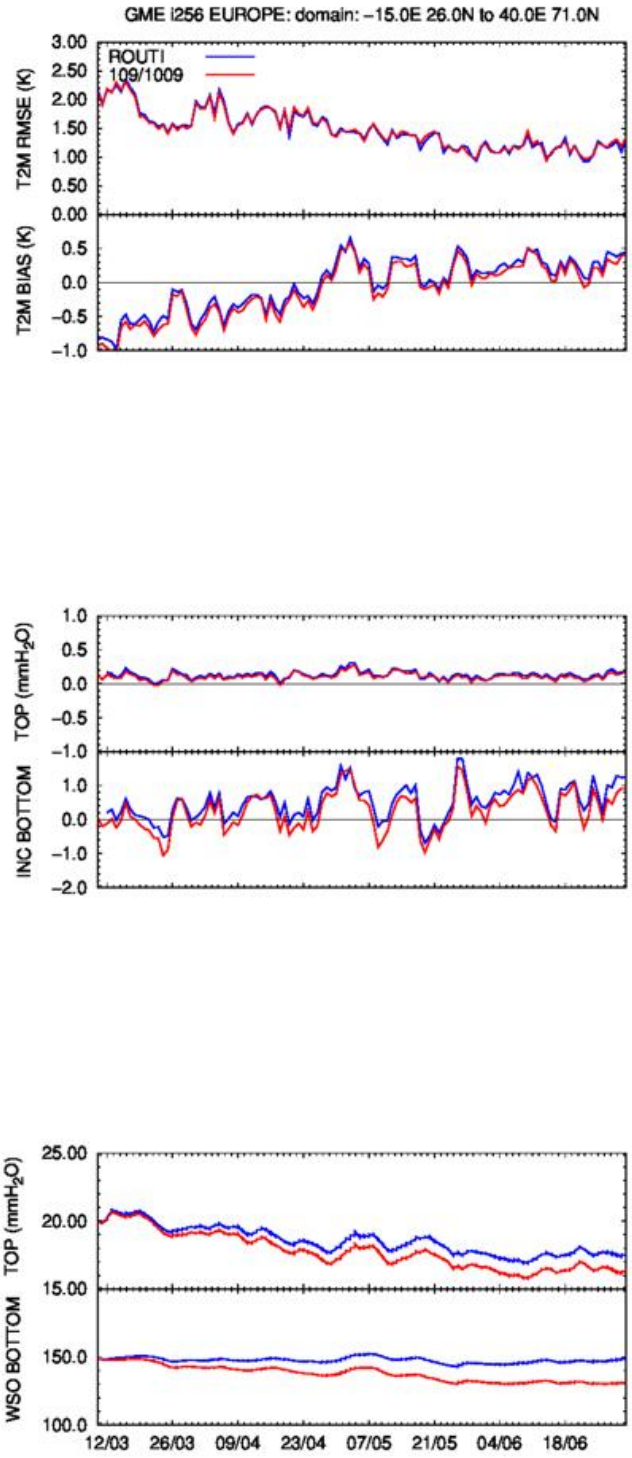

Figure 10: Comparison of operational GME (blue) and GME experiment 109/1009 (red) from soil-moisture analysis monitoring for Europe between 12th March 2011 and 1st July 2011. Shown are RMSE and bias of 2 m temperature (top), soil moisture analysis increments in top and bottom layers (center), and soil moisture evolution for top and bottom layers (bottom).

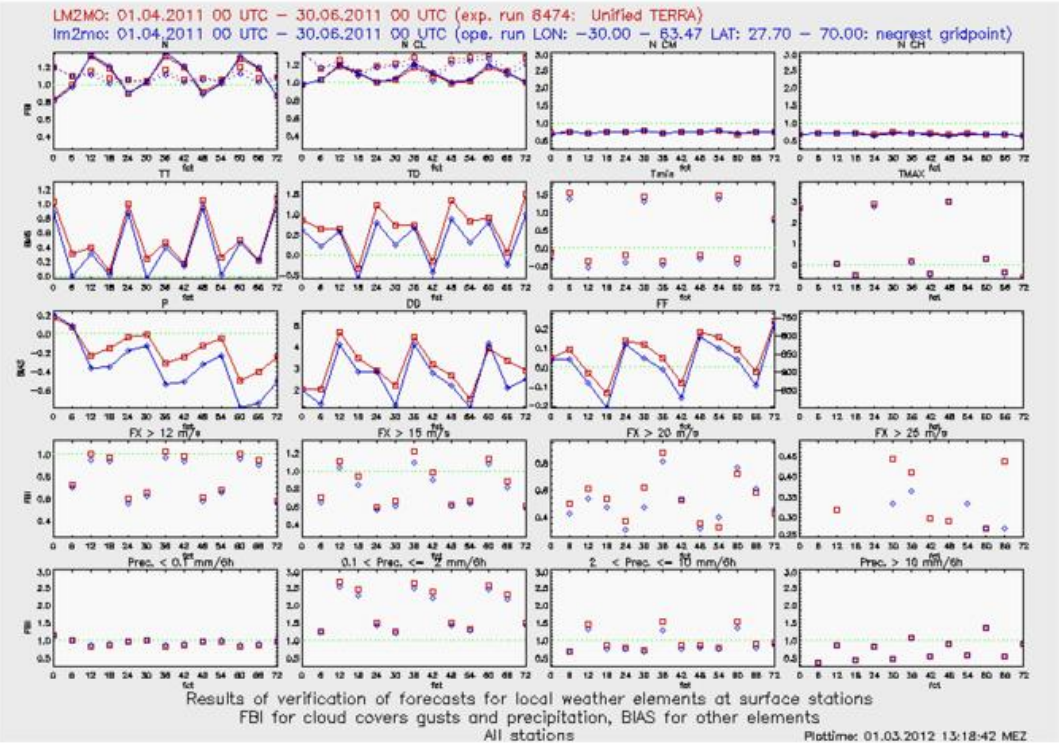

Figure 11: Objective verification up to 72 hours forecast between 1st April 2011 00 UTC and 30th June 2011 00 UTC in the model domain of operational COSMO-EU (blue) and numerical experiment 8474 (red). The verification is based on 00 UTC forecasts and considers FBI of cloud coverage (top row), bias of 2 m-temperature, 2 m-dew point temperature, minimum and maximum temperature (second row), surface pressure, wind direction, wind speed, and vector wind (center row), FBI for wind gusts of different threshold (fourth row), FBI for precipitation of different threshold (bottom row).

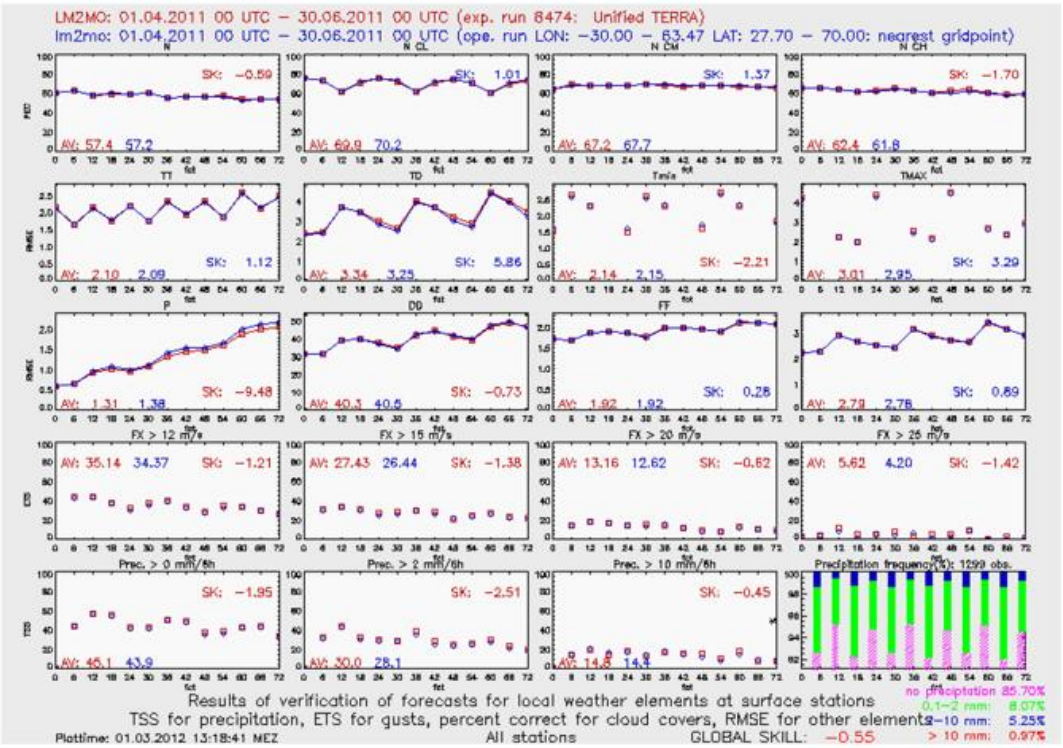

Figure 12: Objective verification up to 72 hours forecast between 1st April 2011 00 UTC and 30th June 2011 00 UTC in the model domain of operational COSMO-EU (blue) and numerical experiment 8474 (red). The verification is based on 00 UTC forecasts and considers PEC of cloud coverage (top row), RMSE of 2 m-temperature, 2 m-dew point temperature, minimum and maximum temperature (second row), surface pressure, wind direction, wind speed, and vector wind (center row), ETS for wind gusts of different threshold (fourth row), ETS for precipitation of different threshold (bottom row).

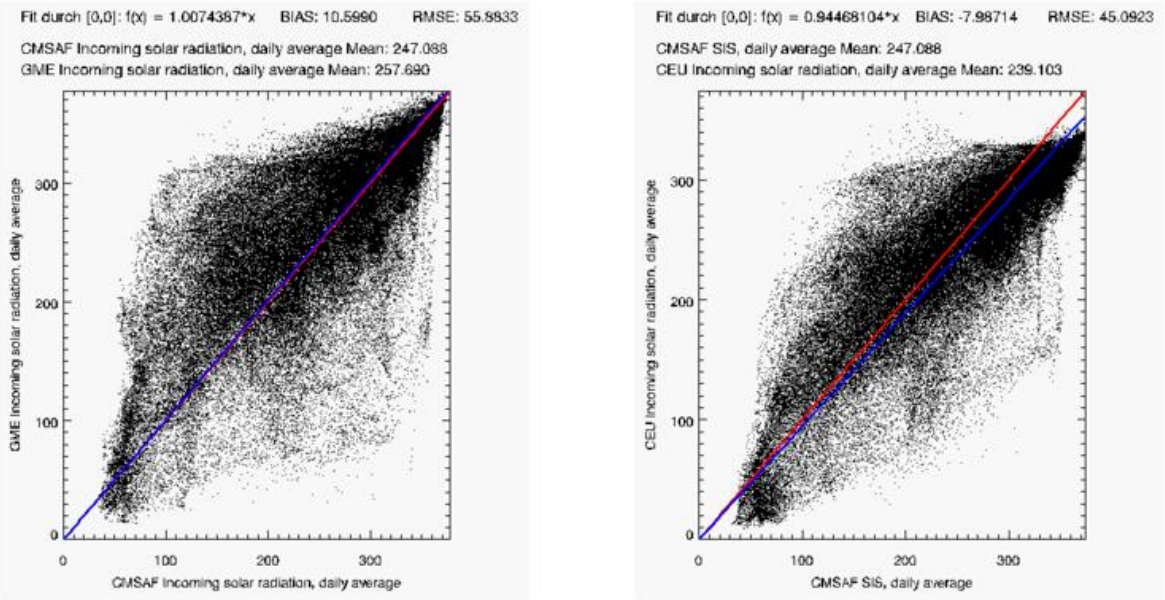

Figure 13: Comparison of the daily averaged solar incoming radiation at surface from the satellite retrieval of CMSAF with GME (left) and COSMO-EU (right) for the 1st June 2013.

4.5 Conclusions

The long-term objective verification over 3 months indicates that considering the global skill the experimental setup improves the operational COSMO-EU in various parameters. However, the question of the increased 2 m-temperature bias and RMSE of the experiment compared to the operational setup remains.

A recent comparison of the satellite retrieval of daily averaged short-wave incoming radiation at surface with COSMO-EU (Fig. 13, right) showed for the operational setup the expected underestimation of incoming solar radiation for cloud-free conditions, i.e. high values of solar radiation, and confirms the conclusions from results of the case study for the 10th April 2011 (Fig. 2, bottom). The comparison with GME supports the application of the aerosol climatology since GME's incoming surface fits better to the satellite retrieval in cloud-free conditions. However an overestimation of solar radiation by COSMO-EU occurs in the intermediate range of incoming solar radiation, corresponding to cloudy conditions. The application of the aerosol climatology with decreased aerosol optical depth in that radiation regime is counterproductive, since it enforces the solar radiation at surface and results in increased 2 m-temperature bias in the experimental setup. Therefore, further investigations are needed to improve the model solar radiation at surface in cloudy conditions.

4.6 Summary and Outlook

This study investigated current uncertainties in the description and simulation of surface characteristics that exist for global and limited area models. The critical issue of the limited knowledge of the external parameters and differences in the soil-vegetation atmosphere transfer model TERRA was considered in numerical experiments with GME and COSMO-EU. These experiments at global and regional scale employed a unified configuration of TERRA. A case study of 36 hours forecasts at 10th April 2011, 12 UTC was used to show the interrelationship between external parameters (e.g. vegetation, aerosol optical depth), surface

radiation budget, fluxes of sensible and latent heat, soil moisture, and screen level (dew point) temperature. For clear-sky conditions it was shown that COSMO-EU with the new configuration improves the agreement with SYNOP measurements compared to the operational setup. Based on 24 hours forecasts of soil-moisture analysis monitoring in Europe a long-term comparison of the behavior of TERRA in spring and summer with the new configuration was performed for the global model GME. It was shown that in connection with a decreased warm 2 m-temperature bias in summer, the SMA diminishes their activity for the experiment by reducing the soil water increments in top and bottom SMA layers, while the soil moisture shows the expected decrease in summer. This improvement on the global scale was traced back to a more realistic behavior of TERRA in the experimental configuration and it is expected that this remains valid in the COSMO-EU. The long-term verification of the COSMO experiment showed an improved global skill compared to the operational setup but further progress is expected after improvement of the surface solar radiation forcing in COSMO for cloudy conditions.

5 Documentation of a new multi-layers snow module (E. Machulskaya)

The snow model that is presented here is a one-dimensional parameterization scheme for the heat and moisture transfer through the snowpack. Two main features of the scheme distinguish it from the snow parameterization scheme that is currently operational in COSMO. First, it allows the water to be in the liquid state within snowpack. Second, the new scheme is multi-layered, i.e. the vertical profiles of temperature, total and liquid water content, and density are explicitly resolved.

The heat and moisture transport through the snowpack is governed by the following set of equations

$$\begin{aligned}
\rho_{sn} C_{sn} \frac{\partial T_{sn}}{\partial t} &= \frac{\partial}{\partial z} \lambda_{sn} \frac{\partial T_{sn}}{\partial z} + L_f (F - M) - \frac{\partial R}{\partial z} \\
\frac{\partial W_{liq}}{\partial t} &= M - F - \frac{\partial q}{\partial z} \\
\frac{\partial W_{tot}}{\partial t} &= -\frac{\partial q}{\partial z} \\
\frac{\partial \rho_{sn}}{\partial t} &= \frac{\rho_{sn}}{W_{tot}} \left(-\frac{\partial q}{\partial z} \left(1 - \frac{\rho_{sn}}{\rho_w} \right) + \rho_{sn} \frac{\rho_w - \rho_i}{\rho_w \rho_i} (M - F) \right) + \sigma(t),
\end{aligned} \tag{1}$$

where T_{sn} is snow temperature, W_{liq} is specific liquid water content, W_{tot} is specific total water (liquid + solid) content, C_{sn} is specific heat capacity of snow, ρ_{sn}, ρ_w and ρ_i are densities of snow, water and ice, respectively, λ_{sn} is snow heat conductivity, L_f is latent heat of freezing, M and F are melting and refreezing rates, respectively, q is the liquid water flux, R is radiative heat flux, and $\sigma(t)$ characterizes the impact of gravitational compaction and metamorphism on snow density.

The first equation is an expression for the energy conservation law. As can be seen, snow temperature changes may be caused by the heat diffusion, latent heat release due to water phase changes (melting of solid part and refreezing of liquid part), and solar radiative heating that can occur not only at the upper snow surface, but also below it. The second equation is the expession for the liquid water balance; the liquid water content may change because of phase changes and percolation of water. The third equation is the total snow water-equivalent balance equation. The fourth equation describes the changes in the snow density. The first and the second terms on the right-hand side of this equation describe the change in snow density due to the changes of the ratio of the solid part (of the ice density) to the liquid part (of the water density). It may occur either because some amount of water is percolated from above (the first term) or because of phase changes (second term). The third term describes the densification of the snowpack due to the weight of the overlying layers and due to internal metamorphism.

Snow heat capacity C_{sn} is computed as

$$C_{sn} = W_{liq} \rho_w C_w + (W_{tot} - W_{liq}) \rho_{dry} C_i,$$

accounting for liquid water content. Here, ρ_{dry} is the density of the solid part of a snow layer and it is equal to

$$\rho_{dry} = \frac{W_{tot} - W_{liq}}{\frac{\rho_w}{\rho_{sn}} W_{tot} - W_{liq}} \rho_w.$$

Snow heat conductivity λ_{sn} depends on snow density and varies therefore with height and time. It is calculated by means of an empirical formula

$$\lambda_{sn} = 2.22 \left(\frac{\rho_{sn}}{\rho_i} \right)^{1.88}.$$

The liquid water flux q consists of precipitation flux at the upper boundary of snow which is provided by the host atmospheric model as an upper boundary condition, and of the flux due to the internal percolation of liquid water within the snowpack. Percolation flux is calculated according to (Colbeck, 1978) as

$$q = \rho_w h \max \left(\left(\frac{W_{liq}/\rho_w - W_{hc}}{\Pi - W_{hc}} \right)^3, 0.0 \right),$$

where $W_{hc} = 0.04$ m^3/m^3 is the volumetric water holding capacity of snow, $h = 0.01$ m/s is snow hydraulic conductivity by maximal liquid water content W_{hc}, and

$$\Pi = 1 - \frac{W_{liq}}{\rho_w} - \frac{W_{tot} - W_{liq}}{\rho_i}$$

is the snow porosity. The percolation flux through the lower boundary of the snowpack is regarded as net snow melting rate and it is used as the upper boundary condition for soil moisture by the soil model.

Radiative heat flux is calculated according to exponential extinction law

$$R(z) = R_0 e^{-\beta z},$$

where R_0 is the net solar radiation flux at the snow-air interface and β is the extinction coefficient. The latter is assumed to be dependent on snow density. A simple linear dependence was constructed based on the data reported in literature

$$\beta = b_1 \rho_{sn} + b_2,$$

where $b_1 = 0.13$ and $b_2 = 3.4$, so that $\beta = 10$ m^{-1} if snow density is 50 kg/m^3 and $\beta = 70$ m^{-1} if snow density is 500 kg/m^3 (fresh snow is more penetrable to sunlight).

Gravitational compaction and compaction due to metamorphism are described by means of the following semi-empirical law:

$$\sigma(z,t) = \frac{\rho_{sn}(z,t)}{\eta(z,t)} \left(\sigma_g(z,t) + \sigma_m(z,t) \right).$$

Here, σ_g describes the effect of gravity and it is equal to the total weight of the overlying layers

$$\sigma_g(z,t) = \int_0^z \rho_{sn}(z') g dz'.$$

The term σ_m describes the compaction due to metamorphism. It is set to a constant value $\sigma_m(z,t) = 75$ Pa.

The factor $\eta(z,t)$ is the compactive viscosity of snow that characterizes the proneness of the snowpack to the deformations due to both abovementioned processes. It is equal to

$$\eta(z,t) = A_1 \exp \left(A_2 \frac{\rho_{sn}(z,t)}{\rho_i} - a W_{liq}(z,t) + \frac{E}{R T_{sn}(z,t)} \right),$$

where $A_1 = 6.6 \cdot 10^{-7}$ Pa $\cdot$ s, $A_2 = 19.3$, $a = 70.0$, $E = 67300$ J/mol is the activation energy and $R = 8.31$ J/(mol K) is the universal gas constant. As can be seen, three characteristics of the snowpack determine its ability to densify: the snow density, liquid water content and snow temperature. The incompacter, warmer, and moister the snowpack is, the easier it shrinks.

Boundary conditions. Since the equation for temperature is of the second order and all other equations of the first order, the first equation requires two boundary conditions, and all other one boundary condition. The upper boundary condition for the temperature transport equation is the heat flux at the snow-air interface, as in the single-layer snow model. The total heat flux is the sum of net solar and infrared radiation, sensible and latent heat fluxes, heat conduction flux into snowpack and the flux of heat which is released by the freezing rain that falls onto the snow surface. Note that the latter flux is not present in the total heat balance in the single-layer snow model.

The upper boundary condition for the total water content also appears in the flux form. It is the precipitation flux, either in the form of snow or in the form of rain. The latter serves also as the upper boundary condition for the equation for liquid water content.

The lower boundary condition for temperature is the conductive heat flux through the soil-snow interface.

The density of the upper surface of the snowpack is determined by the falling snow density. This fresh snow density is calculated as in the single-layer snow model, namely

$$\rho_{fr} = \rho_{frmin} + (\rho_{frmax} - \rho_{frmin}) \frac{T_{air} - T_{min}}{T_0 - T_{min}},$$

where $\rho_{frmin} = 50$ kg/m^3, $\rho_{frmax} = 150$ kg/m^3, $T_{min} = 258.15$ K $= 273.15$ - 15.0 K, $T_0 =$ 273.15K. It is an increasing function of temperature that emulates heavy "moist snow" if the air temperature is close to the melting point.

Numerical implementation. Time discretization. The equation system (1) is solved by means of splitting up method. At the first half time step the heat diffusion is calculated (implicitly), at the second half time step the adjustment is made due to the presence of sources and sinks (explicitly).

The adjustment of the snow temperature and total and liquid water content profiles due to phase changes is made in the one-iteration way. Specifically, if after the temperature diffusion half-step snow temperature T^*_{sn} becomes greater than the melting point $T_0 = 273.15$K, melting is detected ($M > 0$). In this case, if the heat storage excess that should be spent on melting $E = C_i W_{tot}(T^*_{sn} - T_0)\rho_w$ is enough to melt the entire solid part of the layer $W_{tot} - W_{liq}$ (i.e. $E \geq L_f \rho_w (W_{tot} - W_{liq})$), then the melting rate is $M = (W_{tot} - W_{liq})/dt$, the whole layer becomes liquid ($W_{liq} = W_{tot}$), and the rest of energy is transferred into the underlying layer. Otherwise, if the heat stored in the layer is not enough to melt the entire solid part of the layer, it is spent to melt a part of it, the melting rate is then $M = C_i W_{tot}(T^*_{sn} - T_0)/(L_f dt)$ and liquid water content increases by $W_{liq} = W_{liq} + C_i W_{tot}(T^*_{sn} - T_0)/L_f$. In both cases, the temperature of the layer is set to $T^{new}_{sn} = T_0$.

Refreezing rate F is calculated in a similar way. $F > 0$ if the temperature of a layer T^*_{sn} after the diffusion half-step becomes less than the melting point T_0 but some amount of liquid water is present. In this case, if T^*_{sn} is low enough that the whole amount of liquid water can refreeze (i.e. $E = C_i W_{tot}(T_0 - T^*_{sn})\rho_w \geq L\rho_w W_{liq}$), then the new liquid water content is $W^{new}_{liq} = 0$ and temperature of the layer increases by latent heat release as $T^{new}_{sn} = T^*_{sn} + W_{liq} L_f/(W_{tot} C_i)$. Otherwise, if not all the liquid water can freeze, then a part

of it freezes, namely, W_{liq} becomes $W_{liq}^{new} = W_{liq} - C_i W_{tot}(T_0 - T_{sn}^*)/L_f$ and temperature T_{sn}^{new} is set to T_0.

Space discretization. The vertical grid consists of a constant number of layers that is fixed by user with setting the name-list variable *ke_snow*. At each time step the thickness of a layer can change:

1) due to changes in snow density of the layer whereas the total mass of the layer conserves but phase changes occur;

2) due to mass flux as some amount of water percolates from the overlying layer and/or into the underlying layer;

3) the thickness of the uppermost layer can increase if fresh snow has fallen.

Due to these processes the vertical grid becomes irregular even if it is regular at the initial time step. Thus, at the end of the time step a regularization is performed in order to return the grid to the regular one. This procedure sets new equidistant heights of layers and linearly interpolates snow temperature, density, total water and liquid water content values from the old grid to the new one.

To switch between the single-layer and multi-layer snow model the name-list logical variable *lmulti_snow* is used.

6 Implementation of the Martilli Urban Surface Parametrization in COSMO (O. Fuhrer, C. Muller, G. Fontannaz)

6.1 Introduction

Meteorological information has become more and more important in our society, as many activities and life being are largely influenced by the weather. For example, air and maritime transport security, air quality control, global change study, natural disaster forecast, water resources management or simply freetime activities require meteorological forecast and/or analysis. Our capacity to forecast the weather has hence became a great issue. Today half of the worlds' population lives in urban areas, where a wide variety of human activities takes place. Meteorological forecast needs are very important for urban area even if it represents only 0.05 % of the Earth's surface. In order to answer at best to these needs, the numerical forecast models are used. The quality of the information delivered by such models are strongly dependent on their resolution. During the last decade, computers performances have strongly increased, making it possible to constantly improve the model resolution. Being able to take into account finer scale and hence smaller geomorphological features, we could expect an improvement of the model results accuracy. However, results are only improved when different parametrizations, which take into account subgrid effects and the Earth's surface representation (landuse), are regularly updated to fit with the increasing resolution.

Concerning the Earth's surface fluxes exchanged with the atmosphere, increase of the model resolution have led to the adaptation of surface exchange parametrizations to take into account urbanized areas reproduced in mesoscale models by high resolution landuse database. Different solutions are available in order to parametrize the urban area in weather forecast models. The most common is based on the Monin-Obukhov Similarity Theory (MOST), which assumes that a stable surface layer develops above the ground and where turbulence is constant in time and space. A more sophisticated solution is to use Urban Canopy Models (UCM), where the surface fluxes are solved by taking into account buildings, different surfaces of city (roof, road and wall) and their interactions with the atmosphere (Martilli et al., 2002; Masson, 2000). In this study, we investigate the capacity of two parametrization (a MOST based scheme and an UCM) to reproduce the urban area effects in a Numerical Weather Prediction (NWP) model. We focus on the Urban Heat Island (UHI) which is a typically phenomenon for urban areas and relatively easy to measure and quantify. For this purpose, the model of the Swiss Federal Office of Meteorology and Climatology (MeteoSwiss) is used. This mesoscale model called Local Model (LM) uses a traditional urban area parametrization (dry soil and adapted surface roughness) based on MOST. It is used for operational numerical weather prediction since 2001 with a horizontal resolution of 7 km on a domain covering most of western Europe.

In order to see if LM is able to reproduce the urban effect, it is applied to the City of Basel, a mid-size city situated in Switzerland, where an extensive meteorological measurement campaign has been conducted in the city of Basel under the BUBBLE project (Basel UrBan Boundary Layer Experiment) (Rotach et al., 2005) from summer 2001 to summer 2002. This experiment investigates in detail the boundary layer structure over a city. Different modeling studies have been conducted in relation with this experiment (Roulet, 2004; Hamdi, 2005), but none of them with an operational model able to take into account numerous phenomenon, *i.e.* clouds, rain, snow, etc. In this report, the ability of LM to reproduce urban effects, and more particularly the UHI, is evaluated using BUBBLE measurement data as reference, first with the operational configuration of the model, and then with a finer horizontal and vertical resolution. In a second step, we focus on an urban canopy model developed by Martilli et

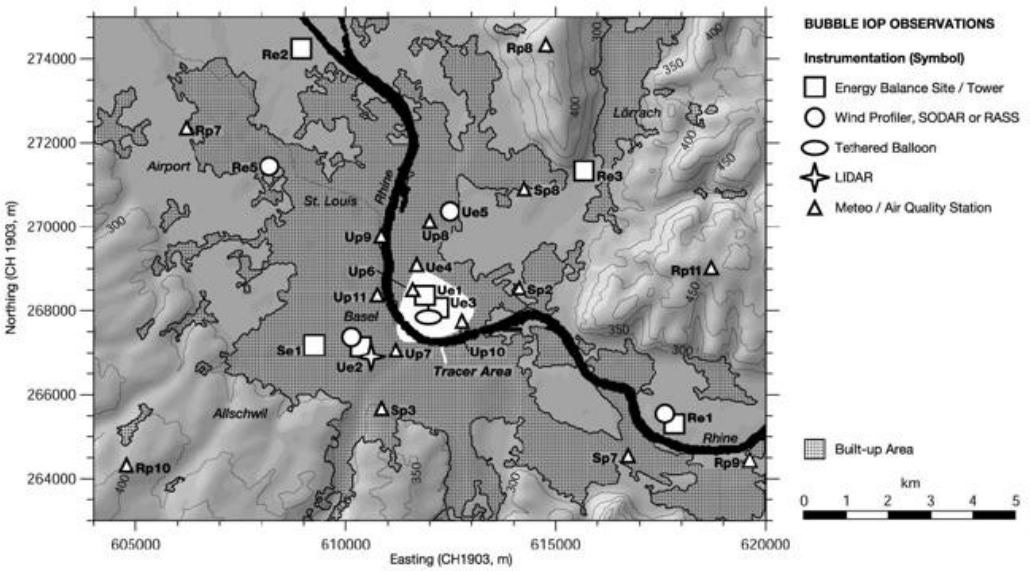

Figure 18: Map of the greater area of the city of Basel with an overview of all sites operated during the BUBBLE IOP in June/July 2002. The thick black line denotes the river Rhine. A complete list of the measuring stations can be found in Appendix 6.9.1

al. (2002). This Urban Effects Parametrization (BEP) is presented and implemented into LM. This implementation and its ability to reproduce the urban effects in LM for the case of Basel city are then evaluated and discussed.

6.2 Bubble

6.2.1 The Experiment

The City of Basel is located in the North-Western part of Switzerland and borders both France and Germany. It is the Switzerland's third most populous city with 190,000 inhabitants. It is situated on the Rhine river, at an altitude of about 260 m and surrounded by gentle but non-negligible topography (750m).

The Basel UrBan Boundary Layer Experiment (BUBBLE) took place from August 2001 to July 2002. Its main goal is to study boundary-layer and surface-exchange processes over different types of surfaces (*i.e.* urban, sub-urban and rural) and their role in the transport and diffusion of air pollution. A more complete description of BUBBLE can be found in Rotach et al. (2005) and on the BUBBLE website. For that purpose, two meteorological towers for turbulence measurements, a Lidar and wind profiler were operated. An Intensive Observation Period (IOP) took place from 15 June and 12 July 2002, with additional surface towers, sodars and tethered balloons (Fig. 18).

6.2.2 Measurements of the UHI

In contrast to rural area, a city represents a dry surface with obstacle (buildings) and a source of anthropogenic heat. The urban area modifies the energy budget, thus creating meteorological differences between urban and rural area. These dissimilarities can be formulated as the differences between urban and rural air temperatures, the first one being usually higher. This phenomenon is called the Urban Heat Island (UHI). As a UHI indicator, averaged and height corrected surface temperature observations within the city are

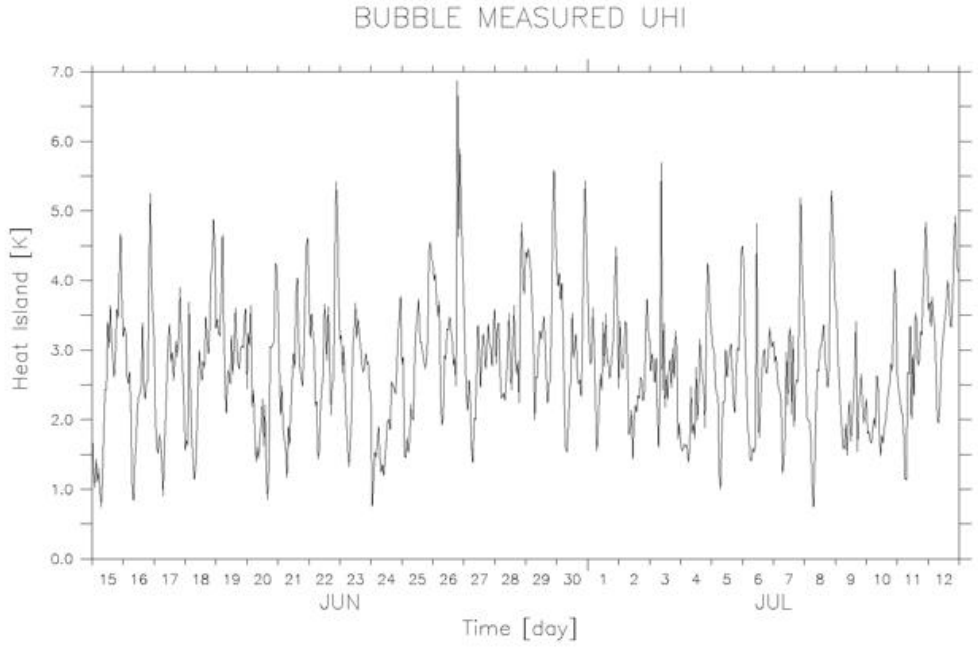

Figure 19: The UHI measured for the city of Basel at 2mAGL during the BUBBLE IOP in June/July 2002

compared with measurements from surroundings rural areas. The BUBBLE campaign provide temperature measurements at 2 m height on several representative sites for urban or rural conditions. Averaging temperature in both areas (urban and rural) allow to obtain a temperature difference between the city and its surroundings, which can be assimilated to the UHI. Figure 19 shows this averaged temperature difference between urban and rural area measured during the IOP. It is always positive and varies from 0.7 to 6.9 °C with an average of 2.8 °C. If we look at the weather bulletin (Appendix 6.9.2) during the IOP, the period from 25 to 27 June is characterized by a very constant meteorological situation and strong daily cycle. The mean UHI over this episode is representative for the IOP with an average of 3.0 °C. This episode is used to study UHI formation over Basel. Furthermore, it corresponds to the period studied by Roulet (2004).

In the following, an in-depth analysis of this UHI episode using measurements and numerical simulations is presented.

6.3 The COSMO Model

6.3.1 Model Description

The LM (Lokal-Modell[1]) is developed within the framework of the COnsortium for Small-Scale MOdeling (COSMO) bringing together the National Weather Services from Switzerland, Italy, Poland and Greece under the lead of the National Weather Service of Germany (DWD). LM is a nonhydrostatic fully compressible limited-area atmospheric model. It has been designed for both operational Numerical Weather Prediction (NWP) and various scientific applications on the meso-β and meso-γ scales (scales from which the nonhydrostatic effects begin to play an important role on the behavior of the atmospheric fluxes (Orlanski, 1975). The LM prognostic variables are horizontal and vertical cartesian wind compo-

[1]A more detailed description of the LM can be found on the COSMO website.

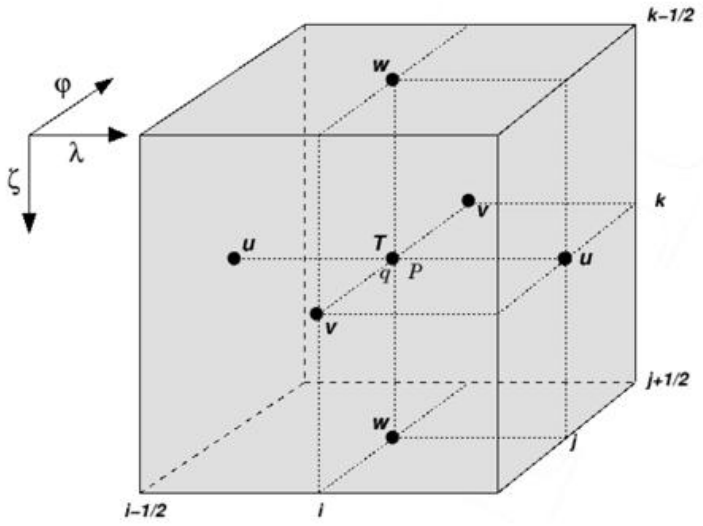

Figure 20: A grid box volume $\Delta V = \Delta\lambda\Delta\phi\Delta\zeta$ showing the *Arakawa-C/Lorenz* staggering of the dependent model variables. The scalar variables T, P and q are defined at the centre (i, j, k) of the box, whereas the normal velocity components are defined on the corresponding box faces $(i \pm 1/2, j \pm 1/2, k \pm 1/2)$.

nents, temperature, pressure perturbations, specific humidity, as well as different cloud water species and turbulence quantities according to the parametrizations chosen for the phenomena. The model is based on the primitive thermo-hydrodynamical equations describing a compressible flow in a moist atmosphere. The model equations are formulated horizontally in rotated geographical coordinates (λ, ϕ) and vertically in a generalized terrain following height coordinate (ζ). These equations are solved numerically using finite difference methods in an Arakawa-C/Lorenz grid (Figure 20 shows a grid box volume). Constant increments $\Delta\lambda, \Delta\phi, \Delta\zeta$ are used to set up the computational grid and the domain is represented by a finite number of grid points (i, j, k). Each of these points is the center of a rectangular grid box volume $\Delta V = \Delta\lambda\Delta\phi\Delta\zeta$.

NUMERICAL INTEGRATION

(a) The Time Integration Scheme

To illustrate the integration used in LM, let consider the model equations in the generic form

$$\frac{\partial\psi}{\partial t} = s_\psi + f_\psi, \tag{2}$$

where ψ denotes a prognostic model variable (u, v, w, T, p' or q), f_ψ the forcing terms due to the slow modes and s_ψ the source terms related to the acoustic and gravity wave modes. Equation 2 is solved using a Kemp-Wilhelmson time-splitting algorithm, where terms related to the slow modes are solved using a large time step dt, whereas the acoustic and gravity waves modes are solved using a small time step $d\tau$. The slow-mode forcing f_ψ is evaluated only once every large time step and kept constant throughout the small time steps, whereas the fast-mode terms contained in s_ψ are calculated for each small time step.

We focus on the turbulent fluxes of heat and momentum which are contained in the slow mode term f_ψ. Horizontal advection is treated explicitly and evaluated at mid-time level n, whereas diffusion evaluated at time level n would be unstable with respect to explicit *Leapfrog* integration scheme. Thus, the computational mixing terms are formulated following a simple forward scheme, *i.e.* they are evaluated at the time level $n-1$. Vertical advection and vertical

turbulent diffusion are treated implicitly using the *Crank-Nicolson* scheme involving the time levels $n-1$ and $n+1$. This results in a vertically coupled set of equations, abbreviated by

$$\frac{\psi^{n+1}-\psi^{n-1}}{2\Delta t} = f_\psi^n = f_\psi(\psi^{n-1}, \psi^n, \psi^{n+1}) \tag{3}$$

Finally for the slow mode tendency $\tilde{\psi}^{n+1}$, evaluating the finite difference equations for u, v, w, T, $p^{'}$ and q from (3) enables to obtain a linear tridiagonal equations system, which may be written in the general form

$$A_k\tilde{\psi}_{k-1}^{n+1} + B_k\tilde{\psi}_k^{n+1} + C_k\tilde{\psi}_{k+1}^{n+1} = D_k(\psi^n, ...), \tag{4}$$

for variables defined on main levels by k ($k = 1, ..., N_\zeta$). Boundary conditions are included in the inhomogeneous term D_k. Thus, we end up with a tridiagonal matrix of dimension $(N_\zeta) \times (N_\zeta)$, which can be solved by Gaussian elimination in LM.[2]

(b) Land-Surface Scheme

The turbulent mixing terms for temperature, moisture variables and horizontal momentum (in both directions u and v) are related respectively to the turbulent fluxes of sensible heat ($\hat{H}^3$), moisture (F_q^3) and momentum (τ^{13} and τ^{23}) respectively. These fluxes are defined at model half levels and at the horizontal position corresponding to the transported quantity. The calculation of the mixing terms requires boundary conditions for turbulent fluxes at the top ($\zeta = 1/2$) and at the bottom ($\zeta = N_\zeta + 1/2$) half level of the model , where N_ζ is the number of vertical levels. At the upper boundary, zero flux conditions are specified:

$$\begin{aligned} (\tau^{13})_{\zeta=1/2} = (\tau^{23})_{\zeta=1/2} &= 0, \\ (\hat{H}^3)_{\zeta=1/2} = (F_q^3)_{\zeta=1/2} &= 0 \end{aligned} \tag{5}$$

At the lower boundary, the turbulent fluxes are specified which a standard bulk-transfer scheme using a drag-law formulation [3]:

$$\begin{aligned} (\tau^{13})_{\zeta=N_\zeta+1/2} &= \tau_{sfc}^{13} = -\rho C_m^d |\vec{v}_h| u, \\ (\tau^{23})_{\zeta=N_\zeta+1/2} &= \tau_{sfc}^{23} = -\rho C_m^d |\vec{v}_h| v, \\ (\hat{H}^3)_{\zeta=N_\zeta+1/2} &= \hat{H}_{sfc}^3 = -\rho C_h^d |\vec{v}_h| (\theta\pi_{sfc} - T_{sfc}), \\ (F_{q^v}^3)_{\zeta=N_\zeta+1/2} &= (F_{q^v}^3)_{sfc} = -\rho C_h^d |\vec{v}_h| (q^v - q_{sfc}^v), \end{aligned} \tag{6}$$

where u, v, θ and q^v are the horizontal velocity components, the potential temperature and the specific humidity at the lowest grid level above the surface ($\zeta = N_\zeta$). $|\vec{v}_h|$ is the absolute horizontal wind speed at the same level. C_m^d denotes the drag coefficient for momentum exchanges at the ground and C_h^d is the bulk-aerodynamical transfer coefficient for turbulent heat. The transfer coefficient for moisture is assumed to be equal to the one for heat in LM. The air density ρ is evaluated from the surface values for temperature, pressure and humidity. Temperature and specific humidity at the ground are either provided by the soil model or externally specified, whereas the surface pressure is determined by hydrostatic extrapolation of the total pressure $p = p_0 + p^{'}$ at the first layer above the ground. The transfer coefficients C_m^d and C_h^d are calculated diagnostically and derived from the Monin-Obukhov Similarity Theory (MOST). Similarity theories are empirical relationships for variables of interest when our knowledge of the governing physics is insufficient to derive laws based on first principles (Stull, 1988). MOST is a first order approximation usually applied to the surface layer and assumes constant fluxes. Thus, in order to apply MOST for surface fluxes parametrization,

[2]The matrix diagonal terms A_k, B_k and C_k, as well as the D_k-term are derived in Doms et al. (2002a).
[3]As described in the Part II of the LM documentation (Doms et al., 2002b).

Table 2: Characteristic parameters for urban and built up areas in TERRA_LM: z_0 is the surface roughness.

Land use class	z_0 [m]	root depth [m]	plant cover		leaf area index	
			Max	Min	Max [-]	Min [-]
urban and built up land	1.00	0.60	10%	5%	4.70	0.10

the lowest grid layer of the model must be within the constant-flux layer. Usually, the top of the surface layer in rural areas is in the range of 10m to 30m.

THE SOIL AND VEGETATION MODEL

Surface fluxes represent the lower boundary conditions for the atmospheric part of the model. Their calculation requires temperature and specific humidity as input in the first soil layer predicted by the soil model. For land surfaces, the multi-layer soil model TERRA_LM (Doms et al., 2002b) provides surface temperature and specific humidity at the ground to the LM model. Most parameters of the soil model (heat capacity, water storage capacity, volume of voids, etc.) strongly depend on soil texture. Five different types are distinguished: sand, sandy loam, loam, loamy clay and clay. Three special soil types are considered additionally: ice, rock and peat. The ground temperature is calculated by the equation of heat conduction which is solved in an optimized two-layer model, to which a third layer called the climatological layer, characterized by constant temperature, is added. The urban and built-up land are described as a loam-clay soil with specific parameters described in Table 2. The temperature at 2 m Above Ground Level (AGL) is computed diagnostically from the ground surface temperature and the temperature in the first model layer according to the land-surface scheme *i.e.*, the Monin-Obukhov Similarity Theory.

6.3.2 MeteoSwiss Operational Implementation

Since April 2001, a nonhydrostatic mesoscale model (COSMO), is used at MeteoSwiss for operational Numerical Weather Prediction (NWP). The current (fall 2006) Swiss version of the model has a horizontal resolution of about 7 km. The domain covers most of western Europe. A terrain following vertical coordinate system is used, with 45 vertical layers and about 50 to 100 m vertical resolution in the lowest 2 km of the atmosphere, and an upper level at a geopotential height of 20 hPa. The 2 mAGL temperature is computed according to MOST using the temperature of the first layer and the surface temperature in the model. The operational run of COSMO at MeteoSwiss is performed twice daily, at 1:30 am and 1:30 pm GMT. Calculations are performed on a NEC-SX/5 supercomputer at the Swiss National Supercomputing Center (CSCS) in Manno (TI). A 72 hour forecast takes roughly 70 minutes real-time. Accurate initial conditions are generated with an additional assimilation system, using observations within the model domain (*e.g.* wind profiler). Boundary conditions are taken from the global model of the European Center for Medium-Range Weather Forecasts (ECMWF) in Reading (UK). A new version, called COSMO2, is currently being developed and tested at MeteoSwiss. It will use a horizontal grid-size of roughly 2 km, a more accurate vertical resolution and is planned to become operational at the beginning of 2008.

Table 3: The main model input parameters are: nx and ny the number of urban grid point in each horizontal direction, ny the number of layer on the grid, dx and dy the horizontal grid resolution, dz_{ground} the lowest layer depth and dt the slow modes time step

The main model input parameters	
nx	13
ny	13
nz	45
dx dy	7 km
dz_{groud}	60 m
dt	12 min
episode	25 to 27 June 2002 (72h)

6.3.3 Model Setup

For this study, the operational COSMO configuration is used, with a domain size limited to the Basel area. The computed domain centered on the city of Basel is 13 by 13 grid point for a total surface of 8281 km^2 with a 7 km horizontal resolution. The vertical resolution is 60 m for the lowest model layer. Boundary conditions are taken from the hourly analysis of COSMO computed by MeteoSwiss and are interpolated to our domain. The run lasts 72 hours and covers the 3 days described above, *i.e.* 25 to 27 June, 2002. The main model configuration parameters are summarized in Table 3.

6.4 COSMO vs. Measurements

A general overview of the model performance for the selected episode is presented in this section. In general, the model shows good agreement with the observed meteorological conditions. As the model is driven using analysis for boundary conditions, this is to be expected. In the following, the computed surface fields over the target area, *i.e.* the city of Basel and its immediate rural surroundings, are analyzed and compared to observations. The computed temperature is generally in good agreement with the measurements in rural area. Figure 21 shows the measured temperature averaged over several rural measuring sites (cf. map in Fig. 18) and the computed temperature averaged over the corresponding grid points. The computed maximum temperature at 2 mAGL in rural area occurs one hour earlier and is 0.5°C lower compared to the measurements for the first two days. During nighttime the simulated temperature fits very well to the measurements. However simulated temperature in urban area are too low by 1.5 to 3.0 °C (Fig. 22). The difference between the urban and rural temperature corresponds to the UHI. Figure 23 shows the measured and computed UHI over the city. The averaged computed UHI is 0.14 °C, hence showing no significant temperature difference between urban and rural areas. The temperature in the city is even regularly lower than the temperature in the rural area, particularly during nighttime. As a conclusion, COSMO with the operational configuration is not able to reproduce the UHI and underestimates the magnitude of the urban-rural temperature difference. One possible reason is a too low horizontal and vertical resolution:

- With a 7 km **horizontal resolution**, the city of Basel fills only one grid point; a finer horizontal resolution would allow to represent the city more accurately.
- The COSMO **vertical resolution** used is too low. An accurate representation of

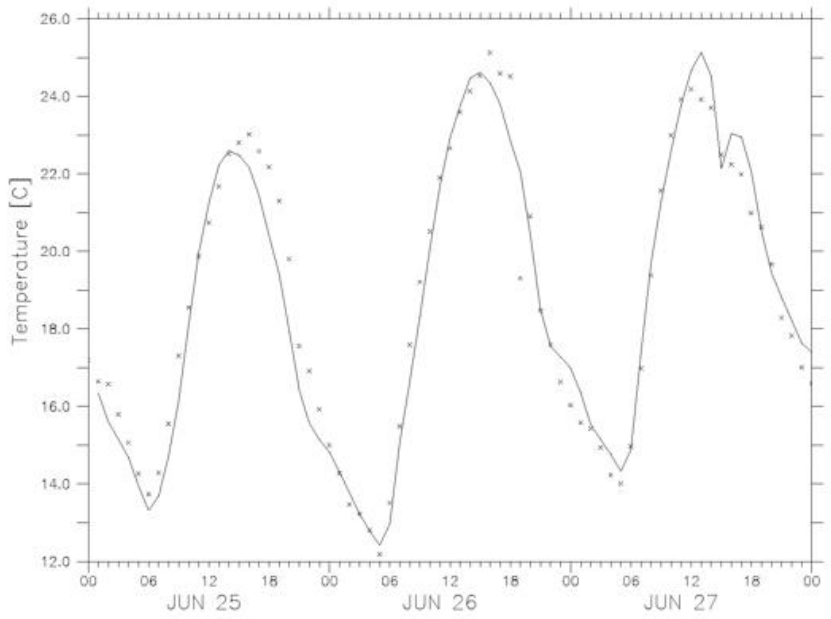

Figure 21: temperature at 2mAGL in rural areas for the period June 25 to 27, measured (crosses) and computed by COSMO (solid line) with the operational configuration.

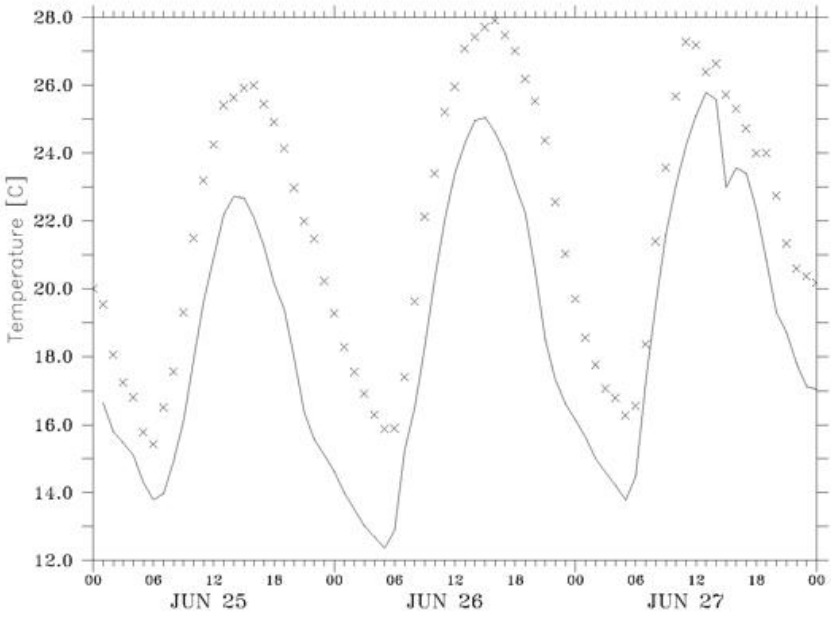

Figure 22: Temperature at 2mAGL in urban areas for a the period June 25 to 27, measured (crosses) and computed by COSMO (solid line) with the operational configuration.

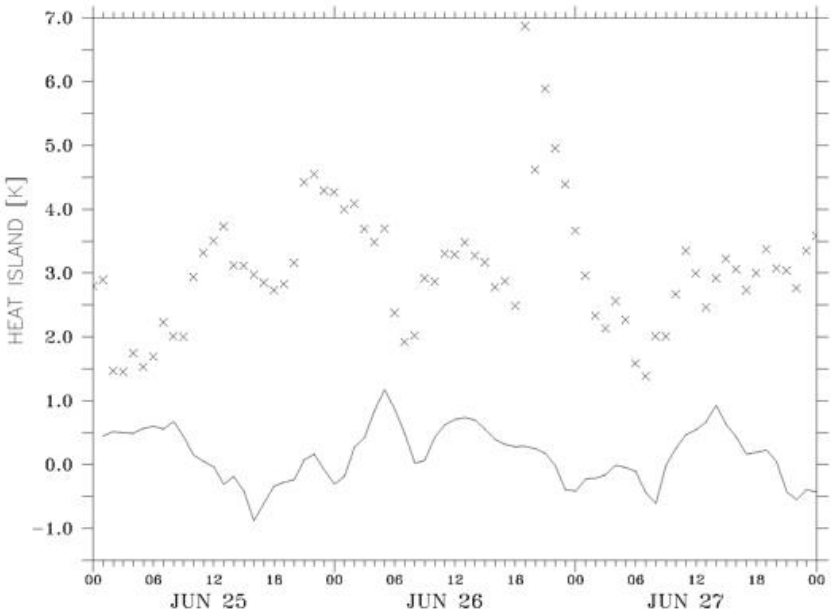

Figure 23: The Urban Heat Island (UHI) at 2mAGL for a three day period (June 25 to 27) measured (crosses) and computed by COSMO (solid line) with the operational configuration.

the boundary layer structure is of crucial importance in order to capture the physics leading to the UHI development.

6.4.1 Increasing The Horizontal Resolution

In order to investigate if the model is able to reproduce the UHI with an increased horizontal resolution, a simulation with the same model setup, and a finer horizontal grid spacing of 2.2 km is performed. This corresponds to the horizontal resolution of the COSMO2 configuration. As with the 7 km resolution, the 2 mAGL temperature in rural area is in good agreement with the measurements (not shown). For urban areas, the temperature is still too low and the UHI is not reproduced (Fig. 24). The average UHI is with 0.1 °C even lower than with a 7 km horizontal resolution. In this case, increasing the horizontal resolution of COSMO has no positive influence on the UHI simulation.

6.4.2 Increasing The Vertical Resolution

In this section, the vertical resolution is increased, applying heights of 20, 26 and 31 m respectively to the first three model layers. The horizontal resolution is kept at 2.2 km, this configuration corresponding to the model setups of COSMO2. As for the simulations with a lower vertical and horizontal resolution, COSMO is not able to reproduce an UHI (Fig. 25). As a conclusion, the ground surface temperature computed by the soil model TERRA_LM and use of the MOST land-surface scheme does not allow to take into account the modifications of the Planetary Boundary Layer (PBL) flow fields induced by the presence of a city. The street canyon geometry reduces sky view factor and wind speed and increases surface area and multiple reflection. Moreover, buildings characteristics modify the energy budget in the city. These factors affect the exchange surfaces-atmosphere from sensible heat and trapping radiation, and cannot be neglected (Oke, 1987). It is necessary to use an adapted parametrization in order to take into account the presence and the effect of a city in the model. For that purpose, the Building Effects Parametrization (BEP), developed by

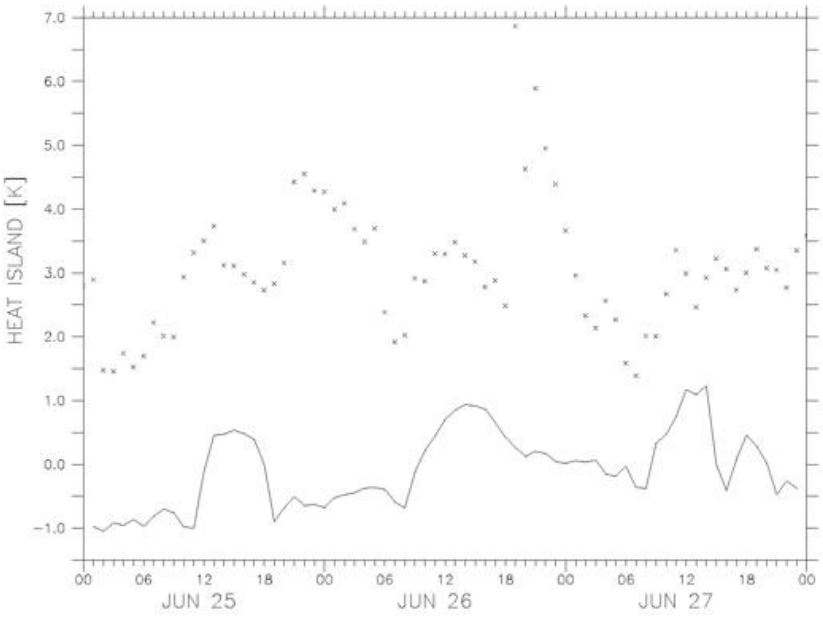

Figure 24: The Urban Heat Island (UHI) at 2m for a three day period (June 25 to 27) measured (crosses) and computed by COSMO (solid line) with an increasing horizontal resolution of 2.2 km.

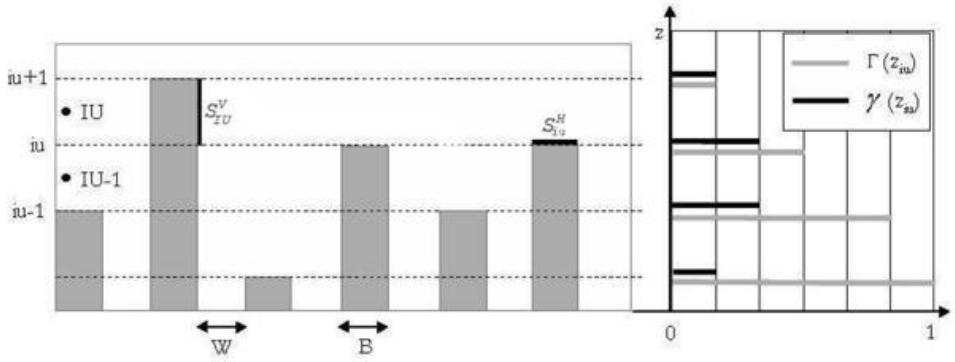

Figure 26: Schematic representation of the city in the urban grid of BEP and the buildings vertical distribution of density $\Gamma(z)$ and probability $\gamma(z)$ (Martilli, 2001).

Martilli et al. (2002) is implemented into the COSMO model.

6.5 BEP : *Building Effects Parametrization*

Results from the last section indicate that there is a clear need to better represent the physical processes of typical urban environments in order to improve the representation of these regions in mesoscale models. In this study we will use the parametrization developed by Martilli (2001) called the Building Effects Parametrization (BEP). It has initially been developed for the mesoscale model FVM and tested extensively on several situation (Martilli, 2002; Roulet et al., 2005) and applied to different cities (Athens (Martilli et al., 2003), Basel (Roulet, 2004), Bogota (Zrate et al., 2006) and Mexico (present work)). This section contains a description of BEP. The next two sections present the implementation of BEP in COSMO and the tests over the city of Basel. BEP takes into account the main characteristics of the urban environment: *(i)* vertical and horizontal surfaces (wall, canyon floor and roofs), *(ii)* shadowing and radiative trapping effects of the buildings, *(iii)* anthropogenic heat fluxes through the buildings wall and roof. In this parametrization the city is represented as a combination of several urban classes. Each class is characterized by an array of buildings (Fig. 26) of the same width B located at the same distance from each other W (canyon width), but with different heights (with a probability $\gamma(z)$ to have a building with height z and a density function $\Gamma(z)$ of buildings with height z or higher). To simplify the formulation we assume that the length of the street canyons is equal to the horizontal grid size. BEP computes urban effects on its own grid. The horizontal resolution is identical to the resolution of the mesoscale grid, while the vertical resolution is generally finer than the mesoscale resolution, and is usually set to 5 meters. Vertically the BEP grid extends up to one layer above the highest buildings. In this parametrization, the fluxes contributions of every urban surface type (canyon floor, roofs and walls) on the momentum, heat and turbulent kinetic energy (TKE) equations are computed separately. Firstly, the contributions of the horizontal surfaces (canyon floor and roofs) are calculated using the formulation of Louis (1979) based on MOST. The roughness lengths used for this calculation are representative for the local roughness of the specific surface types (roofs or canyon floor). Secondly, the exchange of momentum and TKE on the vertical surfaces (walls) are parametrized as the effect of pressure and drag forces induced by the buildings. The temperature fluxes from the walls are a function of the difference between air and wall temperature. They are parametrized using the formulation of Clark (1985) proposed by Arnfield and Grimmond (1998) in their urban energy budget model. The energy budget is computed for every mentioned surface (canyon floor, roofs and walls). Firstly, the direct and infrared radiation at the surfaces are calculated

to take into account the shadowing and radiative trapping effects of the buildings. Then, the surface temperatures for roofs, walls and canyon floor are solved by heat diffusion equation in several layers within the material (concrete or asphalt). After their calculation in the urban grid, the fluxes are vertically interpolated into the mesoscale grid. We will now consider the input parameters that are needed by BEP for each urban class:

Thermal parameters The material thermal diffusivity K_s $[m^2 s^{-1}]$ and specific heat C_s $[Jm^{-3}K^{-1}]$ for each urban surface (roof, canyon floor and wall), as well as building inside temperature T_{int} $[K]$.

Radiation parameters The surface albedo α and emissivity ε for each urban surface (roof, canyon floor and wall).

Roughness parameter The roughness length z_0 $[m]$ for the horizontal surfaces (roof and canyon floor).

Geometrical parameters The street direction, length and width, the buildings height and width, as well as the probability $\gamma(h)$ to have buildings of height h.

Meteorological variables The wind components (u and v), temperature and solar radiation (angle and intensity) from the mesoscale models.

Urban fraction parameter $u_{fraction}(i, j, iurb) \in [0 : 1]$ gives the urban fraction in each cell covering the city.

BEP is then able to compute new surface temperature, momentum, heat and TKE fluxes for each layer of the mesoscale grid influenced by the city.

6.5.1 Temperature at 2 mAGL

The temperatures available for model validation are generally measured at 2 m above the ground. So the model needs to compute the temperature at this height. In COSMO, it is computed as a prognostic variable using MOST, which is based on constant-flux layer approximation in the surface layer. Rotach (1993a,b) shows that the turbulent fluxes are not constant with height in the urban roughness sublayer (1-3 time mean building height) and that similarity theory cannot therefore be applied. As BEP takes into account the presence of a city, its computed fluxes can be used to specify the temperature at 2 m height. For that purpose modifications are implemented in BEP, that will allow to compute diagnostic variables (typically 2 m temperature, 10 m wind) consistent with the land-surface scheme assumptions. The temperature at 2 mAGL corresponds to the temperature simulated in the urban grid, in so far as the first layer near the ground remains thin enough for being considered as the temperature at 2 m. The energy budget equations for sensible heat, momentum and TKE are hence solved in the urban grid. With low horizontal resolution (here 2 km) compared to the high vertical resolution (5 m), vertical fluxes dominate the horizontal fluxes and represent the main source term in the energy budget equation. Therefore the horizontal fluxes can be neglected as shown by Masson et al. (2002) with measurements. The vertical turbulent exchanges balance the fluxes coming from the buildings and the ground, thus the equations for sensible heat, momentum and TKE are parametrized for each layer in the urban grid as follows:

$$\frac{\partial}{\partial z}\left(K_z \frac{\partial \theta}{\partial z}\right) = a_\theta \theta + b_\theta \tag{7}$$

$$\frac{\partial}{\partial z}\left(K_z \frac{\partial U_i}{\partial z}\right) = a_{U_i} U_i + b_{U_i} \tag{8}$$

$$\frac{\partial}{\partial z}\left(K_z \frac{\partial E}{\partial z}\right) = a_E E + b_E + \rho K_z \left[\left(\frac{\partial U_x}{\partial z}\right)^2 + \left(\frac{\partial U_y}{\partial z}\right)^2\right] - \frac{g}{\theta_0}\rho K_z \frac{\partial \theta}{\partial z} - \rho C_\varepsilon \frac{E^{3/2}}{l_\varepsilon} \tag{9}$$

Equations 7 and 8 parametrize respectively the temperature θ and the wind speed U_i for each direction in accordance with Pielke (1984). a_ψ and b_ψ are the flux source terms computed by BEP and K_z $[\frac{m^2}{s}]$ are the vertical diffusion coefficients. Equation 9 $[\frac{m^2}{s^2}]$ is the prognostic equation for the turbulent kinetic energy E according to Bougeault and Lacarrere (1989) with a $k-1$ closure. In this equation, $\rho K_z \left[\left(\frac{\partial U_x}{\partial z}\right)^2 + \left(\frac{\partial U_y}{\partial z}\right)^2\right]$ and $\frac{g}{\theta_0}\rho K_z \frac{\partial \theta}{\partial z}$ are the production terms representing the shear and the buoyancy respectively. The $\rho C_\varepsilon \frac{E^{3/2}}{l_\varepsilon}$ term is the dissipation rate where l_ε is a characteristic length of the energy-containing eddies, and computed as the root square of l_k multiplied by the street width. l_k $[m]$ is a characteristic length for eddies determined as the minimum between street width and height where l_k is computed. C_ε is a numerical coefficient set to 0.71 (Bougeault and Lacarrere, 1989). The system of 4 equations is characterized by 5 unknowns (θ ,U_x, U_y, E and K_z) for each layer of the urban grid. In order to close the system, K_z is defined as a function of E (Bougeault and Lacarrere, 1989) and is written:

$$K_z = C_k l_k E^{1/2}, \tag{10}$$

where C_k is a numerical coefficient set to 0.4 (Bougeault and Lacarrere, 1989).

In BEP, this system is solved by iteration once the flux source terms a_ψ and b_ψ are computed. Firstly TKE is estimated for computing K_z according to equation 10. Then temperature and wind speed are computed with equations 7 and 8, and TKE can be computed with (9). A new K_z is then calculated using the new TKE value, and iterations are made until TKE converge. The energy profile in the urban grid is used to initialize K_z for the next time step. It is necessary to determine the upper-boundary conditions in the urban grid. For wind, they are directly given by the mesoscale models at the height of the urban grid top. For TKE and temperature at the top of the urban grid (above the buildings), it is assumed that a neutral surface layer is developing above the roughness layer (Roth, 2000), which is virtually starting from the zero plane displacement (Oke, 1987) situated in the roughness layer (Fig. 27). In the surface layer, the vertical turbulent fluxes of momentum and heat are assumed to remain constant (Seinfeld and Pandis, 1998). In this case, only the production (shear and buoyancy) and the dissipation terms remain in the prognostic equation for E, *i.e.*

$$\rho C_\varepsilon \frac{E^{3/2}}{l_\varepsilon} = \rho K_z \left[\left(\frac{\partial U_x}{\partial z}\right)^2 + \left(\frac{\partial_U y}{\partial z}\right)^2\right] - \frac{g}{\theta_0}\rho K_z \frac{\partial \theta}{\partial z} \tag{11}$$

In accordance with the assumed surface layer properties, shear is defined as:

$$\rho \frac{U_*^3}{\kappa(z - z_d)}\phi, \tag{12}$$

Where κ is the von Karman constant set to 0.40, under neutral conditions and ϕ is equal to 1 (Businger et al., 1971). U_* is the friction velocity and z_d the zero plan height define as $0.67 * \textit{building height}$ (Grimmond and Oke, 1999). The buoyancy in the surface layer is defined as:

$$\frac{g}{\theta_0}\rho U_* \theta_* \tag{13}$$

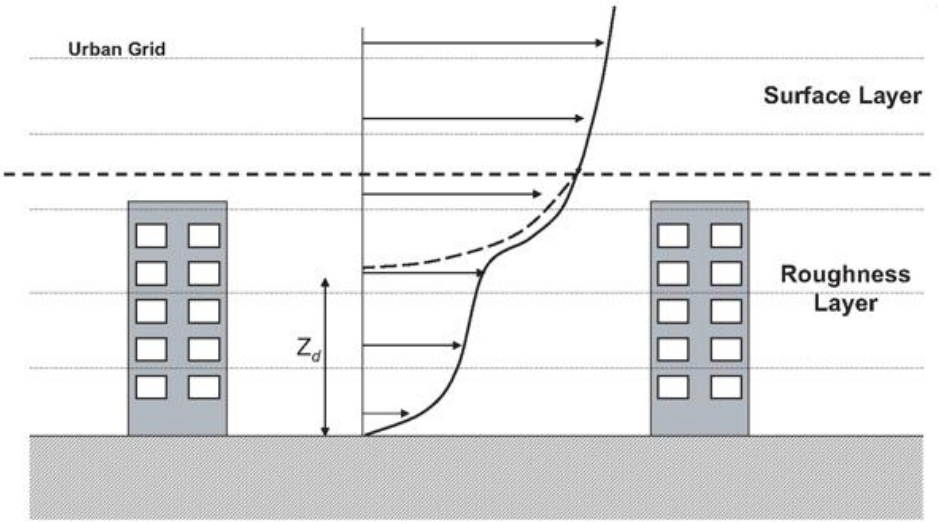

Figure 27: Schematic representation of a wind profile in the roughness layer and in the surface layer. It assumes that a surface layer has developed above the urban canopy and virtually starts at the zero plane displacement height Z_d.

Where θ_* is a potential temperature scale. U_*^2 is the total momentum flux and $U_*\theta_*$ the total heat flux:

$$U_*^2 = \sqrt{(A_{u_x}U_x + B_{u_x})^2 + (A_{u_y}U_y + B_{u_y})^2} \tag{14}$$

$$U_*\theta_* = A_\theta\theta + B_\theta \tag{15}$$

Where A_ψ and B_ψ represent the total source term in the urban grid. Based on (11) and using equations 12 to 15, TKE at the top of the urban grid is estimated as:

$$E_{top} = \left[\frac{1}{C_\varepsilon}\left(\frac{U_*^3}{\kappa} - \frac{g(z-z_d)}{\theta_0}U_*\theta_*\right)\right]^{2/3} \tag{16}$$

The upper-boundary condition for temperature is parametrized with a logarithmic profile (Pielke, 1984),

$$\theta_* = \frac{\kappa(\theta_z - \theta z_d)}{0.74[\ln(z/z_0) - \psi_H(z/L)]} \tag{17}$$

As explained before, the flux θ_* remains constant within the neutral surface layer. A further assumption is to neglect perturbation terms $\psi_H(z/L)$. Temperature $\theta_{z_{top}}$ at the top of the urban grid (z_{top}) can then be expressed as a function of the temperature at the first mesoscale model layer above the urban grid $\theta_{z_{meso}}$:

$$\theta_{z_{top}} = \theta_{z_{meso}} - 0.74\frac{\theta_*}{\kappa}\ln\left(\frac{z_{top} - z_d}{z_{meso} - z_d}\right) \tag{18}$$

The temperature at the urban grid top, $\theta_{z_{top}}$, is linked both to the mesoscale model, by the value above the urban grid $\theta_{z_{meso}}$ and to the urban parametrization, by the potential temperature scale θ_*. This method also solves wind speed and TKE in the urban grid.

6.6 Implementation of BEP in Cosmo

BEP outputs consist of a ground surface temperature and of momentum and heat fluxes profiles calculated over the entire height of the urban grid. In the original version of COSMO, surfaces fluxes are implicitly calculated by the soil module, using the formulations given in equation 6. In the modified version, BEP is implemented in COSMO and runs after the soil module. In the following, two implementation methods are presented.

6.6.1 First Method

The first method is based on the re-computation of the transfer coefficients C_m^d and C_h^d in order to impose surface variable tendencies corresponding to the ones computed in BEP. It is then necessary to find a formulation for the coefficients depending on the tendencies calculated by BEP, (*i.e.* u_{flux}, v_{flux} and t_{flux}). Beginning with the first two equations of system (6):

$$(\tau^{13})_{\zeta=N_\zeta+1/2} = \tau^{13}_{sfc} = -\rho C_m^d |\vec{v}_h| u = -\rho C_m^d \sqrt{u^2+v^2}\, u, \tag{19}$$

$$(\tau^{23})_{\zeta=N_\zeta+1/2} = \tau^{23}_{sfc} = -\rho C_m^d |\vec{v}_h| v = -\rho C_m^d \sqrt{u^2+v^2}\, v, \tag{20}$$

and introducing two new coefficients $C^d_{m,u}$ and $C^d_{m,v}$ to take into account both wind directions u and v:

$$\tau^{13}_{sfc} = -\rho C^d_{m,u} \sqrt{u^2+v^2}\, u, \tag{21}$$

$$\tau^{23}_{sfc} = -\rho C^d_{m,v} \sqrt{u^2+v^2}\, v, \tag{22}$$

with units $[\frac{kg}{ms^2}]$.

BEP module gives the tendencies u_{flux} and v_{flux} with units $[\frac{m}{s^2}]$, coming from wind speed temporal derivative, *i.e.* $\frac{\partial}{\partial t}[\frac{m}{s}]$. Thus, it is possible to find a relation between the tendencies of BEP and the surface fluxes of COSMO. In the following, this relation is derivated for the u-direction:

$$\tau^{13} = \Delta z \rho u_{flux}, \tag{23}$$

where Δz is the height of the first mesoscale layer and ρ is the density. Replacing τ^{13} by (21) and simplifying the density terms, we have:

$$-C^d_{m,u} \sqrt{u^2+v^2}\, u = \Delta z u_{flux}, \tag{24}$$

Finally, resolving for $C^d_{m,u}$ and similarly for the v-direction, we obtain the equations linking the momentum transfer coefficients with the fluxes within BEP:

$$C^d_{m,u,BEP} = -\Delta z \frac{u_{flux}}{u\sqrt{u^2+v^2}},$$

$$C^d_{m,v,BEP} = -\Delta z \frac{v_{flux}}{v\sqrt{u^2+v^2}}, \tag{25}$$

Following a similar approach, we can find a relation between the transfer coefficient C_h^d and the heat flux tendency t_{flux}, with units $[\frac{K}{s}]$. The third equation of (6) becomes:

$$(\hat{H}^3)_{\zeta=N_\zeta+1/2} = \hat{H}^3_{sfc} = -\rho C_h^d |\vec{v}_h| (\theta\pi_{sfc} - T_{sfc})$$

$$= \rho C_h^d \sqrt{u^2+v^2} (T_{sfc} - T_{\zeta=N_\zeta}), \tag{26}$$

with units $[\frac{kgK}{sm^2}]$. We have then to divide $\hat{H}^3_{sfc}$ by a density term ρ and a length term Δz to obtain $[\frac{K}{s}]$. Thus:

$$t_{flux} = \frac{\hat{H}^3_{sfc}}{\rho \Delta z} = \frac{\rho C_h^d \sqrt{u^2+v^2}(T_{sfc} - T_{\zeta=N_\zeta})}{\rho \Delta z}, \tag{27}$$

Again, simplifying the density terms and resolving for C_h^d, lead to an expression linking the transfer coefficient for sensible heat with the tendency given by BEP:

$$C^d_{h,BEP} = \Delta z \frac{t_{flux}}{\sqrt{u^2+v^2}(T_{sfc} - T_{\zeta=N_\zeta})}, \tag{28}$$

These three coefficients calculated by BEP are then used to create the final coefficients for input into COSMO, following a linear combination between BEP's and COSMO's coefficients:

$$\begin{aligned} C^d_{m,i,final} &= u_{fraction} C^d_{m,i,BEP} + (1 - u_{fraction}) C^d_{m,LM}, \\ C^d_{h,sensible,final} &= u_{fraction} C^d_{h,BEP} + (1 - u_{fraction}) C^d_{h,LM}, \end{aligned} \tag{29}$$

where $i = u, v$ and $u_{fraction} \in [0 : 1]$ defines the urban fraction in a mesoscale cell and depends on the landuse type.

We have now to consider the fact that BEP consider urban areas as a set of totally dry surfaces. Thus, the module does not calculate any tendencies for latent heat fluxes. A final coefficient for the latent heat is nevertheless calculated, using the following combination:

$$C^d_{h,latent,final} = (1 - u_{fraction}) C^d_{h,LM}, \tag{30}$$

so that the moisture exchanges at the surface are characterized by the rural fraction $(1 - u_{fraction})$ affected to each urban cell.

As already mentioned, BEP also calculates a street surface temperature tgs_u. The module is defined with three soil layers, the deepest having a constant temperature. At time $t = t_0$, the constant temperature of COSMO is used to initialize the temperature in every soil layers of BEP. Then, the module calculate a thermal gradient over all layers at each time step and gives tgs_u. As for (29) and (30), the final ground surface temperature is calculated with a linear combination between tgs_u from BEP and t_s from COSMO:

$$t_s_{final} = u_{fraction} tgs_u + (1 - u_{fraction}) t_s \tag{31}$$

This temperature finally replaces COSMO's ground surface temperature t_s at each time step.

The advantage of this implementation method of BEP into COSMO is that it requires no knowledge about the code solver and that the model code does not need to be modified. Nevertheless, it is not optimal for several reasons. With such an implementation, only the first mesoscale layer can be influenced by BEP. This means that it is not possible to consider buildings higher than the first mesoscale level. Moreover, terms 25, 25 and 28 show that for low wind speeds the recomputed exchange coefficient may numerically diverge. Thus, it is necessary to control and to limit the transfer coefficients for the low wind speed situations. This implementation method has some limits. Therefore a second method to implement BEP and to take into account the source flux terms above the first layer of the mesoscale model is presented in the next section.

6.6.2 Second Method

The first method is more complex but does not modify the LM code. This second method is simpler and more powerful but modifications must be applied to the implicit LM solver. To avoid the limitations of the first implementation method, a more direct method is presented that needs less modifications in BEP and LM code and acts on each vertical mesoscale layer influenced by urban areas. It relies on the use of tendencies ψ_{flux} and source terms a_ψ and b_ψ, where $\psi = u, v, t$. BEP calculates the tendency u_{flux} using the source terms, as follows

$$u_{flux} = \rho \Delta z (a_u u + b_u), \tag{32}$$

This can be generalized by:

$$\psi_{flux} = \rho \Delta z (a_\psi \psi + b_\psi), \tag{33}$$

where a_ψ and b_ψ are the implicit and explicit source terms respectively and $\rho\Delta z$ a conversion factor from BEP's tendencies and COSMO's fluxes. Now, if we look at equation (33) in term of temporal derivative, we have:

$$\frac{\psi^{n+1} - \psi^n}{\Delta t} = \rho\Delta z(a_\psi \psi^{n+1} + b_\psi), \tag{34}$$

The step is now to implement the tendencies and the source terms in COSMO through equation (4) for k-level only, which means:

$$B_k \psi_k^{n+1} = D_k(\psi^n, ...), \tag{35}$$

Finally, if we take the implicit and explicit terms of (34) and (35), it is possible, by analogy, to connect BEP to COSMO through the source terms:

$$\begin{aligned} B_k &\longrightarrow B_k - a_\psi, \\ D_k &\longrightarrow D_k + b_\psi \end{aligned} \tag{36}$$

Two valuable methods to implement BEP in COSMO have been presented. The choice of the implementation method depends on the user's knowledge of the mesoscale code and on the possibility to modify it. With some adaptations, but keeping the same implementation philosophy, these two methods allow to implement BEP in numerous mesoscale models. Having the possibility to change the implicit solver of LM, the second method is used in this study, which allows to take into account the urban source terms in each layer of the mesoscale grid influenced by the urban canopy.

6.7 Simulation of the Basel UHI

6.7.1 Model Setup

In this part, we keep the same simulation domain over Basel and its surroundings (cf. section 6.3.3) with the COSMO2 configuration *i.e.*, a 2.2 km horizontal resolution, a first layer thickness of 20 m and a 3 day simulation period from June 25 to 27. The characteristics and the fraction of urban area in each cell is determined from the KABA data base (Fehrenbach, 1999). Two city categories are defined:

- *City center*: high density of buildings (15 m high), narrow street and 80% of urban area[4]. Represented by 7 grid points.
- *Sub-urban areas*: smaller density of small buildings (7 m high) and 60% of urban area. Represented by 17 grid points.

Figure 28 shows the simulated domain with cells considered as urban and sub-urban. The properties for both urban and sub-urban categories are determined according to KABA and Roulet (2004) and are presented in Appendix 6.9.3. For the cells containing urban area, the parameters of the rural part have been changed in order to represent park and green area. The main model input parameters are summarized in Table 4.

[4]It means that 80% of the area of the grid cell fluxes are computed by the urban parametrization (BEP) and the rest is handled by the traditional LM parametrization with values for rural area.

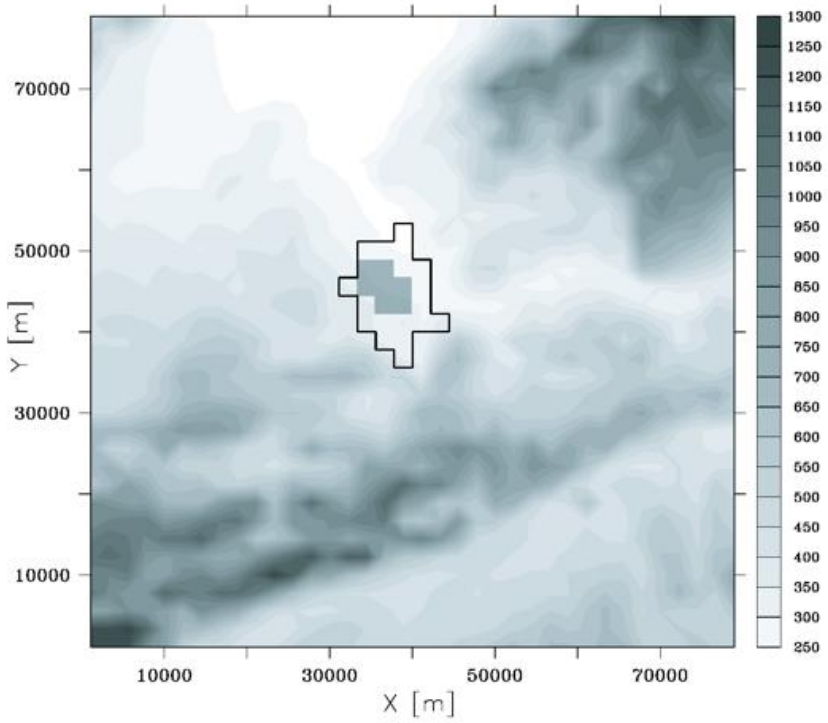

Figure 28: Topography [mASL] of the simulation domain (2.2 km horizontal resolution) over the city of Basel and the urban (gray squares) and sub-urban cells (black shape).

Table 4: The main model input parameters are: nx and ny the number of model grid points in each horizontal direction, nz the number of vertical layers, dx and dy the horizontal grid spacing, dz_{ground} the lowest layer depth and dt the slow modes time step

The main model input parameters	
nx	36
ny	36
nz	60
dx dy	2.2 km
dz_{groud}	20 m
dt	12 min
period	25 to 27 June 2002 (72h)

6.7.2 Results

In this section, we compare results from the mesoscale model calculated both with and without BEP, and give a general overview of the model performance with BEP for the selected episode.

WIND

The wind pattern (Fig. 29 and Fig. 30) is very typical for Basel area with strong inflow from the Rhine valley in the North and going up along the slopes of the terrain. The comparison between simulations with and without BEP shows only slight differences in the wind fields. A small decrease of wind speed over the city is observed with BEP. The air flow simulated without BEP (Fig. 29) is not modified above the city. However, the simulation with BEP (Fig. 30) shows a divergence-convergence system around the city. The simulation shows a divergence and a decrease of the wind speed upstream the city due to drag effect of the buildings. The wind accelerates around the city. Wind speed decreases drastically downstream as a combined effects of drag force and buoyancy due to temperature increase in the city. A convergence is observed south of the city. BEP impacts the air flow up to 7 km upwind and downwind the urban area. Looking hour by hour, we observe that the effect on wind flow increases with wind speed *i.e*, the impact of BEP increases with increasing wind speed.

TEMPERATURE

The simulated temperature at 2 m shows warmer temperature in the urban area with BEP than without. The computed UHI (Fig. 31) is always stronger in the simulations with BEP by 0.7 to 4 °C. The averaged UHI simulated with BEP reaches 2.3 °C, which is in agreement with the measurements (average UHI of 3 °C, Fig. 31). Furthermore, the simulated UHI is late by around 3 hours during the morning and too weak from 18LT to 00LT. We also observed a peak in the measurements at 18 LT on June 26 that the simulation is not able to reproduce. It is instructive to look at absolute temperature values and not differences in order to explain the observed inconsistencies. Figure 32 shows that the city is warmer with BEP particularly during nighttime. The morning temperature increase simulated with BEP comes with a delay, which explains the phase shift of the UHI observed above. Even if the maximum of temperature is too low the first day, it is generally well reproduced with the BEP simulation and the UHI during daytime is well reproduced. The temperature decrease in the afternoon and evening occurs earlier with BEP than in the measurements and a maximum difference between simulation and measurement is reached at sunset (20 LT). This explains the strong UHI anomaly at the end of the day and beginning of the night (cf. Fig. 31). The maximum of measured UHI reached at 18 LT on June 26 is not observed in the urban temperature. This maximum is due to a decrease of the temperature in the rural area (not shown).

Numerous tests have been conducted on the input parameters of BEP used to describe the city. Using typical values found in the literature (Oke, 1987; Masson et al., 2002; Dupont et al., 2004), the following parameters have been varied and sensitivity of the results studied:

- The *Thermal Parameters* of the materials, *i.e.* the thermal diffusivity and the specific heat for roof, wall and ground.
- The *Radiation Parameters* of the surfaces, *i.e.* the albedo and the emissivity of roof, wall and ground.
- The *Roughness Length* of horizontal surfaces (ground and roof).

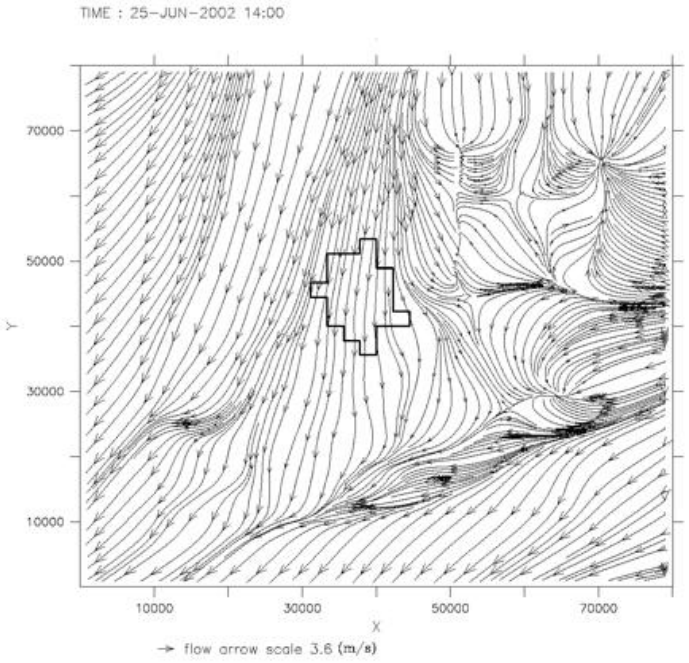

Figure 29: Simulated wind streamline (the size of the arrows indicates the wind speed strength) with COSMO, June 25 at 14LT in the first layer (20 meters height) above and around the city of Basel (black shape).

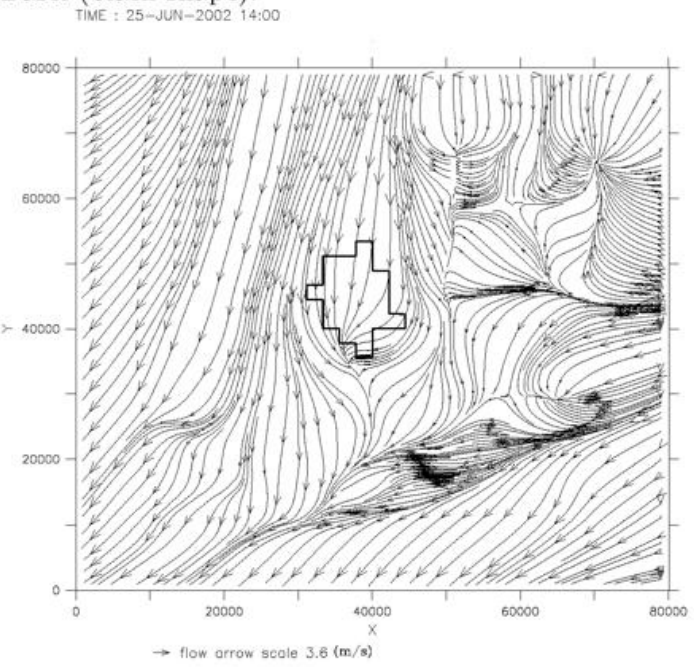

Figure 30: Simulated wind streamline with COSMO/BEP, June 25 at 14LT in the first layer (20 meters height) above and around the city of Basel (black shape).

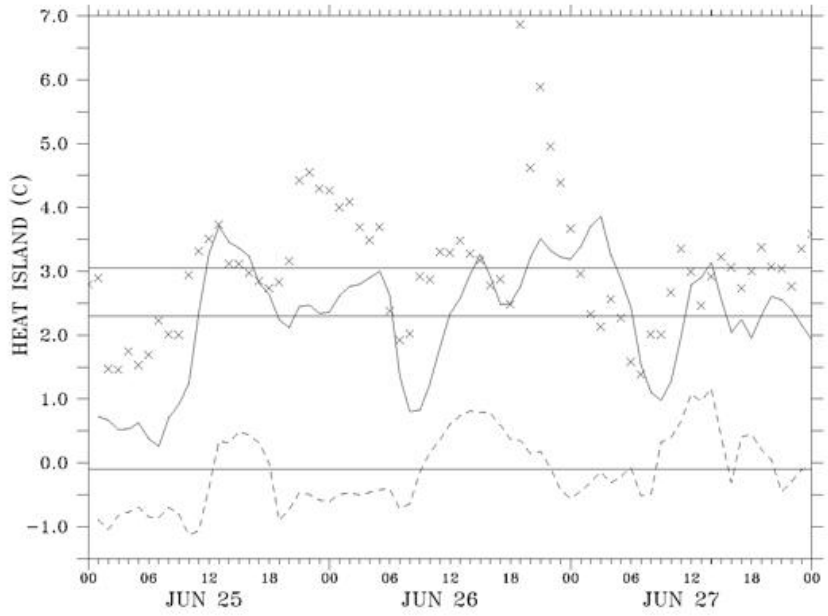

Figure 31: The Urban Heat Island (UHI) at 2m for a three day period (June 25 to 27) measured (crosses) and computed by COSMO with BEP (solid line) and without BEP (dashed line) with an horizontal resolution of 2.2 km

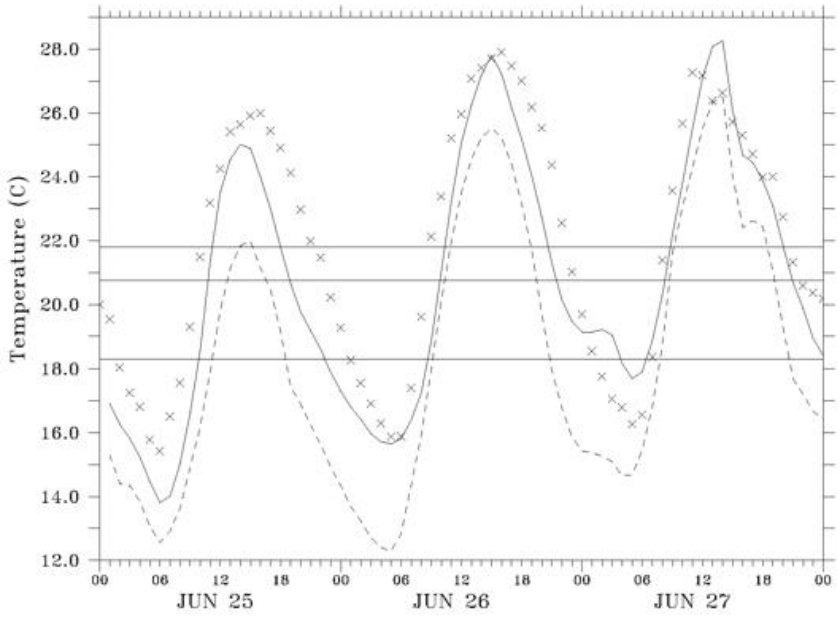

Figure 32: Average temperature at 2 m in the city of Basel, measured (crosses), simulated in COSMO without BEP (dashed line) and with BEP (solid line).

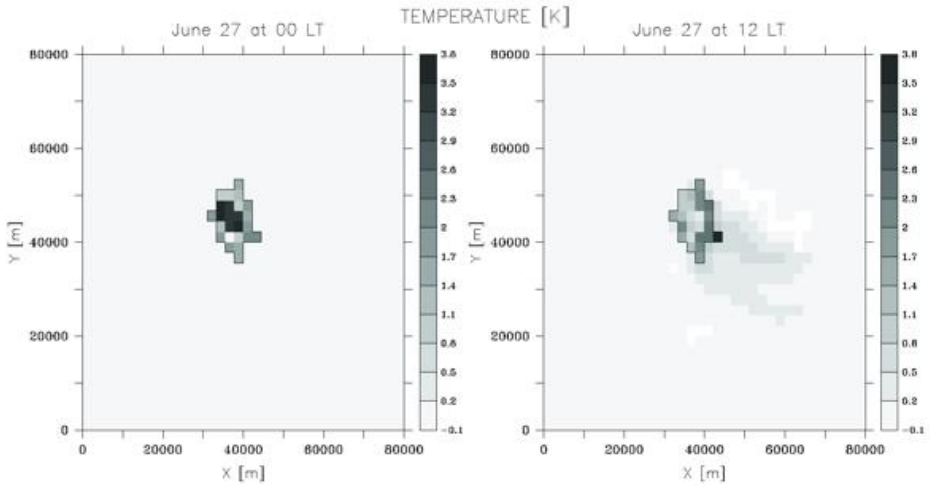

Figure 33: Temperature differences at 2 mAGL [°C] between an COSMO simulation with BEP and without BEP over the city of Basel (black shape) for 27 June, 2002 at midnight (left) and 27 June, 2002 at noon (right)

- The *Geometrical Parameters* of the city, *i.e.* street direction and width, buildings height and width and their repartition.

An impact on the average and on the amplitude of the temperature curve is observed when these parameters are modified. However the shape of the curve is not modified, *i.e.* the morning increase temperature is always late and the temperature decreases too early in the afternoon. Furthermore, modifying the parameters in the range proposed by the literature produces weak impacts (not shown) on the temperature, of around 0.6 °C on the amplitude and 0.3 °C degrees on the average. The results presented above have been computed with the set of parameters that provide the best fit between simulation and measurements. To summarize, the results show that a parametrization of heat and momentum fluxes over urban areas clearly improve mesoscale simulations using an horizontal resolution of 2.2 km. Results with BEP show a much better representation of the UHI as well as the general temperature evolution over an urban area such as Basel. Remaining differences between measured and simulated urban temperatures are dominated by a phase shift in the morning increase and evening decrease. This effect does not show any sensitivity to changes in BEP's input parameters. If measurements are considered representative of the urban environment, this gives an indication that the processes considered in BEP are not complete and some physical mechanisms determining the temperature are not or not well represented.

UHI DISPERSION

Figure 33 shows the difference of temperature at 2 mAGL between a simulation with and without BEP. Two behaviors are observed:

- During nighttime (left panel of Figure 33), the simulation using BEP is clearly warmer above the city by 3.0 to 3.8 °C for the city center and by 1.5 to 2.0 °C for the sub-urban area. During this period, the wind is weak and temperature increase is observed only in the urban cells.

- During daytime (right panel of Figure 33), temperature increase above the city with BEP is weaker than during nighttime (1.5 to 2.5 °C in the city center), however a maximum of 3.4 °C is reached in the east- and southeast-part of the sub-urban area. The wind is stronger during daytime and blows to south east. It creates a displacement

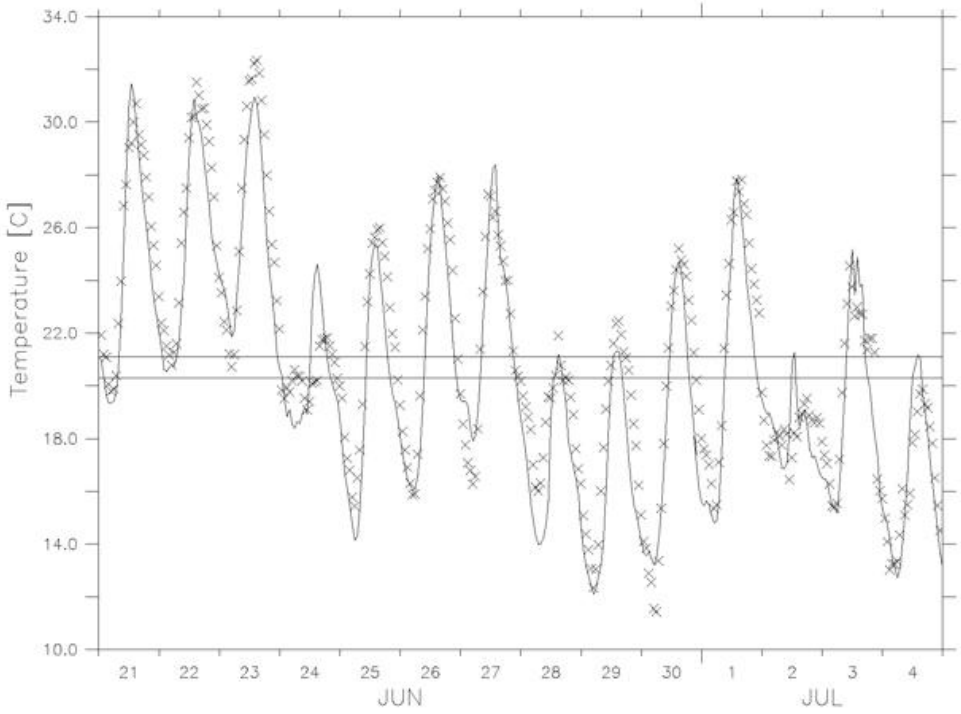

Figure 34: Urban temperature at 2m for a 14 days period (June 21 to July 4, 2002) measured (crosses) and simulated by COSMO with BEP (solid line) with a horizontal resolution of 2.2 km. The horizontal lines are the average of the measured temperature (21.1 °C) and the average of the computed temperature (20.3 °C).

of the maximum and a temperature "plume" which is observed south-east of the city and reaches 0.5 to 1.0 °C.

In both situations BEP increases the temperature in the city. The intensity and diffusion of this temperature increase are strongly dependent on the wind speed, so that BEP modifies not only the urban area but also the nearby area, up to 20 km downwind in the presented case.

6.7.3 14 Days Simulation

Up to now, BEP has only been tested on 2 to 4 day episodes. The implementation of BEP in an operational forecast model gives the opportunity to test it for longer periods (weeks or months) and different kinds of meteorological situations (days with strong cloudiness and/or precipitation). In this section we present a 14 days simulation during the BUBBLE IOP from June 21 to July 4 2002. Figure 34 shows the temperature simulated with COSMO/BEP in the urban area. No tendency being observed, BEP does not accumulate or lose heat during this 14 days period. Thus, BEP is able to compute the urban heat and momentum fluxes for longer period than 3 days. The mean temperature reaches 21.1 °C for measurements, 20.3 °C for the simulation with BEP and 18.3 °C for the simulation without BEP (not shown). The mean temperature is well reproduced with BEP as well as the general temperature behavior. The same tendencies are observed than during the 3 day simulations, which showed a warmer city by 2.4 °C with BEP. During nighttime of 23, 27 and 30 June, BEP slightly overestimates the temperature. The average of the computed UHI (Fig. 35) is 1.6 °C whereas it is around 2.8 °C in the measurements. The difference between measurements and simulation for the UHI is larger than the difference in the urban area temperature

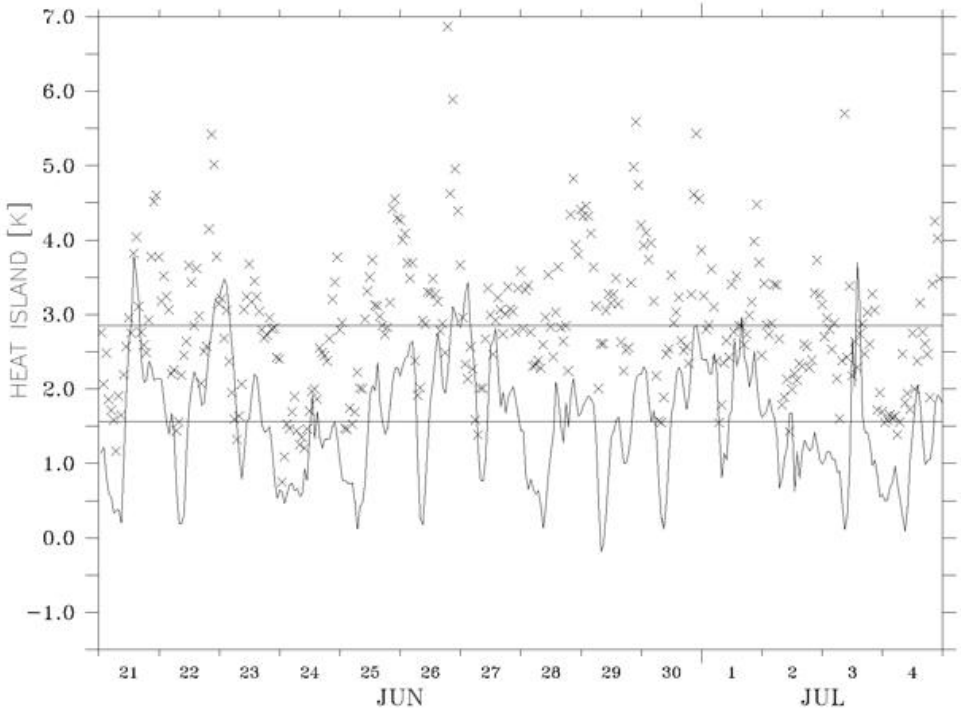

Figure 35: Urban Heat Island (UHI) at 2m for a 14 days period (June 21 to July 4, 2002) measured (crosses) and computed by COSMO with BEP (solid line) with a horizontal resolution of 2.2 km. The horizontal line are the average of the measured and of the computed UHI.

because, in the average, COSMO overestimates the temperature in rural area by 0.4 °C. If we focus on the temperature at 2 mAGL on June 24 when an important rainfall episode occurs form 01LT to 12 LT (Appendix 6.9.2), we observe that the simulation underestimates the temperature during nighttime and overestimates it during daytime. This phenomenon is also observed in the simulation without BEP (not shown), and is probably due to a too weak cloud cover in the simulation. The ground loses too much energy during nighttime by radiative effects and receives too much energy due to incoming solar radiation during daytime. The same phenomenon is observed on July 2 while very weak rainfall is observed during nighttime. However important rainfalls are observed during nighttime from 3 to 4 July and the simulation during this period fits very well to the measurement (Fig. 34). Even if BEP does not take into account latent heat flux, water storage or urban rainfall runoff, the rainfall episode does not deteriorate the results of temperature simulation. Nevertheless, taking into account water budget and latent heat flux in BEP could improve the urban energy balance and the temperature simulation which have shown a too fast cooling at the end of the day (section 6.7.2).

6.8 Conclusion

The presence of a city modifies the fluxes between the atmosphere and the Earth's surface. From August 2001 to July 2002, a year-long measurement campaign (BUBBLE) has been conducted in the city of Basel (Switzerland) and its surroundings with the aim of investigating in details the boundary layer structure in an urban area. During the intensive observation period (IOP), form June 15 to July 12 2002, an Urban Heat Island (UHI) has been underlined by temperature measurements at 2 mAGL inside and outside the city (Table 5). In order to investigate the ability of mesoscale models to take into account the effect of urban areas

Table 5: Average Urban Heat Island (UHI) in °C for the period of June 25 at 00 LT to June 27 at 23LT, for the BUBBLE measurements (left column), an COSMO simulation with 2.2 km horizontal resolution and 20 m vertical resolution for the first layer (center column) and an COSMO simulation and the urban parametrization BEP with the same configuration (right column).

UHI average for June 25 to 27 2002		
Measurement	COSMO	COSMO - BEP
3.0 °C	-0.1 °C	2.3 °C

on atmospheric flow fields and to reproduce the UHI, we have selected a three day episode during the IOP for simulation with the COSMO mesoscale model. COSMO is the operational numerical weather prediction model of MeteoSwiss. It is used on a domain covering most of western Europe with a horizontal resolution of 7 km and a vertical resolution with a 60 m depth for the first layer above the ground. The results obtained with COSMO over the city of Basel and its surroundings shows no UHI. With a 7 km horizontal resolution and a 60 m vertical resolution, the city of Basel and the urban boundary layer are not represented with enough accuracy. In order to investigate if a better resolution allows COSMO to reproduce the measured UHI over Basel, the horizontal resolution has been increased to 2.2 km and the vertical resolution to 20 m for the first layer. The results show that a finer resolution has no impact on the UHI simulation by COSMO (Table 5). As a conclusion, the surface scheme in COSMO based on the similarity theory is not adapted to the urban areas. In order to take into account the presence of a city with a more accurate surface scheme, the Buildings Effects Parametrization (BEP) has been implemented in COSMO. BEP has been modified in order to compute the temperature at 2 mAGL inside the urban canopy. Results show that the implementation is successful and works as expected. The results obtained with BEP show that the urban parametrization modifies the wind flow above and around the city. The wind speed decreases above the city and a system of divergence-convergence is observed around it. Wind divergence-convergence systems are particularly important in air pollution study as they generally lead to a pollution maximum. The temperature is reproduced with a good accuracy in the urban area. Thus, COSMO with BEP is able to reproduce an UHI in the city of Basel (Tab. 5). We have underlined that the temperature increase does not stay confined in the urban area, but extends around the city up to 15 to 20 km. Nevertheless, the UHI computed with BEP is generally too weak (Tab. 5) and even with tuning the urban parameters, BEP is not able to reach the measured values. Sometime, a phase shift is also observed between the measured and simulated temperature. BEP is based on a simplified representation of the urban area and several phenomenon are neglected. The urban parametrization could be adapted in order to take into account different phenomenon, which should modify the urban energy balance:

- The vertical surfaces in BEP are uniform and opaque. Take into account the **windows** will modifying the radiative budget at wall surfaces and in the buildings.
- The **temperature inside the buildings** is maintained constant during the simulation. It will be necessary to take into account its variations in order to represent the buildings energy budget more realistically.
- The **natural ventilation** is the air exchange between inside and outside the buildings (windows opened, ventilation, ...). Koutrakis et al. (1992) estimated that more than 50% of the buildings volume of air can directly be exchanged with the outdoor each

hour.

- The **air conditioning** cools down the air inside and rejects heat in the urban atmosphere. It modifies the balance between inside and outside buildings, and is an important source of heat due to its energy consumption.
- No **urban water budget** is computed in BEP. It doesn't take into account precipitation, pipped water supply of the city and water vapor released due to anthropogenic activities, such as combustion.

A 14 days period has been simulated with COSMO/BEP. It is the first time that BEP is applied for a such long period. That allows to verify that BEP does not accumulate or lose energy and that it can be used for long term simulations. Rainfall episodes are included in these 14 days. BEP does not take into account latent heat flux, water storage and urban rainfall runoff. Nevertheless, the simulation with BEP are in good agreement with the measurements. The results show the importance to have an adapted parametrization for urban areas in order to take into account the modification of the atmospheric flow fields induced by the presence of a city. The increase of horizontal and vertical resolution in COSMO2 is not sufficient to take into account the presence of a city, the use of an adapted parametrization is necessary. BEP implementation in COSMO is a distinct enhancement for the simulation above urbanized region. We have focused our study on the 2 m observations for temperature, 10 m observations for the wind and the horizontal dispersion of the UHI. The urban effects are also present in the vertical direction. It is important to investigate the impact of BEP on the vertical structure of the atmosphere and its capacity to be used with a low resolution mesoscale model for operational forecast purposes.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction

The PP UTCS was completed in September 2012. The interim reports of the project participants are available at the COSMO web page. A summary of the project results as of September 2012 are given below. Results from the efforts, that are initiated within the framework of the PP UTCS but are completed (or still ongoing) past the official end of the project in September 2012, are reported to COSMO through the Working Group 3a. In what follows, the authors of the respective section are given in parentheses.

2 Development and testing of the TKE-Scalar Variance mixing scheme for the COSMO model (Ekaterina Machulskaya and Dmitrii Mironov)

The TKE-Scalar Variance (TKESV) scheme for the COSMO model is developed. The scheme carries prognostic equations for the turbulence kinetic energy (TKE), the liquid water potential temperature variance, the total water specific humidity variance, and the temperature-humidity covariance. These prognostic second-moment equations include the turbulent diffusion terms (divergence of the velocity-velocity and velocity-scalar triple correlations) that are parameterized through the down-gradient approximations. The other second-order moments, viz., the Reynolds stress and the scalar fluxes, are determined through the algebraic diagnostic expressions. The expressions for the scalar fluxes include non-gradient terms that are parameterized with due regard for the turbulence anisotropy. The formulation for the turbulence length (time) scale accounts for the effect of static stability. Recall that within the framework of the current COSMO-model turbulence scheme (one-equation TKE scheme), the time-rate-of-change and the turbulent diffusion terms are retained in the TKE equation only, whereas all other second-order moments, including scalar variances, are determined from the algebraic diagnostic expressions. The expressions for the scalar fluxes do not include non-gradient terms (among other things, this does not allow for up-gradient scalar transfer), and a Blackadar-type turbulence length scale formulation independent of static stability is used.

The TKESV scheme is tested through single-column numerical experiments. Results of simulations with the TKESV and the TKE schemes are compared with observational and numerical large-eddy simulation (LES) data from dry convective planetary boundary layer (PBL) and from cloudy PBLs (BOMEX and ARM shallow cumulus test cases and DYCOMS-II stratocumulus case). The TKESV scheme clearly outperforms the TKE scheme in dry convective PBL. Vertical profiles of the scalar variances and of the TKE computed with the TKESV scheme show better agreement with data. The PBL is better mixed with respect to potential temperature. An up-gradient heat transfer that is known to occur in the upper part of the dry convectively-mixed layer is well reproduced by the TKESV scheme. This is not possible with the TKE scheme, where the down-gradient formulations for the scalar fluxes are used. For cloudy PBLs, the application of the TKESV scheme leads to a better prediction of the scalar variances and TKE and to slight improvements with respect to the vertical buoyancy flux and the mean temperature and humidity. Both schemes tend to overestimate fractional cloud cover in the cumulus-topped PBL. This error is attributed primarily to the shortcoming of quasi-Gaussian statistical cloud parameterization scheme used by both TKESV and TKE schemes to determine fractional cloudiness (which in term strongly affects the buoyancy flux). A detailed analysis of simulation results suggests that a quasi-Gaussian cloud scheme is unable to accurately describe fractional cloudiness in the

cumulus regime even though the characteristics of turbulence (first of all, scalar variances that serve as input to the cloud scheme) may be predicted perfectly. A somewhat more sophisticated cloud scheme that accounts of non-Gaussian effects is required.

The TKESV scheme is implemented into the COSMO model and tested through a series of parallel experiments including the entire COSMO-model data assimilation cycle. Both COSMO-EU and COSMO-DE model configurations operational at DWD are used (the horizontal mesh size of these configurations is ca. 7 km and ca. 2.8 km, respectively). Results from parallel experiments with the TKESV scheme performed to date look promising. Verification of results against observational data indicates improvements as to some scores, e.g. fractional cloud cover and 2m temperature and humidity. Further analysis of the new TKESV scheme performance within COSMO is underway.

Reduced minimum (background) diffusion coefficients of 0.1 m^2/s are used in some parallel experiments. Recall that in the current operational COSMO-model configurations a large value of 1 m^2/s is utilized for both momentum and scalars, which is often detrimental for stably stratified boundary layers and for the inversions capping convective boundary layers (this is a long-standing problem of the COSMO model). It is worth noting that some improvements in terms of verification scores can be achieved by just reducing the minimum diffusion coefficients, without the use of the new TKESV scheme. However, the application of the TKESV scheme and the reduced minimum diffusion coefficients leads to a better overall COSMO-model performance as compared to the model configuration with the reduced coefficients only. Furthermore, minimum diffusion coefficients are insensitive to the mixing regime. That is, a reduction of minimum diffusion coefficients is desirable in stably-stratified parts of the flow, but relatively large diffusion coefficients may be needed in other parts of the flow as a (unphysical) proxy for unaccounted mixing processes. This is impossible to achieve with constant minimum diffusion coefficients. On the contrary, the TKESV scheme is selective in terms of mixing regimes. Importantly, it does not produce excessive unphysical mixing in the stably-stratified PBL and in the capping inversion. A combination of the TKESV scheme and reduced minimum diffusion coefficients is a promising option for the COSMO model.

As the results from the LES study of Mironov and Sullivan (2010) demonstrate, the stably-stratified PBL should be parameterized with due regard for the heterogeneity of the underlying surface (first of all, with respect to the temperature). This can be achieved through the application of a tile approach to compute surface fluxes. The use of tiled surface scheme allows to account for the enhanced mixing in the SBL over heterogeneous surfaces in a physically plausible way (cf. large background diffusivity discussed above), and to prevent the PBL turbulence from dying out entirely as the (grid-box mean) static stability increases. The idea is successfully tested through single-column numerical experiments. The number of tiles should not necessarily be large (otherwise the tiled scheme becomes computationally expensive) but the tiles with the largest difference in terms of thermal inertia should be accounted for. In this regard, the treatment of the sub-grid scale (SGS) water bodies is crucial. As the thermal inertia of water is (much) larger than the inertia of most other land types, the inclusion of SGS water allows to maintain the temperature difference between tiles and hence to account for the enhanced mixing due to surface heterogeneity. The implementation of tile approach into the COSMO model is underway at DWD, where the mosaic approach implemented by Felix Ament is taken as a starting point. A parallel COSMO-EU experiment with a two-tile surface scheme is performed, where a land tile with the land-use type the same as in the operational COSMO model and inland water tile (lake) are considered in each COSMO-model grid box. The surface temperature of the inland-water tile is computed with the lake parameterization scheme FLake. Recall that in the operational COSMO configurations, only the grid boxes with the inland-water fraction in excess of 0.5 are treated as the

inland-water-type grid boxes whereas the SGS water bodies with fractional area coverage less than 0.5 are entirely ignored. Results from the parallel experiment indicate some improvements of the COSMO-model performance, e.g. warm bias of the near-surface temperature during summer is slightly reduced.

In summary, the TKESV scheme holds considerable promise in terms of the improvement of the COSMO-model performance. The TKESV scheme is currently not coded as a separate module. Changes associated with the TKESV scheme are implemented into the current COSMO-model TKE scheme developed by Matthias Raschendorfer. Since massive modifications to the current TKE scheme (many of them being of technical and re-organizational order) are prepared by Matthias Raschendorfer and should soon be included into the official COSMO code, modifications associated with the TKESV scheme will be implemented into the COSMO version following the version with Matthias changes. The implementation process will be controlled by the COSMO source code administrator. Every effort will be made to complete the implementation and testing of the tile approach. To this end, the software to generate external-parameter fields (e.g. the field of lake depth) should be modified. This may require considerable effort and take much time. A deadline for the tile approach implementation cannot be set at the time being.

A brief outline of the TKESV scheme, a discussion of the scheme performance in various clear and cloudy boundary-layer regimes as revealed by off-line single-column tests, details of the implementation of the new scheme into COSMO, and some results from numerical experiments with the full-edged COSMO model are given in Machulskaya and Mironov (2013). Documentation of the scheme is in preparation.

3 Comprehensive testing and further development of the current COSMO-model turbulence scheme, including the surface-layer transfer scheme

3.1 Comprehensive testing of the COSMO-model TKE turbulence scheme (Balazs Szintai)

The performance of the COSMO model was evaluated in the Planetary Boundary Layer for different conditions. Next to the mean prognostic variables, the turbulence characteristics of the model were also verified. The following conclusions can be drawn from the experiments.

It has been shown that the COSMO model is able to reproduce the main evolution of the boundary layer in dry convective situations with the operational parameter setting if the external parameters are realistic and if the initial conditions are adequate. However, it has been found that the COSMO model tends to simulate a too moist and too cold PBL, with shallower PBL heights than observed. During stable conditions the operational parameter setting has to be modified significantly (e.g. the minimum diffusion coefficient) to obtain a good model performance.

The reasons for the inadequate temperature and humidity profiles in convective conditions have been investigated with the component testing approach. The budget terms in the TKE equation have been validated separately against LES data and turbulence measurements. The turbulent transport term (third order moment) has been found to be significantly underestimated by the COSMO model. This results in inaccurate TKE profiles and thus missing entrainment fluxes at the top of the PBL. A solution to increase the TKE transport in the PBL was proposed, resulting in a more realistic TKE profile and higher entrainment fluxes.

This modification of the turbulence scheme has also been tested in a parallel experiment over a one-month period. Results show only minor impacts on the operationally verified fields.

The impact of the horizontal resolution on the simulation results has also been studied. It was shown that the three-dimensional structure of the PBL is significantly different in the 1 km simulation than in the 2.2 km run, and the former shows great sensitivity towards the horizontal diffusion. The standard isotropic three-dimensional turbulence scheme was compared to the fourth-order numerical diffusion and to the newly implemented first-order Smagorinsky closure. It can be concluded that without horizontal diffusion the 1 km simulation exhibits unrealistically strong waves in the PBL. Based on these findings, it is recommended to use the three-dimensional turbulent diffusion scheme with horizontal mesh sizes on the order of 1 km, because it is more physically based than the fourth-order numerical filter. For flat convective conditions with very low horizontal wind field deformation the Smagorinsky closure in its classical formulation generates too low mixing, however, the extension of the scheme to include the horizontal shear of vertical wind might be beneficial for these cases.

3.2 Detailed investigation of diurnal cycle of the near surface quantities, revision of the surface-layer transfer formulation (Matthias Raschendorfer)

A final COSMO-SC (single column) version adapted to COSMO version 4.24 has been composed including the recent running developments of Task 2.1 and 2.3 and being ready for component testing.

The new COSMO-SC version includes a couple of bug fixes and extensions and the possibility of forcing with measured surface fluxes, which caused related modifications not only in the SC framework and the turbulence code (MODULE src_turbdiff) but also in that for soil processes (MODULE src_soil_multlay, with particular difficulties in relation to forcing the soil moisture calculation with measured evaporation) and in that for implicit vertical diffusion (MODULE slow_tendencies, which is going to become obsolete due to the development of a new universal code, see Task 2.3).

Some component tests have been performed with COSMO-SC attendant to the current model development.

A revised formulation of the complete transfer resistance in the surface-to-atmosphere transfer scheme has been developed, but not yet implemented. However as a first step, the code structure has been modified in order to allow for an easier implementation of the new formulation. As a second step an adopted profile function for stable stratification has been implemented in the current test version as an option that needs to be tested soon.

Future plans for a pending priority task (ConSAT):

- detailed investigation of the problems with daily cycle of near surface variables using measurements and COSMO-SC;
- implementation and verification of the full revised transfer formulation.

Future plans for later years:

- implementation of a canopy/skin layer.

3.3 Generalization of non-local formulation of the turbulence length scale to account for moist processes (Veniamin Perov and Mikhail Chumakov)

The new formulation for turbulence length scale based on the Bougeault and Lacarrere (BL89) proposal have been developed and implemented in 3-D COSMO model. We use a postulate proposed by BL89 that for each level in the atmosphere turbulence length scale l can be related to the distance that a parcel of originating from this level and having an initial kinetic energy equal to the mean TKE of the layer, can travel upward and downward before being stopped by buoyancy effects. More precisely, if we define l_up and l_down then l must be related to some average value between l_up and l_down. The main advantage of the method is to allow for remote effects of stable zones on the definition of the turbulence length scale. For instance, using l_up, the vertical depth of an unstable layer capped by a strong inversion is automatically selected as the length scale for turbulence.

The non-local length scale algorithm was generalized for cloudy boundary layers, in order to consider the influence of moist processes and phase transition of moisture on the scale of turbulence. The new algorithm uses a turbulent kinetic energy equation in conservative variables for non-precipitating processes. The new algorithm was tested for stratocumulus-capped boundary layers. From the results we can conclude that the new mixing length gives more realistic results, because the reference mixing length formulation gives an anomalously high dissipation inside the cloud, near the inversion.

The new algorithm was implemented in the module TURBDIFF of COSMO. Convective summer cases were analysed. Firstly, we have found a significant difference in change with height of a local (reference scheme) and nonlocal (new scheme) turbulence length scale. The nonlocal l results in a strong damping of turbulence as soon as stable conditions (inversion at the top of convective layer) are encountered, while local l results a monotonic increase with height. The results suggest that boundary layer (BL) with reference length scale underestimates surface temperature T_s and generate a colder and shallow convective mixed layer. The BL scheme with the new length scale yields better T_s and improved vertical profiles of temperature and humidity. Thus, the height of the boundary layer was 20 percent higher, the temperature of convective layer has increased by 1.5-2.0 °C. In conclusion, we assume that the new mixing length algorithm is preferred when the turbulent structure of atmospheric boundary layer is not known in advance.

Proposals for the future work:

- Use the new algorithm for cases with a stable boundary layer. The goal is to reduce a negative bias of T2m (2-4 °C), which is often observed in COSMO-RU in winter;
- Develop a new boundary-layer scheme over mountainous terrain.

3.4 Development of a unified turbulence scheme for COSMO, COSMO-SCM and ICON (Matthias Raschendorfer)

The code of MODULE src_turbdiff has been revised, reorganized and reformulated in large parts in order to achieve a better modularization, as well as a numerically and conceptually better representation of the whole system of 2-nd order equations, including sub grid scale condensation, TKE diffusion and the integration of scale interaction. A special focus was turned on artificial security measures to guarantee realizability, that is to avoid singularities. A further intention was to unify the formulation of implicit vertical diffusion and to gain

more flexibility with respect to grid structure, time step organization and so on, in order to use the MODULE also in ICON. Some modifications have also been done in order to allow a better vectorization of the code.

A lot of modifications refer to the solution of second order equations (TKE equation and stability functions) as well as to the description of moist physics. Each of both tasks is now treated as a specific SUBROUTINE that is called from both, the turbulence model (turbdiff) and the scheme for surface-to-atmosphere-transfer (turbtran). In the prior code, for both sub-models these tasks are formulated explicitly, each with specific modifications.

The positive definite solution of TKE equation has been modified, allowing less serious restrictions for realizability. These restrictions can now be selected and modified by NAMELIST-input in order to test their effect in detail, in particular for stable stratification.

Numerics of solving for the stability functions have been changed, introducing a matrix preconditioning and the possibility to better control how far TKE can be apart from equilibrium without generating singularities in the solution.

Since all aspects of moist physics, in particular the calculation of conservative variables and the local saturation adjustment, are treated now in a single SUBROUTINE, these aspects are now treated consistently in turbdiff and turbtran, and - since conservative variables and not the model variables should be interpolated onto the 2m level - are applied even to 2m-diagnostics. This modularization further allows for a better control in case of modifications Thus, the mixed water-ice phase that already exists in an earlier sub version of the code (used by E. Avgoustoglou) can now be implemented here again with less modification effort.

Despite their formulation based on conservative scalar variables, sub grid scale variations of condensation need to be considered in our turbulence scheme as well, not at least because the buoyancy source term for TKE is dependent on it. By means of our statistical saturation adjustment assuming a Gaussian distribution function of local oversaturation this issue has already been implemented before. However, due to condensation coupling the turbulent vertical fluxes of scalar model variables are linear combinations of the respective fluxes in conserved variables and hence have no strict flux gradient representation being a prerequisite of our implicit solution for vertical diffusion. Although analytical inspection showed that we can apply vertical diffusion simply with the flux gradient form as long as a grid scale saturation adjustment is applied at the end of each time step, we invented a general method of gradient correction in order to gain a 3-diagonal linear system for the implicit diffusion equation even in the case of non gradient fluxes. This case had to be treated by an explicit (moist) diffusion correction before. As an alternative it is also possible to apply vertical diffusion to the conserved thermodynamic variables followed by subsequent transformation of the updated variables into the model variables by means of statistical saturation adjustment. So far it is a question of model configuration and numerical accuracy or efficiency what option should be used.

The TKE diffusion is now calculated by means of a common SUBROUTINE for semi-implicit vertical diffusion applicable to all variables to be diffused including passive tracers. This routine contains options as to how to consider explicit tendencies or corrections of vertical gradients, where the latter option enables expressing non gradient fluxes by effective vertical gradients.

This new scheme for semi-implicit vertical diffusion is going to substitute the current code for that purpose being a part of the numerical core in COSMO, where similar code is written explicitly for each diffused variable, in particular for each passive tracer. The lower boundary condition can be chosen by NAMELIST input (either concentration condition or flux

condition), and in case of a flux condition, the surface fluxes can be specified. Otherwise the resulting surface flux has an implicit part as well depending on the degree of implicitness.

The current representation of the circulation term, still expressed in terms of a flux divergence, is treated as a gradient correction as well, avoiding an extra explicit formulation for it. Nevertheless, this current representation of the circulation term is going to be changed into a thermal SSO term, what unfortunately had to be delayed again.

All the above mentioned development is present in a still private test version based on COSMO version 4.24. Due to the quite fundamental modifications of the code, it was not yet possible to test the code sufficiently and to provide an optimal parameter setup. Nevertheless, the code is already running and provides reasonable results. But final tuning and consolidation as well as formal adoptions to the official COSMO version may take some more time.

A stability correction of turbulent master length scale according to Deardorff has been implemented into the official code, which might currently be missing.

In order to gain a theoretical framework for a comprehensive and consistent parameterization of sub-grid scale processes, a concept of scale separation has been developed and described in an internal still growing document. This concept takes into account the fact that generally valid closure assumptions cannot exist in principle and that consequently the full generality of sub grid scale processes needs to be split somehow into separated regimes valid for the application of specific closure assumptions. In this sense turbulence is a regime defined by the fundamental closure assumptions allowing a quite consistent solution of the 2-nd order budget equations. Since the separator has been related to the filter operator associated with discretization, a separated treatment of turbulence automatically generates additional interaction terms in the 2-nd order equations for turbulence that formally will make the scheme applicable, if non turbulent sub-grid scale processes are present as well and may be of particular importance when a solution without interaction terms is not possible and thus requires artificial manipulation (like in the strongly stable boundary layer) for the lack of missing physics.

According to the concept of scale separation three scale interaction terms have been introduced into our prognostic TKE equation, representing a transfer of sub grid scale kinetic energy towards turbulent scales by the action of shear generated by related non-turbulent sub-grid scale flow patterns. These are production terms by SSO wakes, convective plumes, and separated horizontal shear eddies. The SSO term is expressed using the SSO tendencies of momentum and the convection term is buoyant convective kinetic energy production derived form the convection scheme (Tiedke and shallow convection). The horizontal shear term is the horizontal shear production with respect to a special non isotropic length scale. All the 3 additional terms are based on an assumed equilibrium of production and scale transfer being treated like a dissipation term. They are implemented in the official code and can be switched on by NAMELIST input. At DWD the SSO source term has been already switched on in the operational code, the others need to be verified. However, these source terms are already used as important predictors of atmospheric turbulence for aviation purpose. Their effect is being tested in more detail by our aviation department using the package TMOS (turbulence model output statistics) developed during an internal DWD project parallel to UTCS.

A crucial problem of an UTCS is the consistent representation of sub-grid scale variation in terms of moist physics. In the framework of a single set of 2-nd order equations this can be tried by means of a statistical saturation adjustment, as we do it in our moist turbulence scheme, at which this procedure requires the existence of saturation equilibrium and the

knowledge of the distribution function of oversaturation. However, as far as the whole sub grid scale variability is represented by each of the governing statistical moments, the ice phase and precipitation cannot be neglected, in particular if deep convection is included. Since both of these condensates are known not to be in saturation equilibrium and since the overall distribution functions may be rather arbitrary, attempts in that direction are very likely to fail. Thus some analytical work has been done in order to treat this problem in the framework of scale separation, what is necessary anyway according to the previous arguments. The main result of this analysis is the finding that a modified mass flux approach can be a solution, if simplified averaged budget equations are considered for convective sub-domains. Considering the necessary construction constraints for these sub-domains, estimates of their volume fraction can be provided and the full model microphysics can be applied to these sub domains. In this approach turbulence is assumed to be either a sub grid scale process with respect to the sub domains maintaining lateral mixing, or it provides initial convective sub domains. Thus turbulence and convection would really be interacting and the governing scales of convection would develop by the governing physics. Finally a separation to resolved scales can be formulated for convection as well. The concept has been worked out only in a manuscript yet and an excerpt of it has been compiled as PPT file.

Future plans for related work after the PP UTCS:

- generation of an official well-tested code valid for COSMO, SCM and ICON, ready for operational forecast, containing all the development present in the private test code being active, in particular the new routine for vertical diffusion;
- finding an optimal mode for vertical diffusion with respect to the lower boundary condition, the consideration of explicit tendencies and of moist corrections;
- switching on the implemented scale interaction terms after verification against SYNOP data (operational verification).

Future plans for a medium range prospect:

- reformulation of the current circulation term to be a thermal SSO source term for TKE;
- implementation of SSO/roughness layer terms based on an extended boundary layer approximation in a vertically resolved roughness layer;
- consideration of missing mixing by non-turbulent sub-grid scale motions themselves (in case of SSO wakes and horizontal shear eddes).

Future plans for later years:

- implementation of a scale separated mass-flux convection interacting with turbulence and providing volume fractions of convective sub-domains (final step of a scale separated UTCS).

4 Evaluation of SGS cloud schemes against satellite data and data from measurements in the surface air layer (Euripides Avgoustoglou)

COSMO model uses operationally two sub-grid schemes for stratus clouds. A semi-empirical one based on relative humidity used in the radiation module, denoted as RH scheme, and

a parameterizable statistical one used in the turbulence module, denoted as SGSLI scheme. The main objective of the work was to show whether SGSLI could be operationally implemented in the radiation module.

Although the task looked straightforward, several issues needed to be settled as the work was progressing.

The main issues of consideration were:

- the availability of a code version that could properly include the cloud-ice content into the statistical scheme;
- the proper boundary conditions;
- the availability and comparison with real time data;
- the selection of the test cases.

The test version was provided by Matthias Raschendorfer and is based on COSMO version 4.6. Although this version is relatively old, any comparative tests that were made with newer versions did not change the diagnostics.

The domain was centred around the Hellenic geographical area characterized by equal sea and land partitions. This choice gives rise to the strong mixing of continental as well as marine clouds which is one of the most challenging features regarding the operational use of numerical weather prediction models by the Hellenic Meteorological Service.

The choice of the initial and boundary conditions was considered an issue because the main synoptic features are carried by the global model used. Over the first diagnostic tests, GME as well as ECMWF forecasts were used without any important differences between them. However our main evaluations were delivered through GME analysis mode over 3-hour intervals of 36 or 48-hour spans provided by DWD.

The default parameterization of the SGSLI scheme was mainly used, however several other diagnostics were performed either through different parameterization of SGSLI or mixing of SGSLI and RH.

The main strategy regarding the choice of the considered test cases was to have synoptic conditions that favour stratus clouds over the domain under consideration without any significant convection and over the full seasonal span.

Over the fist stages of the project, direct heuristic comparisons of the model total cloud cover with MSG satellite images at the 10.8 and 8.7 micron channels were performed. The main outcome of these comparisons was that the implementation of the SGSLI scheme was realistic but not conclusive. Further comparisons were made regarding 2-meter minimum and maximum daily temperatures as well as daily 2-m temperature variations for about 50 synoptic Hellenic meteorological stations. The revealed feature was that the 2-meter minimum temperature was better simulated when the SGSLI scheme was implemented in the radiation module while the 2-meter maximum temperature was better simulated when the default RH scheme was implemented in the radiation module.

An important boost towards the relative impact of the cloud schemes came from a close comparison of artificial satellite images provided by the model with the real ones provided directly at the Hellenic Meteorological Service by MSG. These comparisons were accomplished via the CineSat software and became possible by the Remote Sensing Division of the Hellenic National Meteorological Service that provided access to the available tools and

database structure in order to create the necessary look-up tables and perform the statistics. It became clear from these direct comparisons that the implementation of the SGSLI scheme leads to an underestimation of low cloud cover by the model in contrast to the implementation of the default RH scheme. However, another important feature was that the implementation of the SGSLI scheme leads to a relatively better simulation for medium cloud-cover. Nevertheless, the total cloud cover is better estimated by the default relative humidity scheme, and so are the radiation temperatures in the 10.8, 3.9, 6.2 and 7.3 μm.

Although the SGSLI scheme cannot in its present form replace the RH scheme in the radiation module, it is an important asset to COSMO model that can be used as a reference to support the ongoing research in this crucial area of atmospheric physics.

A further investigation of the cloud schemes associated with different COSMO parameterizations in an updated model version (like changing the default values of vertical turbulent diffusion coefficients) in the fashion of QPF Project could be considered as an extension to the project.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Abstract

The APSU Priority Project focussed on the improvement of the ensemble forecast systems run by the COSMO members, developing both the perturbation methodology and the post-processing. The aim was to improve the forecast issued by the convection-permitting (CP) scale modelling system, particularly for severe and high-impact weather events. The research and development work covered three main areas:

- development of model perturbation methodologies, including new methods and the development of surface/soil perturbations;
- development of post-processing methods for the convection-permitting ensembles, especially focused on the forecast of selected severe weather phenomena;
- better use of the KENDA analyses as Initial Conditions (ICs) to initialize the CP ensembles and improvement of the perturbed Boundary Conditions (BCs).

The project provided also the occasion to discuss and plan the transition of the ensembles to the ICON-LAM model.

2 Introduction

The APSU Priority Project was initiated due to the need of improving the ensemble systems run by the members of the COSMO Consortium, in particular for the prediction of near-surface weather parameters at high spatio-temporal resolution.

During the WG7 meeting held in Offenbach in March 2017, it was recognised that the perturbations applied to the model in the ensemble configurations do not provide yet a satisfactory representation of the model error, as evidenced by the spread-skill relation for near-surface parameters (Marsigli et al., 2019). The shared opinion was that the spread of the ensembles in terms of near-surface parameters (temperature, wind) should be increased, in order to better match the forecast error. This should be done with care, since it is recognised that the ensemble spread cannot be increased up to exactly reaching the forecast error, because the latter includes also the systematic error, which should be tackled by improving the model, not by increasing the spread. On top, observation error should be considered in the computation of the forecast error (Ben Bouallegue et al., 2020). What should be better represented in the ensembles is that part of the error which depends on the uncertainties in the determination of initial and boundary conditions as well as in the description of the physical processes in the model, which are mainly due to the variability of the model performance in dependence of the meteorological situation, usually called "error of the day" or flow-dependent error (see for example Leutbecher et al., 2017). To reach this goal, it is needed to work on a better representation of the model error. The strategy proposed in APSU is based on testing new approaches for model perturbation which have been recently developed or made available to the COSMO model, and to review and improve the already existing ones. More specifically:

- further develop and test the new stochastic approach to model the model error developed at DWD
- develop an additive perturbation method based on the Stochastic Pattern Generator (Tsyrulnikov and Gayfulin, 2017)

- test of two new available methods for model perturbations: iSPPT (independent SPPT, Christensen et al., 2017) and the perturbations based on analysis increments (Piccolo et al., 2018)
- develop perturbations of the soil/surface and test the combination of the different perturbations

It was also noted that the potential of the ensembles is not fully exploited for the operational duties, in particular for high spatial and temporal resolution forecasts, therefore it was identified the need to continue working on ensemble post-processing and interpretation. In particular it is needed to:

- develop suitable probabilistic products for operational applications. In order to benefit from the link with the SRNWP-EPS Project of EUMETNET, the focus was on products for thunderstorms and fog;
- further develop suitable calibration procedures for the CP ensembles.

This activity has a strong link with the activities carried out in WG4.

On top of these development areas, the transition from the COSMO to the ICON model implies also a transition of the ensemble systems. To make this possible, a planning of the needed activities was started in the APSU PP. A first concrete task was performed at DWD, where the Parameter Perturbation methodology was transferred and tested in the new ICON-LAM ensemble.

3 New model perturbation methods

New methodologies for model perturbations have been tested in the APSU PP, and further developed.

3.1 SMME: Stochastic model of the model error (M. Sprengel, T. Heppelmann, C. Gebhardt, DWD)

3.1.1 Method

At DWD, a prognostic stochastic model of the model error ("EM-scheme", Ekaterina Machulskaya) has been developed. The concepts of the EM scheme have been the basis for the development of an improved framework called "stochastic model of the model error" (SMME). The development of SMME is carried out within the project Gridcast and its precursor EweLine which both are collaborative research projects of the DWD with the Fraunhofer IEE and the German transmission system operators (TSOs) in the context of renewable energies. The growing share of renewable energy in power generation increases the impact of the weather on the stability of the electrical power grid. Especially prior to severe weather events, not only high-quality weather forecasts but also information about forecast uncertainties is needed by the TSOs to prepare stability provisions. Improving the description of the inherent model error is therefore one of the goals of the research project Gridcast. Even if this development is focused on optimizing the use of renewable energies, it can be beneficial for NWP model development in general and therefore fits well as a contribution to PP APSU.

The EM-scheme and the SMME have in common that the errors of the tendencies of different model variables are assumed to obey the Langevin-type stochastic differential equation being correlated in space and time and stochastically driven by Gaussian noise as in equation (1).

$$\frac{\partial \eta_X(x,t)}{\partial t} = -\gamma(\tau_X)\eta_X(x,t) + \gamma(\tau_X)\nabla \cdot \left(\lambda^2(\tau_X)\nabla\eta_X(x,t)\right) + \sigma(\tau_X)\xi(x,t), \tag{1}$$

where

- $\tau_X = \tau_X(x,t)$ is the tendency of the predictor variable X,
- γ is the damping,
- diffusion λ guarantees spatial correlation,
- ξ is a standard normal random field with standard deviation σ.

The weather-dependent values of the parameters γ, λ, and σ of this equation are determined by predictors, whereas the dependencies of the parameters on the predictors are inferred from past data. The solution η_X of eq. 1 is our model of the model error and is added to the dynamic equations of the model to correct the tendencies from the NWP online for a set of variables X:

$$\frac{\Delta X}{\Delta t}(x,t) = \left[\frac{\Delta X}{\Delta t}(x,t)\right]_{\text{phys}} - \eta_X(x,t).$$

The method is applied to temperature and zonal and meridional wind as prognostic variables with the tendency τ_X of each variable X acting as predictor for the respective error model parameters.

Going from the EM-scheme to the SMME, the method for estimating the parameters has been re-developed from scratch by taking the spatial diffusion term into account from the very beginning of the development. This approach enabled us to have a consistent framework for all three parameters γ, λ, and σ that includes the spatial diffusion without the need for a separate treatment.

As first COSMO-D2-EPS experiments with the method showed an increased forecast spread but at the expense of a substantial degradation of the RMSE (see later in section 3.1.3), a new method for estimating γ has been developed based on results of (García-Ojalvo et al., 1992):

Assuming spatially constant coefficients, we can discretize the stochastic partial differential equation eq. 1 in space and perform a spatial Fourier transform to obtain a system of stochastic ordinary differential equations. For these equations certain expectation values and correlations can be derived analytically. For example for the stationary correlation function at different times t and t' and Fourier modes k and k' one finds

$$\left\langle \eta_k(t)\eta_{k'}(t')\right\rangle^{st} = \frac{\sigma^2 N_x \Delta x N_y \Delta y}{2\gamma c_k} e^{-\gamma c_k |t-t'|}\delta_{k,-k'} \tag{2}$$

where Δx and Δy denote the horizontal grid spacing, N_x and N_y are the number of grid points, and c_k is the Fourier transform of the differential operator. For the Fourier modes $k = k' = 0$ this further simplifies and we can take the quotient at different times $t' = t + \Delta t$ and $t' = t + 2\Delta t$ to obtain

$$\frac{\left\langle \eta_k(t)\eta_{k'}(t+\Delta t)\right\rangle^{st}}{\left\langle \eta_k(t)\eta_{k'}(t+2\Delta t)\right\rangle^{st}} \overset{k=k'=0}{=} e^{\gamma \Delta t}. \tag{3}$$

This method resulted in a much better RMSE (see later in section 3.1.3).

3.1.2 Parameter estimation

The estimation of the parameters γ, λ, and σ from past data requires the estimation of the model error tendencies on the left-hand side of eq. 1 which in turn requires an approximation of the truth to be compared with model forecast. For SMME, the truth is approximated by analysis fields of KENDA for COSMO-D2 and the model error is defined as the deviation of short-range forecasts of COSMO-D2 from these analyses. Other approaches exist to estimate the model error tendencies by comparing forecasts only (see for example Tsyrulnikov and Gayfulin, 2019 and Christensen, 2020).
This section exemplifies important aspects of the dependencies of the estimated parameters γ, λ, and σ on their predictors, on the forecast time and the time of the day as well as on the vertical model level. The training period for the parameter estimation is 5 months in autumn 2018 and 2019 with the exclusion of the application month October 2018. The training data are the operational COSMO-D2 forecasts started at 03 UTC up to 45 hours of forecast time and the operational analyses for the same period. Fig. 1 shows the changes of the damping parameter γ with forecast time for temperature at ca. 300m above ground.

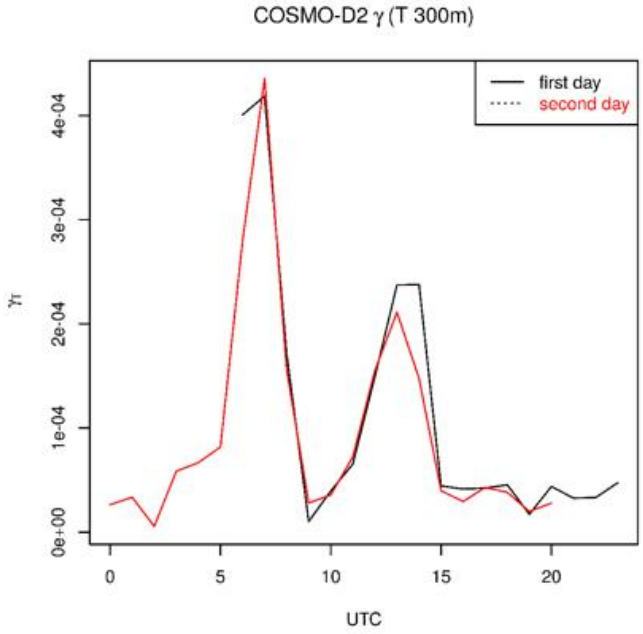

Figure 1: Estimated γ for temperature at ca. 300m as a function of the time of the day for lead times 1h to 45h (first day in black, second day in red, forecast start is 03 UTC).

There is a clear dependence on the time of the day without a significant difference between day 1 and day 2. The dependence on the time of the day decreases with increasing height of the vertical model level (not shown). The parameter γ depends on the prognostic variable X but hardly on the size of its tendency τ_X (not shown). However, there is a clear dependence of the diffusion parameter λ on the predictor tendency τ_X (Fig. 2).

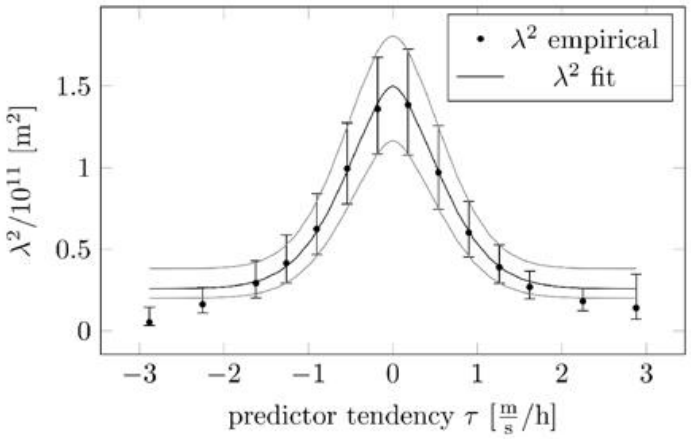

Figure 2: Estimated λ for the zonal wind at 97m above ground and fitted to a function of type $\lambda(\tau) = \lambda_a e^{-(|\tau|/\lambda_b)^{\lambda_c}} + \lambda_d$. The error bars are the 95%-confidence intervals estimated from the sample of days for training. The black line is the fit to the empirical values of λ and the grey lines fit to the limits of the confidence intervals.

The tendencies have been arranged in equally populated bins for the parameter estimation. A parametrized function can be nicely fitted to the empirical values.

Fig. 3 shows the combined effect of forecast time, time of the day and atmospheric height on λ for temperature.

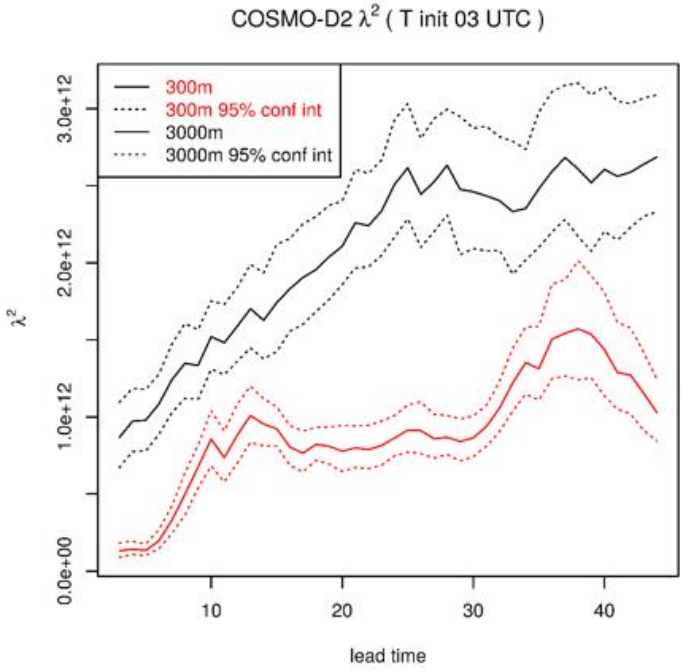

Figure 3: Estimated λ for temperature (solid line) at two atmospheric heights (300m in red, 3000m in black) as function of forecast lead time. The dashed lines are the 95%-confidence intervals estimated from the sample of days for training.

The values of λ are larger for higher altitudes and a given forecast lead time. There is a general trend of increasing λ with increasing lead time which is modulated by a daily cycle in the boundary layer. This dependence on the time of the day shows an increase of λ starting

after dawn with the onset of boundary layer mixing with a moderate decrease in the evening and a quasi-plateau during the night. In general, the characteristics of λ for temperature apply to the horizontal wind components as well.

Since the parameter σ is calculated on the basis of the estimated γ and λ it basically inherits the dependencies on time and height from those parameters. In Fig. 4, the dependence of σ on model level and predictor tendency for zonal wind is shown.

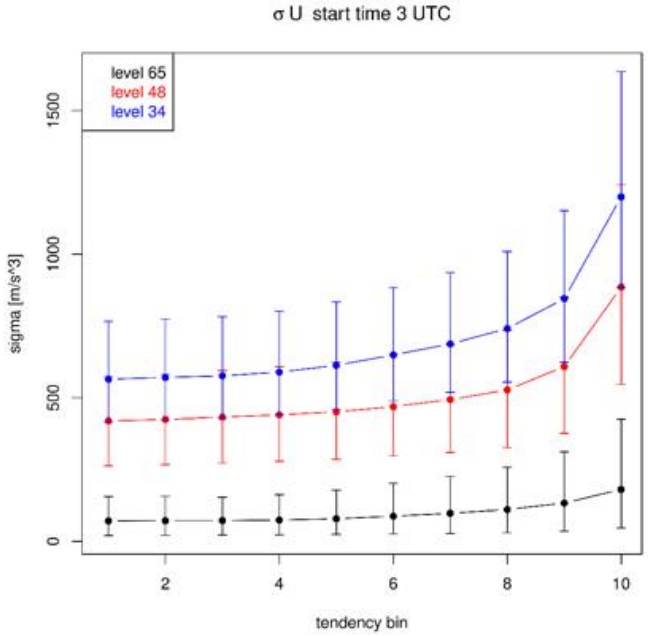

Figure 4: Estimated σ for zonal wind at different atmospheric heights (different colours) as function of tendency bin τ_U, i.e. numbers on the abscissa are bin counts. The error bars are the 95%-confidence intervals estimated from the sample of days for training. The levels 65, 48, and 34 correspond to the heights 10m, 757m, and 3000m, respectively.

There is an increase of σ with height as well as with the magnitude of τ_U, the latter being negligible to moderate for lower values of the tendency. The increase of σ with τ_U is larger higher up in the atmosphere.

In practice, the parameters γ, λ, and σ are estimated for distinct model levels only (at 10m, 757m, and 3000m for U and V; and 300m, 757m, and 3000m for T). Accordingly in the application, the model error η is calculated for these three levels and linearly interpolated vertically between those levels. Above the highest level $k_{max} = 34$ at 3000m (and for T below $k_{min} = 55$ at 300m) η is exponentially damped towards zero (recall that smaller k correspond to greater height):

$$\eta_X^k(x,t) = \eta_X^{k_{max}}(x,t)e^{-(k_{max}-k)} \quad \text{for } k = k_{max}-1,\ldots,k_{max}-4,$$

and similarly for T at $k = k_{min}+1,\ldots,k_{min}+4$.

Investigations about the model of the model error in the global ICON-EPS within the project Gridcast have shown further dependencies of the parameters (land/sea grid points, geographical latitude) which can be neglected for the application of SMME to the limited domain of COSMO-D2.

3.1.3 Experiments and verification results

Based on the parameters γ, λ, and σ as estimated from a training data set of the operational COSMO-D2 forecasts and analyses for autumn 2018 and 2019, two experiments were performed for October 2018 with the operational COSMO-D2-EPS settings. All forecasts start at 03 UTC and run for 45 hours. Verification shown in this section is against SYNOP observations.
The first experiment resulted in an increased spread for several prognostic variables, but there was a significant increase in the forecast error as well (e.g. for 10m wind speed, see Fig. 5).

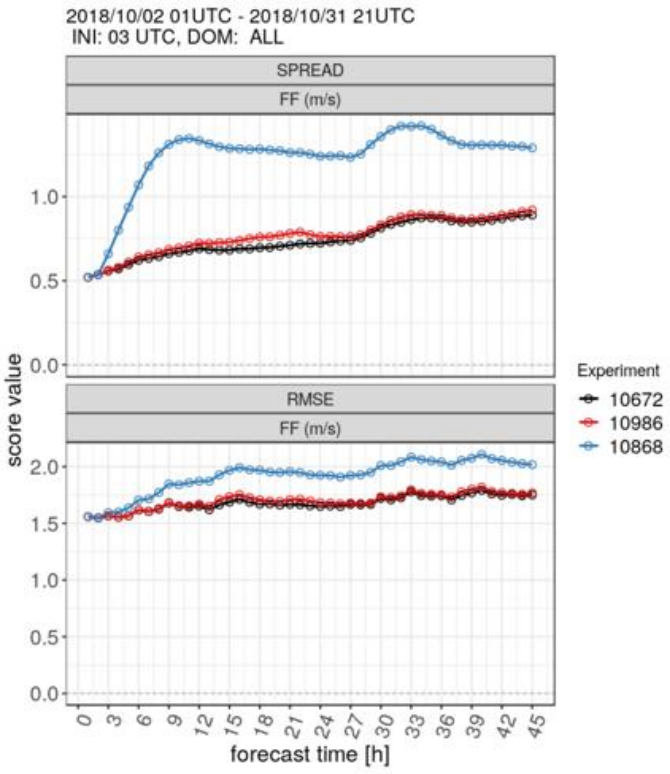

Figure 5: EPS spread (top) and root mean squared error (bottom) of the ensemble mean for 10m wind speed as function of forecast lead time for the first experiment with the model of the model error (blue, experiment 10868), the modified SMME experiment (red, 10968), and a reference run with operational settings but without model error (black, 10672).

These results initiated the changes in the estimation method for the damping parameter γ following García-Ojalvo et al. (1992) as mentioned in section 3.1.1. The effect of this methodological change in comparison to the first experiment can be seen in Fig. 5 as well. The results are mostly neutral compared to the reference, with a slight increase of the spread for wind speed in the afternoon hours of the first forecast day.

The new experiment incorporated a further methodological adjustment. The model tendencies acting as predictors for the parameters in the application of SMME are calculated during the forecast as changes with respect to the model time step. However, the estimation of the tendency-parameter relation from the training data has to refer to the output frequency of the model data, i.e. hourly steps being much larger than the model time step. This leads to a more frequent occurrence of relatively large tendencies in the application compared to the training of the parameters. To account for this effect, the properties of the tendency

distributions are harmonized between the two different time scales by applying a factor of 0.43–0.58 to the variance of the tendency distribution during the model forecast.

Fig. 6 shows several verification scores for 10m wind speed and 2m temperature for the experiment with SMME based on the improved estimation method in comparison to the operational set-up.

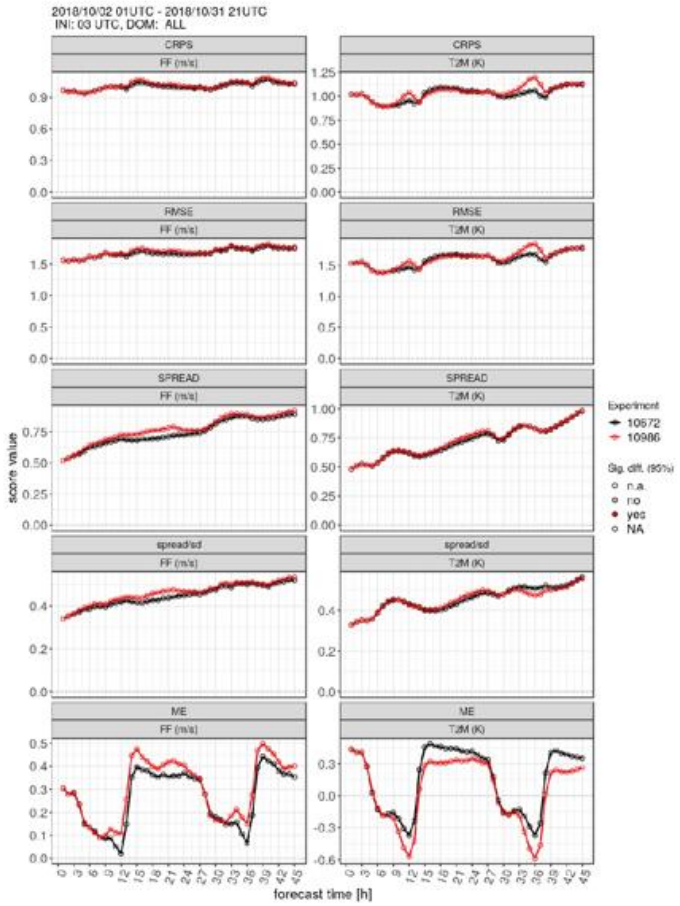

Figure 6: Continuous ranked probability score (CRPS), RMSE, EPS spread, ratio of spread to the standard deviation of forecast errors and mean error of the ensemble mean (from top to bottom) for 10m wind speed (left) and 2m temperature (right) as a function of forecast lead time for the modified SMME experiment (red, experiment 10968) and a reference run with operational settings but without SMME (black, 10672).

The results are mostly neutral compared to the operational set-up. There are slight increases in CRPS and RMSE for 2m temperature around 15 UTC day time, but the differences are not significant (as indicated by the non-filled circles in the plot). There is an increase of spread for wind speed during the first forecast day which is also not significant.

Most obvious differences occur in the mean error of the EPS mean for both variables. The SMME run produces consistently an EPS mean of 10m wind with a slightly larger bias than the reference run which itself has a positive bias. The 2m temperature bias shows qualitatively the same daily cycle with slightly colder temperatures in SMME. Note that the SMME is effective only from 2.5 forecast hours onward to allow for the spin-down of forecast tendencies resulting from minor deviations of analysis fields from the balance properties of the model dynamics. This leads to almost identical mean errors of the SMME and the reference run in the first forecast hours.

In general, the SMME in its current set-up leads to neutral results and the methodological changes were successful in avoiding the forecast deterioration seen in the first experiments. This neutral implementation of the SMME into the COSMO-D2 is a promising starting point for further improvements. A first step for improvements is described in the next section.

3.1.4 Bulk Richardson number as additional predictor

Fig. 7 shows the time series of the mean error of the 24 hours EPS mean forecast of 10m wind speed for the SMME and the reference run.

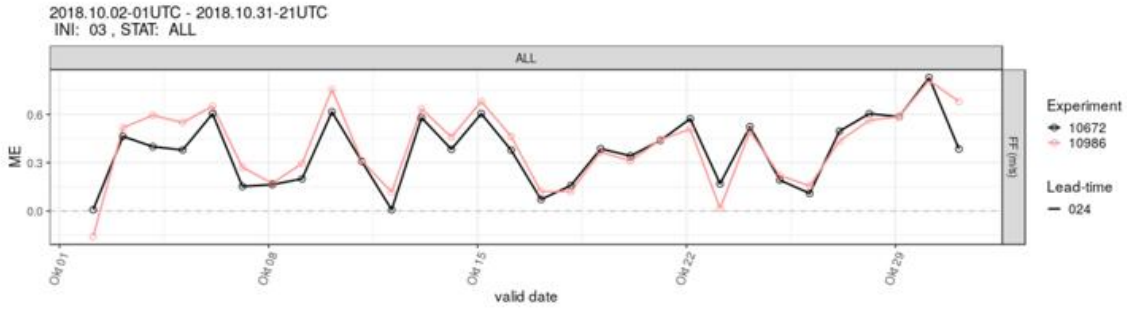

Figure 7: Time series of the mean error of the 24 hours EPS mean forecast of 10m wind speed for the SMME (experiment 10986) and the reference run (experiment 10672).

There are periods with an increased bias in the SMME run, but also periods with neutral results by the SMME approach. A conditional verification showed that the SMME increases the error particularly in nights with stable PBLs. This leads to further investigating how to include knowledge about the stability of the PBL into the SMME. The suggestion is to introduce the bulk Richardson number as a further predictor in addition to the tendency of the respective variable.

We chose to discriminate three cases: stable, unstable, and neutral PBL. To this end, we calculate the bulk Richardson number

$$R_B = \frac{(g/T_v)\Delta\theta_v \Delta z}{(\Delta U)^2 + (\Delta V)^2} \tag{4}$$

for a bulk layer of levels 65–55 (10m–300m) and perform a horizontal smoothing over 7×7 grid points. In eq. 4 we use the following definitions:

- g gravitational constant,
- absolute T_v virtual temperature,
- Δz layer thickness,
- $\Delta\theta_v$ change in virtual potential temperature across layer,
- ΔU, ΔV change in wind speed across same layer.

Our thresholds for the three cases are

$$R = \begin{cases} \text{stable} & R_B >= 1.5 \\ \text{neutral} & R_B \in (0.25, 1.5) \\ \text{unstable} & R_B <= 0.25. \end{cases} \tag{5}$$

Fig. 8 provides the fields of the bulk Richardson number for a stable (14th October) and an unstable (24th October) case.

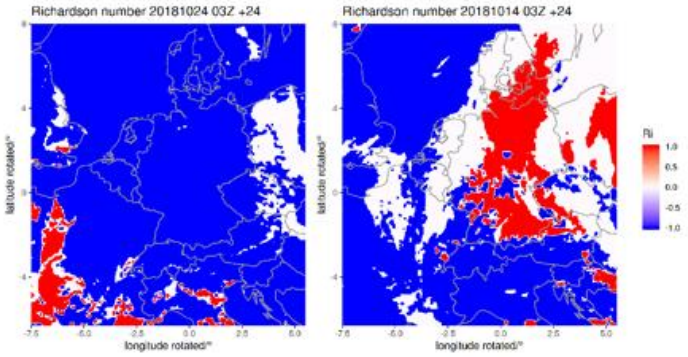

Figure 8: Bulk Richardson number for an unstable (24th October) and a stable (14th October) case.

These fields together with Fig. 7 exemplify the link between nocturnal stable/unstable conditions and their effect on the wind forecast of the COSMO-D2-EPS using the SMME method. The stratification along the three cases stable, unstable, and neutral boundary layer according to R_B leads to differences in the estimated parameters as can be seen in Fig. 9 for the diffusion parameter λ. The stratification of the estimation of the parameters γ, λ, and σ by the bulk Richardson number and the use of R_B as an additional predictor will be adopted in further experiments with SMME.

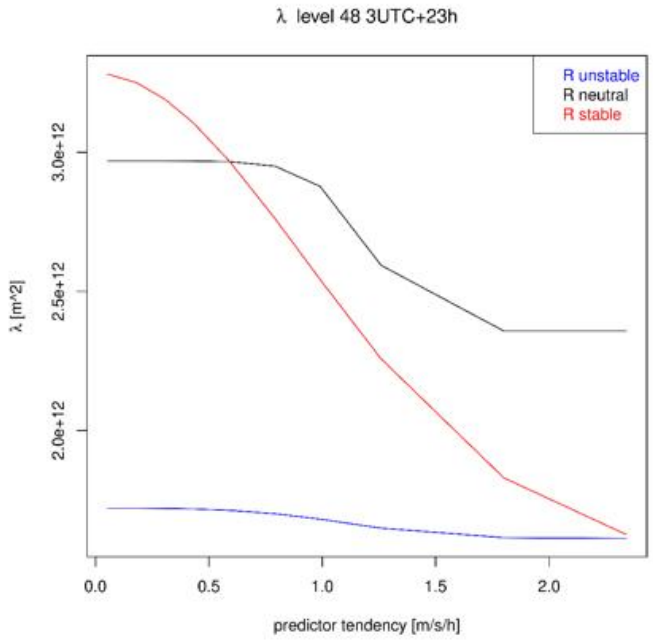

Figure 9: Diffusion parameter λ for zonal wind at 757m at 2 UTC during the night for stable (red), neutral (black), and unstable(blue) conditions.

The next steps in the development of the SMME will be its application to ICON-D2-EPS in its current state, analysing potentials for further improvements of the methodology, and speed-up of the method from a computational point of view.

3.2 AMPT: Additive Model-error perturbations scaled by Physical Tendencies (M. Tsyrulnikov, D. Gayfulin, E. Astakhova, RHM)

In this section, we introduce a new ad-hoc approach to generation of model-error perturbations. The idea is to generate additive perturbations as four-dimensional random fields whose magnitude is determined by the area-averaged modulus of physical tendency. The AMPT (Additive Model-error perturbations scaled by Physical Tendencies) scheme is applied to both atmosphere and soil. Nearly-Gaussian and significantly non-Gaussian fields are treated. Results of numerical experiments with a COSMO-model ensemble prediction system are given.

3.2.1 SPPT in a nutshell

To facilitate the presentation of the new AMPT scheme, we first outline Stochastic Perturbation of Physical Tendency (Buizza et al., 1999), the very popular technique to represent errors in physical parametrizations. This simple and effective technique relies on the assumption that the magnitude of error in physical tendency is proportional to the magnitude of physical tendency itself. There is also a flavour of SPPT called iSPPT in which tendencies from different physical parametrizations are perturbed independently (Christensen et al., 2017).

By $\mathbf{P}(x,y,\zeta,t) = (P_1(x,y,\zeta,t),\dots,P_{n_{\text{fields}}}(x,y,\zeta,t))$ we denote the vector valued physical tendency (sometimes called the *net* physical tendency, generated by all physical parametrizations combined) at the spatial grid point with the horizontal coordinates (x,y), the vertical coordinate ζ, and the time step t. Here $P_i(x,y,\zeta,t)$ is the component of $\mathbf{P}(x,y,\zeta,t)$ in the i-th model field (variable) X_i, and n_{fields} is the number of model fields selected to be perturbed, normally, temperature, winds, and humidity.

In SPPT, the perturbed physical tendency $\mathbf{P}^*$ is postulated to be

$$\mathbf{P}^*(x,y,\zeta,t) = (1+\epsilon\,\xi(x,y,t))\cdot\mathbf{P}(x,y,\zeta,t), \tag{6}$$

where $\xi(x,y,t)$ is a *scalar* (i.e. common for all physical tendency components) zero mean and unit variance spatio-temporal random field and ϵ the parameter that controls the magnitude of the perturbation (normally, 0.4–0.8). For stability reasons, the point wise probability distribution of $\xi(x,y,t)$ is specified in such a way that $1+\epsilon\,\xi(x,y,t)>0$, that is, avoiding sign reversal of the physical tendency (Leutbecher et al., 2017). Note that in SPPT the random pattern ξ is two-dimensional in space.

From eq. 6, the SPPT perturbation is seen to be multiplicative:

$$\delta\mathbf{P} = \mathbf{P}^*(x,y,\zeta,t) - \mathbf{P}(x,y,\zeta,t) = \epsilon\,\xi(x,y,t)\,\mathbf{P}(x,y,\zeta,t). \tag{7}$$

Here and elsewhere δ denotes a perturbation.

3.2.2 AMPT

Motivation

The following three deficiencies of SPPT led us to propose the new approach.

1. In SPPT, perturbations are large when and where the physical parametrizations generate a *large* physical tendency $\mathbf{P}$. This formulation gives rise to a meaningful scaling

of perturbations in situations when the model predicts high subgrid-scale variability and produces a large physical tendency. But it cannot cover situations in which the model error magnitude is large whereas the magnitude of the physical tendency is small. This occurs, for example, if in some grid cell convection is initiated in nature whilst a convective parametrization fails to be activated.

2. In SPPT, the *multivariate* perturbation vector $\delta\mathbf{P}(x, y, \zeta, t)$ is strictly proportional to the physical tendency vector $\mathbf{P}(x, y, \zeta, t)$ (see eq. 7). This implies that *SPPT tacitly assumes that the model error is only in the magnitude* of the vector $\mathbf{P}$, whilst the *ratios* between the physical tendencies in different variables (i.e. between $\delta P_i(x, y, \zeta, t)$ for different variables labelled by i at the same grid point x, y, ζ, t) are *error-free*, which is highly unlikely. Indeed, eq. 7 implies that the relationship between any two components of $\mathbf{P}$, say, those that correspond to temperature T and zonal wind u, i.e. P_T and P_u, is the same before and after the perturbation:

$$\frac{P^*_\mathrm{T}}{P^*_u} = \frac{P_\mathrm{T}}{P_u}. \tag{8}$$

   The *ratios* of the components of the physical tendency vector are, thus, not perturbed in SPPT (in iSPPT, this is the case for each individual physical parametrization).

3. Similarly, as the SPPT random pattern ξ does not depend on the vertical coordinate ζ, the ratios of physical tendencies at different *vertical levels* are not perturbed:

$$\frac{P^*_i(x, y, \zeta_k, t)}{P^*_{i'}(x, y, \zeta_{k'}, t)} = \frac{P_i(x, y, \zeta_k, t)}{P_{i'}(x, y, \zeta_{k'}, t)} \tag{9}$$

   for any two variables i, i' and any two vertical levels k, k'. This implies that there are *no errors* in those ratios, which, again, is unlikely.

Approach

We propose to address the above deficiencies of SPPT in our AMPT scheme as follows.

1. In SPPT, as it follows from eq. 7, the standard deviation of the perturbation in the i-th prognostic field (given $\mathbf{P}$) is $\epsilon|P_i|$ so that the standard deviation of the multivariate (vector) perturbation is proportional to the modulus of the physical tendency: $\mathrm{SD}(\delta\mathbf{P}|\mathbf{P}) = \epsilon|\mathbf{P}|$. In AMPT, we retain this linear dependency of the magnitude (standard deviation) of model-error perturbations on the modulus of physical tendency. But we define this dependency to be more general than just *point wise*.

   Specifically, we propose to generate model-error perturbations in the *additive* (rather than multiplicative as in SPPT) way and postulate their magnitude to be proportional to an *area-averaged* (rather than point wise as in SPPT) $|\mathbf{P}|$ in the horizontal. This allows AMPT to generate non-zero perturbations even at grid points with zero physical tendency — if there are nearby points with non-zero physical tendency.

2. We allow for errors in the relationships between physical tendencies in different model variables by introducing *independent* driving random fields for different model variables.

3. We allow for errors in the relationships between physical tendencies at different model levels by making ξ a *four-dimensional* random field $\xi(x, y, \zeta, t)$ rather the three-dimensional field $\xi(x, y, t)$ as in SPPT.

It is worth remarking that the SPPT perturbations at any given horizontal-grid point and time step are perfectly correlated between different variables and different levels, whereas the AMPT perturbations are uncorrelated between different variables and partly correlated in the vertical. This suggests that a hybrid SPPT+AMPT scheme might be considered. In this study we focus on the pure AMPT.

3.2.3 AMPT model-error perturbations: "Gaussian" atmospheric variables

In the context of limited-area modelling, we define the area-averaged magnitude of physical tendency for nearly Gaussian distributed fields such as temperature T and the two wind components u, v (T, u, v are denoted generically as Y in this section) through averaging over the *whole domain* in the horizontal:

$$\mathcal{P}_{\mathrm{Y}}(z,t) = \widehat{\mathbb{E}}|P_{\mathrm{Y}}(x,y,\zeta,t)|, \tag{10}$$

where ζ stands for the vertical coordinate, P_{Y} is the tendency in Y due to all physical parametrizations, and $\widehat{\mathbb{E}}$ is the horizontal averaging operator on the model grid. Then, the perturbation is defined to be

$$\delta Y(x,y,\zeta,t) = \epsilon_{\mathrm{Y}} \cdot \mathcal{P}_{\mathrm{Y}}(\zeta,t) \cdot \xi_{\mathrm{Y}}(x,y,\zeta,t), \tag{11}$$

where the multiplier ϵ_{Y} is the external parameter that controls the overall magnitude of the perturbation and $\xi_{\mathrm{Y}}(x,y,\zeta,t)$ is the Gaussian pseudo-random field with zero mean, unity variance and the tunable spatio-temporal structure (that is, spatial and time scales). The four-dimensional pseudo-random fields ξ are to be generated "online", that is, in the course of the forecast model's time integration. In this study we used the Stochastic Pattern Generator (Tsyrulnikov et al., 2017) for this purpose. The perturbations $\delta T(x,y,\zeta,t), \delta u(x,y,\zeta,t), \delta v(x,y,\zeta,t)$ (and any other perturbations referenced below) are computed and added to the model state at each time step.

Note that theoretically, specifying mutually uncorrelated random stream function and velocity potential fields instead of specifying uncorrelated random u and v wind components is to be preferred. The reason is that the former approach allows for *isotropic* vector-wind perturbations (Monin et al., 2013), unlike the latter approach. However, in practical terms, we were not able to identify any significant flaw in the vector field composed of two independent u and v fields. For this reason and due to the almost complete lack of evidence on the actual structure of model errors, we stick to the simpler formulation of AMPT with mutually *independent* $\delta u(x,y,\zeta,t)$ and $\delta v(x,y,\zeta,t)$ in this study.

From $\delta T(x,y,\zeta,t)$, we compute the pressure perturbation $\delta p(x,y,\zeta,t)$ integrating the hydrostatic equation (in which δq is neglected as a small contribution to a small perturbation). The integration goes from the model's top pressure downwards.

3.2.4 AMPT model-error perturbations: Humidity and hydrometeor fields

In contrast to roughly Gaussian distributed physical tendencies for T, u, v, physical tendencies for specific humidity q_{v}, cloud water content q_{c}, and cloud ice content q_{i} are highly non-Gaussian. Specifically, there are areas of high physical tendencies (related, mainly, to precipitation) and there are much (orders of magnitude) lower tendencies in non-precipitating areas (not shown). To simplify notation, we denote in this subsection any of these fields generically by Z in this section.

The highly variable magnitude of the physical tendency for non-Gaussian fields in different areas across the forecast domain makes the above whole-domain averaging (eq. 10) not meaningful. For these fields, we propose the *local-area* (moving-window) averaging as a means to compute the *local* (instead of global) area-averaged magnitude of physical tendency:

$$\mathcal{P}_{\mathrm{Z}}(x,y,\zeta,t) = \frac{\iint_G h_A(x-x',y-y')\cdot|P_{\mathrm{Z}}(x',y',\zeta,t)|\,\mathrm{d}x'\mathrm{d}y'}{\iint_G h_A(x-x',y-y')\,\mathrm{d}x'\mathrm{d}y'}, \tag{12}$$

where G is the model domain and h_A is the averaging kernel chosen to have the simplest "boxcar" shape:

$$h_A(x,y) = \frac{1}{A^2} \qquad \text{if } |x| < \frac{A}{2} \text{ and } |y| < \frac{A}{2} \qquad \text{and 0 otherwise} \tag{13}$$

(A is the averaging radius). The *local* averaging of the absolute (i.e. the absolute value or modulus of the) physical tendency, eq. 12, allows us to model the non-Gaussian perturbation field δZ still using the Gaussian SPG random pattern ξ_{Z}:

$$\delta Z(x,y,\zeta,t) = \epsilon_{\mathrm{Z}}\cdot\mathcal{P}_{\mathrm{Z}}(x,y,\zeta,t)\cdot\xi_{\mathrm{Z}}(x,y,\zeta,t), \tag{14}$$

where ϵ_{Z} is the external parameter (like ϵ_{Y} in eq. 11). In mathematical terms, eq. 14 implies that δZ is conditionally Gaussian given $\mathcal{P}_{\mathrm{Z}}$ and thus unconditionally non-Gaussian due to the random nature of the $\mathcal{P}_{\mathrm{Z}}$ field.

After the perturbation δZ is added to the model state at the current time step, $Z^* = Z + \delta Z$, we limit the perturbed humidity and hydrometeor fields below by nullifying negative $Z^*(x,y,\zeta,t)$. We do *not* apply a humidity supersaturation limiter (because otherwise the perturbations led to biases in perturbed forecasts).

Note that if the local averaging radius A is big enough, the moving-window scheme becomes equivalent to the formulation of AMPT with the whole-domain averaged magnitude of physical tendency. Therefore, we will assume by default that the AMPT scheme is formulated with the *moving-window-averaged* area-averaged magnitude of physical tendency $\mathcal{P}$ (as described in this section). Thus, for the i-th field, we specify its own averaging radius A_i, larger for Gaussian and smaller for non-Gaussian model variables (see section 3.2.8 for the actual choices we made).

Note that the local-averaging formulation of AMPT is applicable for the global domain as well as for the local (regional) domain.

3.2.5 AMPT model-error perturbations: Soil fields

In the land-surface model, tendencies of the two prognostic fields are perturbed: soil temperature T_{so} and soil moisture (more specifically, soil water content W_{so}), at n_{z} levels in the soil (which are counted downwards).

Due to the lack of reliable error statistics in the soil, we set up a scheme which is (i) as simple as possible, (2) consistent with statistics of the soil fields, and (iii) provides a reasonable forecast spread both in the soil and just above the land surface in the atmosphere.

The approach is to apply the above AMPT scheme. The differences with the atmospheric AMPT are:

1. In the soil AMPT, we perturb the *total* (not physical) tendency, assuming that all processes in the soil that contribute to the total tendency are modelled with substantial uncertainty.

2. The area-averaged absolute tendencies, $\mathcal{P}_{T_{\rm so}}$ and $\mathcal{P}_{W_{\rm so}}$, are computed using grid points over land only.

3. The perturbation patterns (SPG random fields) in the soil, $\xi_{T_{\rm so}}(x,y,t)$ and $\xi_{W_{\rm so}}(x,y,t)$, are two-dimensional (not three-dimensional as in the atmosphere).

4. The range of $W_{\rm so}$ is limited so that the volumetric soil water content

$$\eta_{\rm so}(x,y,z,t) = \frac{W_{\rm so}(x,y,z,t)}{\Delta_z} \tag{15}$$

(where Δ_z is the thickness of the z-th soil layer) lies between the wilting-point $\eta_{\rm wp}$ and field capacity $\eta_{\rm fc}$:

$$\eta_{\rm wp} \leqslant \eta_{\rm so}(x,y,z,t) \leqslant \eta_{\rm fc}. \tag{16}$$

If the perturbed soil water content $W_{\rm so}(x,y,z,t)$ (at any spatial grid point and any model time step) does not satisfy the constraint eq. 16, it is truncated accordingly.

For $T_{\rm so}$, the *domain* averaging is used to compute the area-averaged tendency $\mathcal{P}_{T_{\rm so}}$ (as in eq. 10). For $W_{\rm so}$, the *moving-window* averaging is employed to compute $\mathcal{P}_{W_{\rm so}}$ (as in eq. 12). These choices are motivated below in section 3.2.9.

3.2.6 Initial soil perturbations

In the soil, processes have much longer time scales than in the atmosphere, therefore weeks of cycling are needed to reach equilibrium in the ensemble statistics there. To avoid long cycling, we developed a generator of *initial* $T_{\rm so}$ and $W_{\rm so}$ perturbations.

The initial soil *temperature* perturbation is specified to be

$$\delta T_{\rm so}^{\rm ini}(x,y,z) = \sigma_{T_{\rm so}}^{\rm ini} \cdot \varkappa_{T_{\rm so}}^{1-z} \cdot \xi(x,y), \tag{17}$$

where $\sigma_{T_{\rm so}}^{\rm ini}$ is the external parameter that defines the magnitude of the perturbation at the uppermost level, $\varkappa_{T_{\rm so}} > 1$ is the vertical-decay external parameter, $z = 1, 2, \ldots, n_{\rm z}$ labels the vertical level, and $\xi(x,y)$ is the 2D SPG pseudo-random field. Note that the perturbation pattern ξ is the same for all vertical levels, whilst the magnitude of the perturbation exponentially decreases downwards (the decrease was motivated by the experimental results given below in section 3.2.9).

With the soil moisture $W_{\rm so}$, the technique is to perturb the Soil Moisture Index

$$S = \frac{\eta_{\rm so} - \eta_{\rm wp}}{\eta_{\rm fc} - \eta_{\rm wp}} \tag{18}$$

as follows:

$$\delta S^{\rm ini}(x,y,z) = \sigma_{S}^{\rm ini} \cdot \varkappa_{W_{\rm so}}^{1-z} \cdot \xi(x,y), \tag{19}$$

where $\sigma_{S}^{\rm ini}$ is the magnitude parameter like $\sigma_{T_{\rm so}}^{\rm ini}$ in eq. 17 and $\varkappa_{W_{\rm so}}$ is the vertical-decay parameter. If at some grid point the perturbed S appears to lie outside the meaningful range $[0,1]$, the perturbation $\delta S^{\rm ini}$ is truncated accordingly.

Using equations(18) and (14), we finally convert the perturbation $\delta S^{\rm ini}(x,y,z)$ into the perturbation of $W_{\rm so}$:

$$\delta W_{\rm so}^{\rm ini}(x,y,z) = \Delta_z \cdot [\eta_{\rm wp} + \delta S^{\rm ini}(x,y,z)(\eta_{\rm fc} - \eta_{\rm wp})]. \tag{20}$$

3.2.7 Stability

Stochastic-dynamic schemes in which the magnitude of forcing depends on the current state of the system can be unstable due to the positive feedback loop: a larger perturbation at the current time step may lead to a greater deviation of the state from its time-mean value, which may result in a larger physical tendency at the next time step, which would give rise to a larger perturbation, etc. until explosion.

To break this vicious circle, we considered two strategies. A technically simpler one, which we adopted in this study, is to update $\mathcal{P}_i$ not at every time step, but less frequently, once per $\mathcal{T}_{\mathcal{P}_i}^{\text{update}}$ lead time, where $\mathcal{T}_{\mathcal{P}_i}^{\text{update}}$ is the external parameter defined below in section 3.2.8.

A somewhat more involved but potentially more powerful approach (which we left for future research) is to calculate $\mathcal{P}(x, y, \zeta, t)$ from the *unperturbed* (control) model run (possibly, on a coarse spatio-temporal grid) and then use it to compute AMPT perturbations for all ensemble members. This will completely destroy the harmful positive feedback.

3.2.8 Experimental setup

The domain is shown in Fig. 10 (the Sochi Olympics-2014 area). Note the complexity of the area, which contains high mountains adjoining the sea and the valleys. The centre of the domain is located nearly at 44° N. The climate at the sea level is humid subtropical. Numerical experiments were carried out in this study mostly for the winter-spring season: in February and March, for which we had access to all data needed to run and verify an EPS. Some sensitivity experiments were also conducted for May cases.

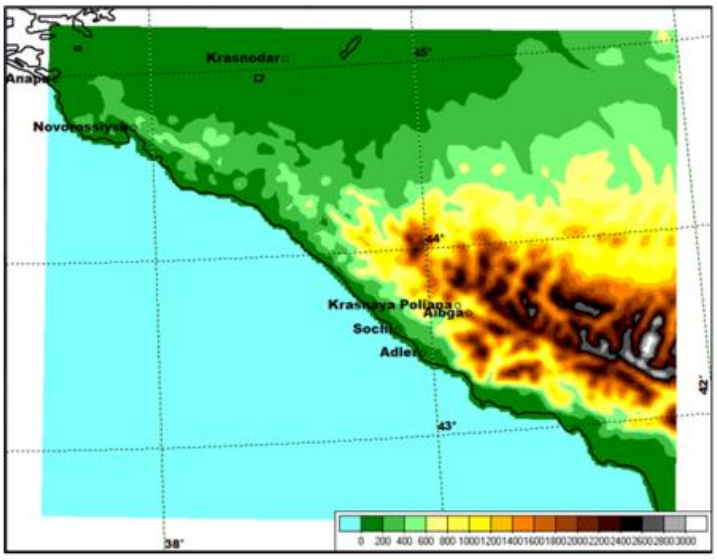

Figure 10: Model domain and orography.

The COSMO model (Baldauf et al., 2011) (version 5.01) in the convection permitting configuration with the horizontal grid spacing of 2.2 km, with the grid of 172*132 points in the horizontal, and 50 vertical levels was used for numerical experiments in this study. The model integration time step was 20 s. All calculations were performed in a single precision mode. The model's vertical coordinate was the height-based hybrid (Gal-Chen) coordinate (Gal-Chen et al., 1975).

The following AMPT parameters were selected for numerical experiments. The horizontal

length scale L_i of the SPG driving random fields ξ_i (where i labels the perturbed fields) was equal to 50 km (i.e. 20–25 horizontal mesh sizes) for T, u, v, 70% of this value (i.e. 35 km) for q_v, and 50% (25 km) for the cloud fields.

The time scales $\mathcal{T}_i$ of the atmospheric random fields ξ_i were specified as L_i/U , where U is the characteristic velocity. By trial and error, we found that $U = 15$ m/s worked well (and is physically meaningful). For both soil fields, i.e. T_so and W_so, the common time scale $\mathcal{T}_\mathrm{so}$ was specified as the time scale for atmospheric temperature, $\mathcal{T}_\mathrm{T}$, multiplied by a factor $\tau_\mathrm{so} > 1$ that reflects a much greater inertia of the soil as compared to the atmospheric air, so that $\mathcal{T}_\mathrm{so} = \tau_\mathrm{so} \cdot \mathcal{T}_\mathrm{T}$. The optimally tuned value of the soil inertia factor τ_so was 12 (i.e. the time scales were, roughly, 1 h in the atmosphere and 12 h in the soil).

The time-update interval $\mathcal{T}_{\mathcal{P}_i}^{\mathrm{update}}$ (see section 3.2.7) for the model field X_i was set equal to the time scale $\mathcal{T}_i$ of the respective random pattern ξ_i. Note that with $\mathcal{T}_{\mathcal{P}_i}^{\mathrm{update}}$ much lower than $\mathcal{T}_i$, the perturbed model may become unstable (see section 3.2.7), whereas with $\mathcal{T}_{\mathcal{P}_i}^{\mathrm{update}}$ much greater than $\mathcal{T}_i$, the resulting area-averaged $\mathcal{P}_i$ may become irrelevant in a rapidly developing meteorological situation.

The magnitude parameter of the initial T_so perturbation, $\sigma_{T_\mathrm{so}}^{\mathrm{ini}}$, was set to 1 K. The magnitude parameter of the initial soil moisture index perturbation, σ_S^{ini} was set to 0.01 (larger values led to unrealistically large model tendencies in T_so).

After some experimentation, the model-error multipliers ϵ_i were specified equal to 0.75 for T, u, v, T_so, and W_so, and 0.5 for q_v, q_c, and q_i.

The absolute-physical-tendency averaging length scale A_i (see section 3.2.4) was specified equal to the length scale L_i of the respective SPG random field ξ_i for q_v, q_c, q_i, and W_so. For the nearly Gaussian fields T, u, v, the respective A_i were selected large enough to ensure the whole-domain averaging of $|P_i|$.

In the ensemble prediction experiments presented below, we actually perturbed only temperature and winds because this configuration produced stable and positive results. As for humidity and cloud fields perturbations, they led to mixed results in EPS verification scores and so were not included in the model-error perturbation scheme.

We also compared AMPT with SPPT, implemented in the COSMO model by L. Torrisi and tuned by Maurer et al., 2014. In the SPPT, the standard deviation of the random field was set to 0.8, the spatial scale to 5° (i.e. some 500 km), and the time scale to 6 h. Temperature, wind, and humidity were perturbed.

Tapering, that is, a gradual reduction of the perturbation magnitude (1) in the lower troposphere towards the surface and (2) in the stratosphere from the tropopause upwards, was handled in the SPPT as follows. The stratospheric tapering was always active in our experiments because it is believed that the radiation tendency, which is dominant in the stratosphere, is quite accurate in clear-sky conditions (e.g. Leutbecher et al., 2017). As for the lower-tropospheric tapering, which is intended to prevent instabilities due to inconsistencies of perturbed physical tendencies and unperturbed surface fluxes (Wastl et al., 2019), we found that the SPPT worked better without it. Specifically, our experiments showed that, on the one hand, the SPPT without tapering was stable in the boundary layer. On the other hand, with tapering, SPPT led to an unacceptably small ensemble spread in the near-surface fields, so we switched off the lower-tropospheric tapering in the SPPT. In AMPT, tapering was switched off in the experiments described below.

Note that the above spatial and time scales employed in AMPT were an order of magnitude less than those in the SPPT (50 km vs. 500 km and 1 h vs. 6 h). This is reasonable because

in SPPT, the perturbation is *multiplicative*, i.e. the random field (pattern), $\xi(x, y, t)$, is multiplied by the physical tendency, $\mathbf{P}(x, y, \zeta, t)$, which is a rather small-scale random field itself, so that the perturbation, $\xi(x, y, t) \cdot \mathbf{P}(x, y, \zeta, t)$, appears to be a reasonably small-scale field even if $\xi(x, y, t)$ is large-scale. If $\xi(x, y, t)$ were small-scale in SPPT, the product $\xi \cdot \mathbf{P}$ would be too patchy, which would reduce the effect on the forecast. In contrast, AMPT introduces an *additive* perturbation, which needs to be small-scale in order to represent the errors in parametrizations of *subgrid-scale* processes.

To find out if this argument is reasonable, we ran the SPPT with the smaller time scale of 1 h and the spatial scales of 50 and 100 km. The resulting spread in the ensemble forecast was very small, confirming the conclusions of Maurer et al., 2014 (made for a different domain, orography, physiography, etc.) and justifying the choice of the SPPT parameters for our domain (the setup was also consistent with that employed in AROME-EPS, (Bouttier et al., 2012)). For the set-up of SPPT in COSMO, see also Klasa et al. (2018).

Note that in what follows, by "model perturbations" we mean model-error perturbations generated by AMPT and SPPT in the atmosphere and also the initial and model-error perturbations generated by AMPT in the soil.

3.2.9 Unperturbed T_{so}, W_{so} total tendencies

Fig. 11 shows the unperturbed tendencies for T_{so} and W_{so} at the soil level $z = 2$ and lead time 2 h (the forecast started at 00 UTC on the 1st of May 2014). The tendencies were computed as one-time-step differences and recalculated w.r.t. 1 h (so that the T_{so} tendency is measured in K/h).

The T_{so} tendencies (left panel in Fig. 11) look more or less uniform (albeit with a few isolated outliers) and thus not far from Gaussian. For this reason, the AMPT perturbation scheme for T_{so} model-error perturbations was selected to involve whole-domain (not moving-window) averaging of the modulus of the tendency.

The W_{so} tendencies on the contrary (right panel in Fig. 11), are highly inhomogeneous and thus non-Gaussian. This motivated the use in the AMPT perturbation scheme for W_{so} of a *moving-window* averaging of the modulus of the tendency to scale the model-error perturbation of W_{so}.

In the vertical, the mean absolute tendency in $\mathrm{T_{so}}$ roughly halved when going one level down in the soil (not shown). So did (again, roughly) the maximal absolute tendency in $\mathrm{W_{so}}$[1].

We found no significant dependencies in the magnitude and spatial structure of soil tendencies on the soil type (there were only two soil types in the COSMO model across the domain, not shown).

One can see a signature of orography (Fig. 10) in the soil tendency fields (Fig. 11).

3.2.10 Testing AMPT in an ensemble prediction system

Numerical experiments were carried out to study the effect of AMPT model perturbations in COSMO-Ru2-EPS (Montani et al., 2014 and Astakhova et al., 2015), the ensemble prediction

[1]The *maximal* absolute tendency looks more appropriate to measure the magnitude of the tendency in $\mathrm{W_{so}}$ than the *mean* absolute tendency — because the magnitude of the soil moisture tendency exhibits very big changes over the model domain (see Fig. 11, right panel) so that the averaged value is irrelevant for areas of both big and small model tendencies (that is, almost everywhere).

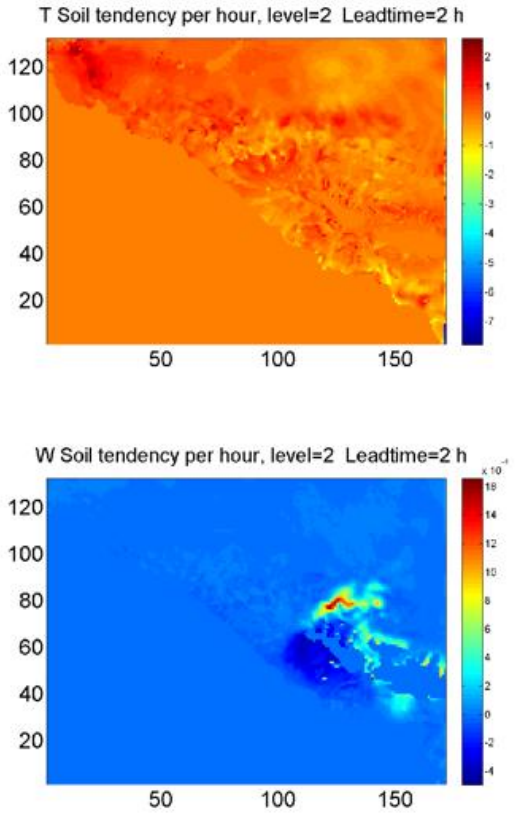

Figure 11: Total tendency of T_{so} (left, K/h) and W_{so} (right, W_{so} units per hour) at level 2, forecast lead time 2h. The forecasts were initialized at 00 UTC 1 May 2014. Tick labels are grid points in the longitudinal (x-axis) an latitudinal (y-axis) directions

system developed within the FROST-2014 project (Kiktev et al., 2017) and CORSO priority project of the COSMO consortium (Rivin et al., 2018). For the COSMO model set-up used in the ensemble prediction system, see above section 3.2.8. The ensemble size was 10. COSMO-Ru2-EPS performed a dynamical downscaling of the forecasts of the driving COSMO-S14-EPS system developed by ARPA-SIMC for the Sochi Olympics (Montani et al., 2013). Thus, both initial and lateral boundary conditions for the control forecast and the ensemble members were provided by COSMO-S14-EPS. In turn, COSMO-S14-EPS was a clone of the consortium ensemble prediction system COSMO-LEPS (Montani et al., 2011) with a smaller ensemble size and shifted to the area of the Sochi Olympics. COSMO-S14-EPS had the horizontal grid spacing of 7 km and 40 levels in the vertical.

Experiments setup

A continuous series of experiments was performed with COSMO-Ru2-EPS for the two-month period of February-March 2014 without model perturbations as well as using AMPT and SPPT with the parameters indicated above (section 3.2.8). The forecasts were initialized every day at 00 UTC. The local time for the region considered was UTC+3 h. The results were verified against near-surface observations (about 40 stations) using the COSMO unified verification system VERSUS (Raspanti, 2009). Ensemble forecasts in the free atmosphere were verified against zero-lead-time ECMWF forecasts (with the horizontal resolution of about 16 km).

Below we show verification scores for the whole two-month period. Similar results were obtained for each of the two months separately (not shown).

We concentrate on the impact of model perturbations on probabilistic forecasts of $T_{2\mathrm{m}}$ and precipitation.

The list of experiments and their basic features are presented in Table 1.

Table 1: List of experiments with COSMO-Ru2-EPS

Experiment	Model perturbations in addition to initial and lateral-boundary ones
NOPERT	None
SPPT	SPPT model-error perturbations in the atmosphere
AMPT-NOSOIL	AMPT model-error perturbations in the atmosphere
AMPT-SOIL	AMPT perturbations: atmosphere + soil

Deterministic verification

Fig. 12 shows the root-mean-square error (RMSE) of the $T_{2\mathrm{m}}$ *ensemble mean* forecast (the upper bunch of curves). One can see that, excluding the initial transient (spinup) period of some 3 h (likely, due to imbalances in the initial perturbations), the RMSE had a prominent diurnal cycle with a broad minimum at night and a narrower maximum shortly after midday. This corresponds to the known systematic error in $T_{2\mathrm{m}}$ in the COSMO model (Fig. 2 in Kirsanov et al., 2020).

Fig. 13 displays the normalized ensemble-mean RMSE reduction w.r.t. NOPERT (to highlight the barely seen in Fig. 12 differences between the experiments), that is, $(RMSE_{NOPERT} - RMSE)/RMSE_{NOPERT}$. SPPT led to a persistent slight reduction in RMSE. AMPT model perturbations gave rise to a more significant decrease in the $T_{2\mathrm{m}}$ RMSE most of the time except for the rather short time periods in the afternoon, when the ensemble-mean forecast deteriorated. Soil perturbations added skill to the ensemble mean forecast: the RMSE reduction is higher in the experiment AMPT-SOIL than in AMPT-NOSOIL.

Reliability

The lower bunch of curves in Fig. 12 shows the ensemble spread, which was a bit too low with both SPPT and AMPT. This implies that the ensemble forecast was lacking reliability, though AMPT perturbations increased the spread to a much greater extent than SPPT perturbations. The effect of the AMPT perturbations on the spread was nearly the same for all lead times. The gradual overall growth of the spread with time was, likely, caused by the lateral boundary perturbations as they propagated from the boundaries to the domain interior. This explanation is consistent with the gradual reduction in the differences between the experiments (since they had the same lateral boundary perturbations).

Higher in the atmosphere, the RMSE of temperature and wind speed was negligibly affected by AMPT perturbations while the related spread grew most efficiently near the surface and fell with height.

For temperature, the AMPT atmospheric perturbations resulted in a spread growth by 0.3 K at 20 m, 0.25 K at 150 m, and 0.1 K at 1000 m. The soil perturbations added only about 0.08 K to the spread below 150 m and their effect vanished towards the top of the boundary layer.

For wind speed, the spread gain due to the AMPT purely atmospheric perturbations was

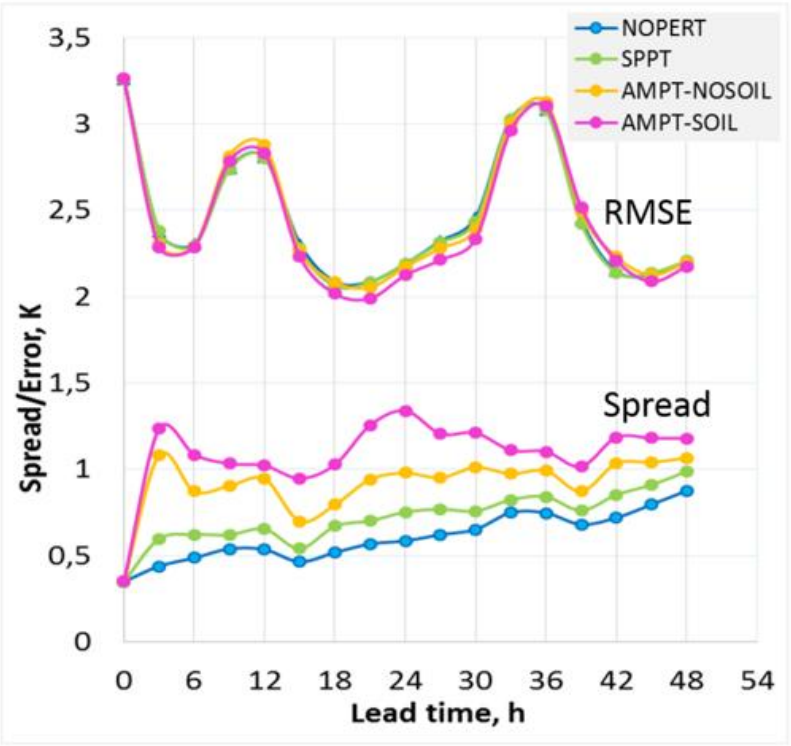

Figure 12: RMSE of T_{2m} ensemble mean and spread. Experiments NOPERT (blue), SPPT(green), AMPT-NOSOIL (orange), and AMPT-SOIL (magenta).

about 0.3-0.4 m/s below 150 m and reduced to 0.2 m/s at 1000 m. The impact of soil perturbations on the wind speed was rather weak. Even at the lowest model level (20 m) the spread difference between AMPT-NOSOIL and AMPT-SOIL was only 0.01 m/s.

AMPT perturbations of humidity and cloud fields generated significant spread in precipitation and in the upper-air temperature during precipitating events but the effect of those perturbations on the ensemble prediction performance scores was mixed (not shown). Further experiments are needed to reach more conclusive results.

Probabilistic verification

Standard probabilistic scores for near-surface variables were calculated for all experiments. The continuous ranked probability score (CRPS), which generalizes the mean absolute error to the case of probabilistic forecasts, is presented in Fig. 14 for T_{2m}. CRPS measures the difference between the predicted and occurred cumulative probability distributions. Both SPPT and AMPT improved CRPS but AMPT was undoubtedly more successful, especially with additional soil perturbations.

The advantage of AMPT over SPPT for T_{2m} is also supported by the analysis of the Brier score, which characterizes the magnitude of the probability forecast error, see Fig. 15. In fact, this result could be expected as CRPS is usually interpreted as the integral of the Brier score over all possible threshold values (Hersbach,2000).

We also examined the ability of our EPS with different model perturbations to discriminate between two alternative outcomes (say, "T is below a threshold" and "T is above the threshold"). The relative operating characteristic (ROC) is normally used to assess the discrimination ability of an EPS. Fig. 16 shows the area below the ROC curve (ROCA) for two thresholds. Note that the perfect value for ROCA is 1 and the value less than 0.5 indicates

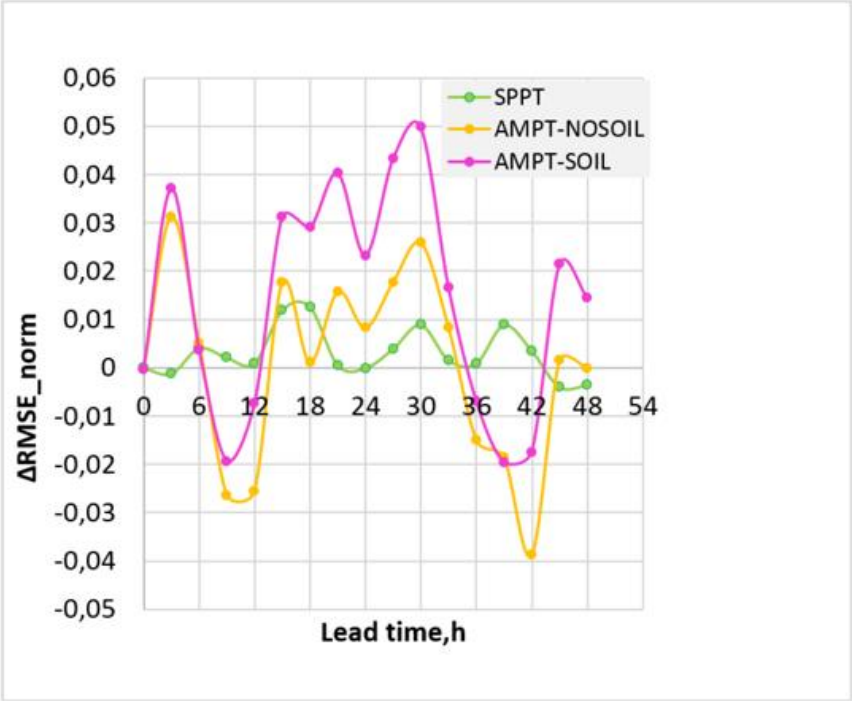

Figure 13: Normalized $T_{2\mathrm{m}}$ ensemble-mean RMSE reduction (the greater the better).

no skill. Actually, ROCA in Fig. 16 is quite high, indicating that the EPS was skillful. Like the previously mentioned probabilistic scores, ROCA demonstrates the advantage of the EPS configuration AMPT-SOIL for both thresholds indicated in Fig. 16 and for the majority of other thresholds we tested (not shown).

The effect of T, u, v perturbations on precipitation was rather ambiguous (see Fig. 17)), perhaps because the time period considered was rather dry (Vasil, 2015). The first half of February 2014 was characterized by an anticyclonic weather, that favoured the precipitation deficit. Only during the second ten-day period of March 2014 considerable amounts of precipitation were observed. Further experiments are needed and will be conducted after this study.

3.2.11 Discussion on AMPT

Limitations of the experimental setup

1. The initial and lateral-boundary (driving) ensemble was under dispersive. This factor might lead to an overestimation of the tuned AMPT *model-error* parameters (the model-error perturbations might be forced to, partly, do the job of initial and lateral-boundary perturbations).

2. The study is conducted on a small model integration domain and for a time period of only one season, which may imply that additional experiments with AMPT on a domain in a different climate zone, different orography and physiography in different seasons and weather conditions need to be conducted to get more conclusive results.

3. In particular, the period of February-March 2014 was rather dry, so it was hard to justify the effect of AMPT perturbations on precipitation. However, sensitivity exper-

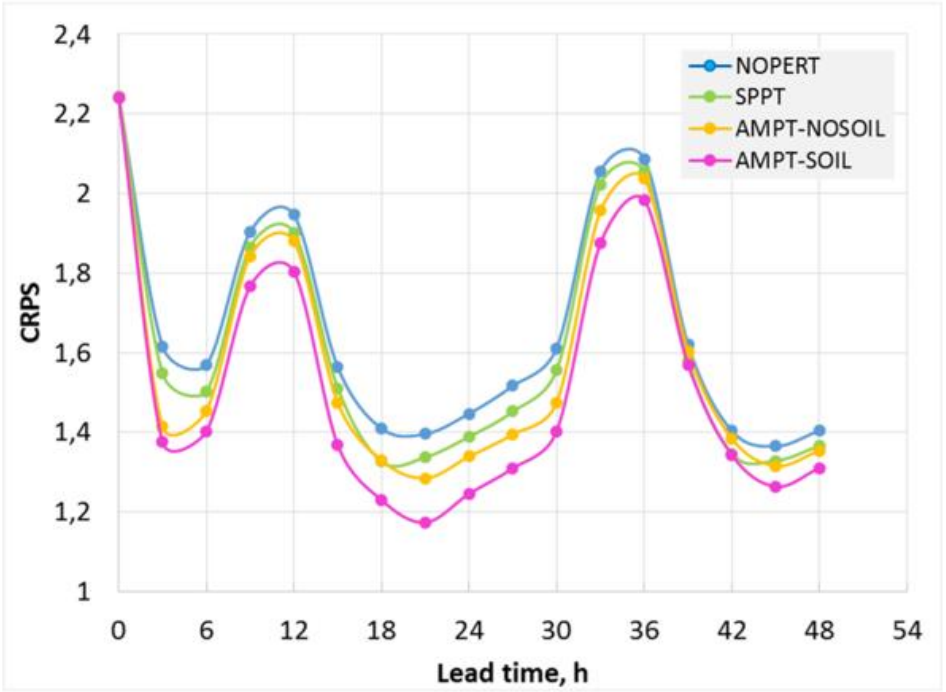

Figure 14: CRPS for $T_{2\mathrm{m}}$. The lower the better.

iments for May 2014, not presented in this report, suggest that AMPT humidity and cloud-fields perturbations can be important during periods with convective events.

4. For the same reason, we do not present here results of experiments with humidity perturbations. Only perturbations of temperature, wind, and soil were introduced in the above experiments.

Advantages and limitations of AMPT

Theoretically, potential advantages of AMPT w.r.t. SPPT are:

- AMPT generates *additive* model-error perturbations, which can represent errors in physical parametrization schemes when they produce an erroneously small physical tendency. SPPT cannot do that because its perturbations are multiplicative.
- AMPT can account for errors in the *relationships* between errors in different variables and at different model levels. In SPPT, these relationships are, effectively, assumed to be error free.

A potential disadvantage of AMPT w.r.t. SPPT is:

- AMPT produces, likely, less balanced perturbations than SPPT because the latter preserves the relationships between different variables and between different model levels. But model-error perturbations (imposed at every model time step) are very small and so are the imbalances. In our numerical experiments we found no evidence of problems related to the imbalances, unless the AMPT perturbations were "too big" (i.e. having an excessive magnitude and/or spatial or time scale). For "not too big" AMPT perturbations, the model was able to cope with the small imbalances without any indication of spinup-like behaviour.

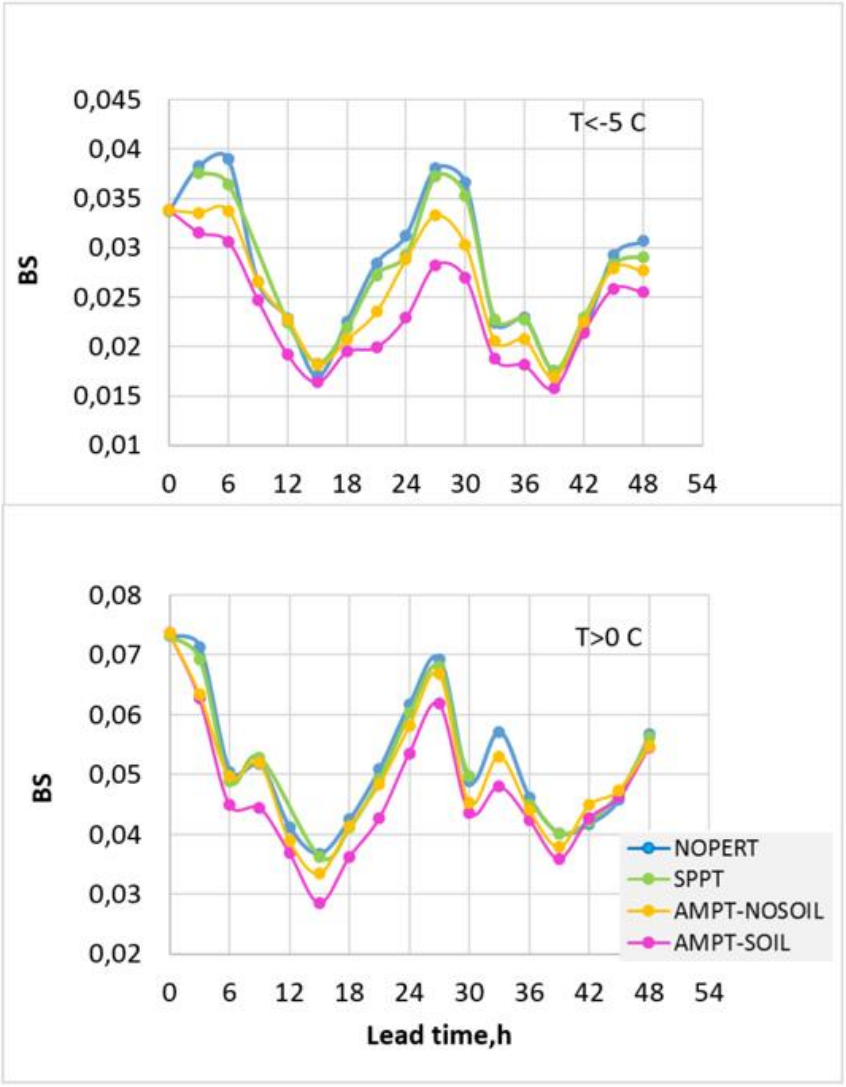

Figure 15: The same as Fig. 14 but for the Brier score for the events $T_{2\mathrm{m}} > 0$ C (the upper panel) and $T_{2\mathrm{m}} < -5$ C (the lower panel). The lower the better.

3.2.12 Conclusions on AMPT

- A new technique called Additive Model-error Perturbations scaled by physical Tendency (AMPT) is proposed. AMPT employs the Stochastic Pattern Generator (Tsyrulnikov et al., 2017) to generate four-dimensional random fields with tunable spatio-temporal correlations. The SPG random fields in AMPT are independent for different model fields. They are scaled by an area-averaged modulus of physical tendency and added to the model fields at every model time step. Gaussian and non-Gaussian fields are treated by AMPT.
- Three-dimensional model fields of temperature and winds were perturbed.
- Three-dimensional soil fields (temperature and moisture) are perturbed as well.
- In ensemble experiments, it was found that AMPT perturbations were very effective in generating spread in the ensemble.

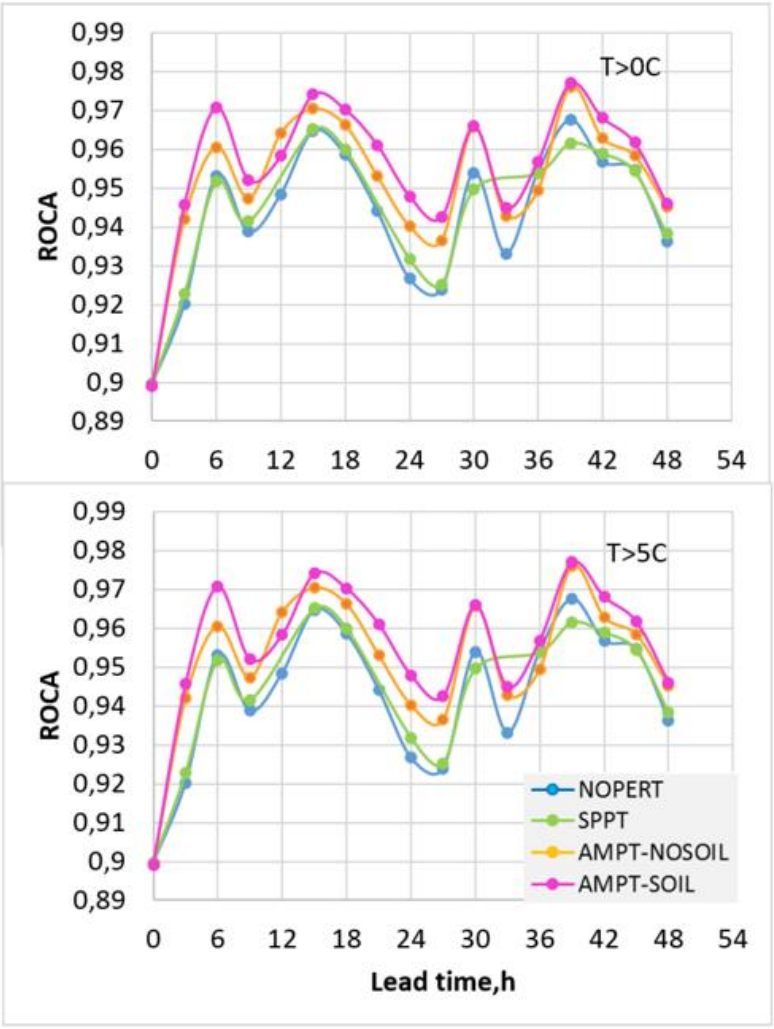

Figure 16: The same as Fig. 14 but for ROCA for $T_{2\mathrm{m}}$ for the events "$T > 0$ C" and "$T > 5$ C". The higher the better.

- Perturbing humidity and cloud fields generated significant spread in precipitation and upper-air temperature during precipitating events (not shown).
- Soil perturbations contributed significantly to the spread of near-surface fields.
- AMPT was able to reduce the average root-mean-square error (RMSE) of the ensemble mean w.r.t. no model perturbations and w.r.t. SPPT, however sometimes RMSE was degraded.
- Probabilistic ensemble verification scores (CRPS, Brier score, and ROC area) for near-surface temperature and wind speed were improved due to AMPT model perturbations in the atmosphere w.r.t. no model perturbations and w.r.t. SPPT.
- AMPT soil perturbations further improved the probabilistic verification scores.
- Probabilistic verification of precipitation gave mixed results, perhaps due to the insufficient number of precipitating events during the time period examined.

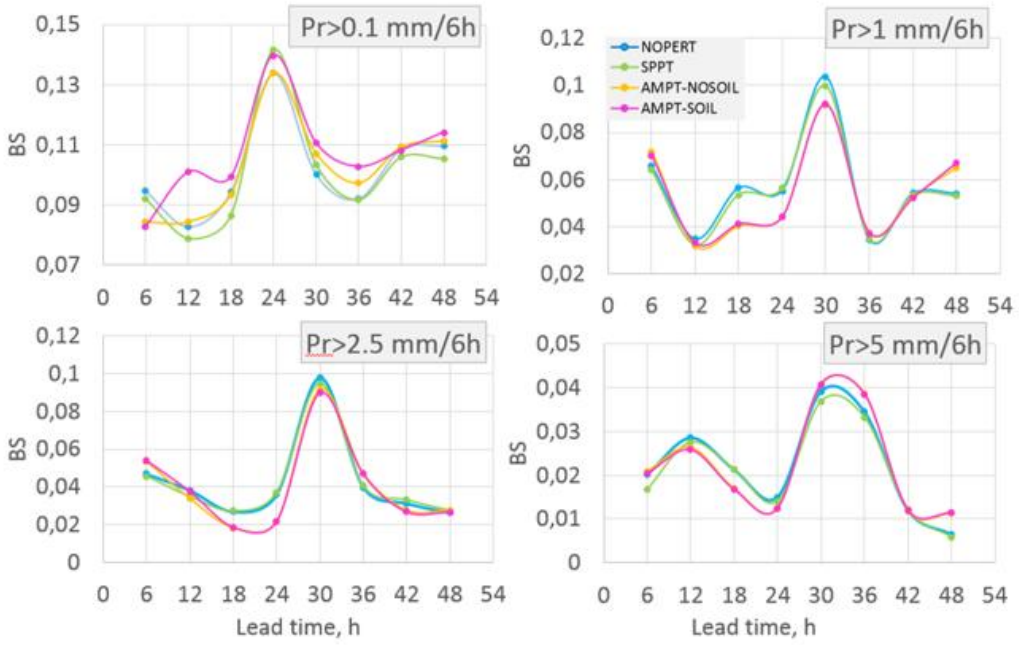

Figure 17: Brier score for total precipitation for the various thresholds indicated in the panels. The lower the better.

3.3 Model perturbations at IMGW (A. Mazur and G. Duniec, IMGW)

At IMGW, the basic instance of the COSMO model runs in a deterministic mode, using the initial (IC) and boundary (BC) conditions from the global ICON model. ICON generates a sets of IC/BC for 78-hour mesoscale COSMO forecasts. In turn, COSMO model with a horizontal resolution of 7 km (COSMO-7) uses nudging-based data assimilation to correct the forecasts of the global model by retrieving the latest data from the WMO network. The forecast results with a resolution of 7 km are further used as sets of IC/BCs for a nested COSMO model instance with a higher resolution of 2.8 km, and 48-hour forecasts. These deterministic COSMO-2.8 km forecasts define the basis for the operational configuration of the Ensemble Prediction System (EPS). In the final configuration of the operational EPS at IMGW, the set of twenty ensemble members is grouped into four packages, staggered in time by 6 hours from one another, obtained from previous model runs. Each package contains five members (Mazur and Duniec, 2015). All forecast (ensemble) results are then processed to provide the selected statistics (ensemble mean, spread, probability of exceedance of selected thresholds, etc.) in a graphical form. Model perturbations are added, by perturbing the parameter describing evaporation from the soil (c_soil).

3.3.1 Perturbations based on adapted Random Number Generator.

Computer-generated random numbers are called "pseudo-random" numbers as they are designed to mimic randomness but they are determined in a deterministic, though often very complex, way. Due to the ever-growing demand for good pseudo-random numbers, the literature describes many ways to generate them, and many people are still working on new methods. To generate numbers from the uniform distribution are used, among others, the following algorithms: Wichmann-Hill (Wichamnn and Hill, 1982), Marsaglia (Marsaglia,

2003), Knuth (Knuth, 1981). In general, a Random Number Generators (RNG) is a deterministic function. It uses the so-called "seed" that completely determines the values of the subsequent pseudorandom numbers. The seed is the value on the basis of which successive random numbers will be constructed. For a permanent generator and seed, identical random numbers will be generated regardless of the operating system or computer type. This property can be easily exploited. By controlling the selection of the seed, it is possible to obtain identical sequences of random numbers on different computers. In this way, one can repeat the simulation results, reproducing these results on other computers, or continuing calculations interrupted by some error. However, the basic selection of seed has its weaknesses. The seed on most computers is based on machine time (generally milliseconds). On high-speed machines, seeds can be identical for many, if not all, processes (threads). This problem is illustrated in the Fig. 18. More threads means more likelihood to have identical seeds. With an exemplary operating configuration of 400 threads versus 999 milliseconds, one will not get 999 ms (and, hence, 999 values of seed) on high-speed machines, but much less. This increases the probability that multiple threads (the blue diamonds) will have the same grain (red rectangles). The basics of the new RNG have already been presented in the framework of the Priority Project SPRED. Here, therefore, just to reminder is provided: the basic scheme of the new RNG assumes a sequence (in particular, even several stages) of generating seed values. That is, the first operation in a sequence generates a (pseudo-random) number which is the input to the next operation, and so on (see Fig. 18). Ultimately, the final seed value suitable for the RNG is obtained. At the expense of a slight extension in time, significantly randomized seed values are obtained.

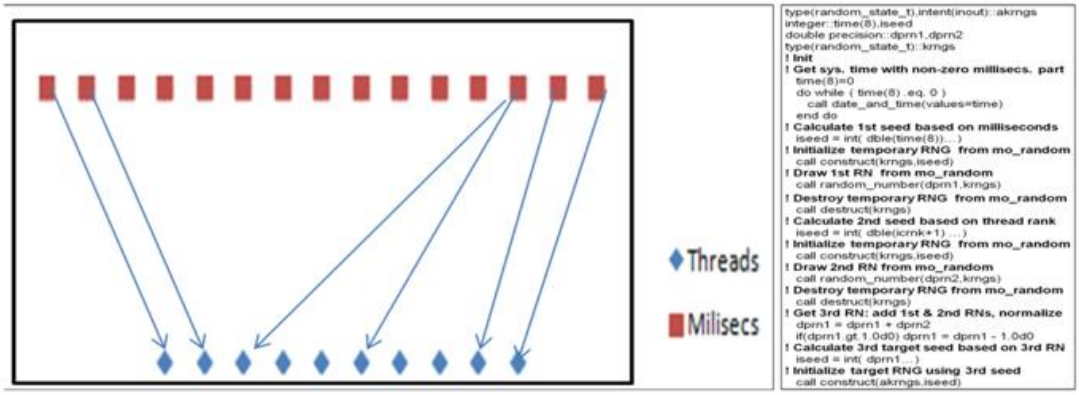

Figure 18: Left (a): Problem with parallel threads of stochastic computations - seeding RNG with machine time (milliseconds). Right (b): Block scheme of new seeding for RNG

Changing the RNG to the proposed one causes (may cause) a problem related to the loss of reproducibility of the results, mentioned in the introduction. However, from a mathematical point of view, the reproducibility requirement cannot be applied to single samples of partially or wholly nondeterministic phenomena, although it still applies to a probabilistic description of these phenomena, with the error tolerance defined by the probability theory. Apart from repeatability for technical or comparative tests, however, it is difficult to see too many arguments in favour of choosing permanent seeds. Perturbations based on an adapted Random Number Generator (RNG) were prepared for the years 2011-2015 (archive data).

This part of the report presents a comparison between a "new" RNG vs. a standard one. Essentially, the "new" RNG has been operating in operational mode since 2019, replacing the "old" one. The modification was made when the perturbed parameter (c_soil) was defined in the code. The main reason for choosing where to introduce the random variation was code maintenance. By introducing variations in the original position (defining the field of the

disturbed parameter) on all nodes, it is possible to avoid excessive communication between the processors during the redistribution of the field. The use of machine time was due to the fact that initialization is performed only once (i.e. at the beginning of the model launch). The disturbed parameter is used only in the soil model (only once after the model started), and further during computations the distribution is no longer needed. The procedure does not repeat afterwards and does not affect efficiency in any way, but it seems to be one of the best sources of stochastic initiation. The results of the initial application of the new RNG were presented in PP SPRED, while further results of the RNG use tests are shown here. The influence of the RNG on the air temperature and dew point at 2m, wind speed at 10m and relative humidity at 2m is shown (Table 19 and Fig. 20, compared to values obtained with the standard "old" generator.

Spread values	Reference (standard RNG)	Modified RNG (operational)	Reference (standard RNG)	Modified RNG (operational)
	T2M (K)		TD2M (K)	
Mean	0.1218173	0.250191	0.13452	0.282912
Max	2.813	3.212	3.541	4.189
	U10M (m/s)		RH2M (%)	
Mean	0.17813	0.22381	0.965178	2.694192
Max	2.412	3.258	12.419	16.617

Figure 19: Average spread values for T2m and Td2m for years 2011-2015, modified RNG (left) and standard RNG (right). Tests with perturbations included, lagged members excluded.

Upon completion of the tests, the standard RNG was turned off. Currently, taking into account the quality from the new RNG, a new method of seed generation is operationally used for perturbations.

3.3.2 Perturbation of soil surface temperature in combination with upper air perturbation

The usage of other types of model perturbations has been tested and the results are here presented. Perturbations include soil surface temperature, coefficient of performance and combinations thereof. The following cases were considered:

a. operational set-up: perturbation of the parameter describing evaporation from the soil (c_soil);

b. eff-coeff: perturbation of the collection efficiency coefficient;

c. laf-pert: perturbation in soil surface temperature (initial values, with the amplitude of perturbation depending on the type of soil, see Duniec and Mazur, 2020);

d. combination of b) and c)

The general perturbation scheme have the following form:

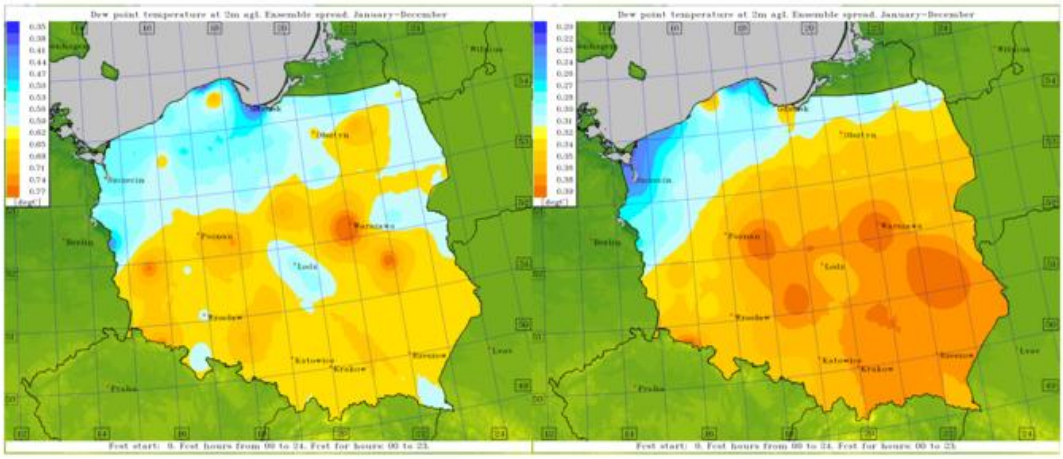

Figure 20: TD2M average spread values for years 2011-2015, modified RNG (left) and standard RNG (right). Tests with perturbations included, lagged members excluded.

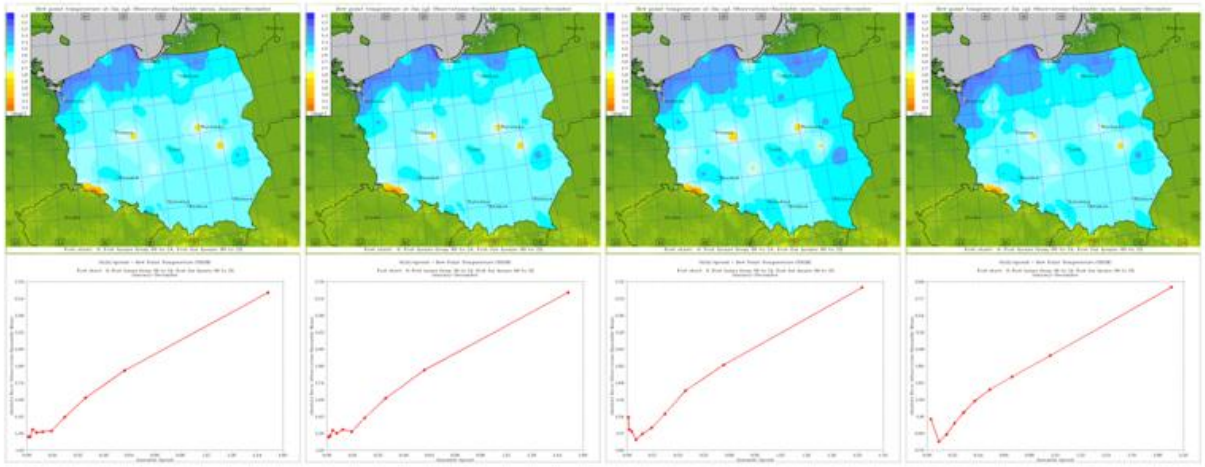

Figure 21: Upper panels: observations minus ensemble means, lower panels: spread-skill diagrams. Left to right are shown the 4 configurations of the ensemble: (a), (b), (c), (d) (see explanations in the text). Averaged values for the years 2011-2015.

perturbed_value=basic_value * [1+(random_number -0.5) * amplitude]

where the "random_number" (obtained from a computing dependent pseudorandom number generator, see section 3.3.1) varies from 0 to 1. In the laf-pert perturbation it is assumed that the ability to transfer heat and water is related to the compactness of the soil. If the soil is coarse (like sand), the amplitude of the disturbance is one, and the more compact the soil texture, such as peat or clay, the smaller is the disturbance amplitude. For example, for sand the amplitude was set to 1.0, for clay it was set to 0.6 and for peat it was set to 0.5. Thus, for sand, the perturbation ranged from 0.5 to 1.5 of the original (undisturbed) value. A climatological analysis for the warm period of a selected year was presented in Duniec and Mazur (2015). The overall results were also presented at the ICCARUS 2020 seminar. In Fig. 21 are reported only the most significant results, a comparison of different perturbation methods vs. measurements at SYNOP stations in Poland.

Research results essentially confirmed that:

1. the influence of the perturbation of the efficiency coefficient is, as expected, significant only in the case of precipitation;

2. the combination of different types of perturbations does not necessarily have a linear effect on the spread value and, moreover, on the quality of the forecasts. In some cases, the size of the spread produced by the perturbation combination was significantly greater than the algebraic sum of the spread produced by the perturbations applied separately;

3. compared to the operational EPS setup, new types of perturbation improve the quality of the forecasts in terms of skill and spread. The most effective perturbation scheme in terms of MAE and spread, averaged over the period 2011-2015, was the combination of perturbation types, with the mentioned restriction concerning point (1).

3.4 Perturbations based on SPPT with independent pattern (iSPPT) (André Walser and Linda Füzér, MCH)

The operational ensemble prediction system (EPS) of MeteoSwiss, COSMO-E, is underdispersive, i.e. the forecast shows a lack in the ensemble spread near surface, particularly in the short-range during the winter season. Stochastic perturbation of physical tendencies (SPPT) is operationally used in COSMO-E to represent model errors by perturbing the sum of the physical tendencies from the parametrization schemes. Although SPPT increases the spread significantly, there are still opportunities for further improvements. Christensen et al. (2017) suggest a modified version of SPPT called independent stochastically perturbed physical tendencies (iSPPT) which allows more flexibility in the perturbation setup and yields a better spread-error relationship in a global ensemble prediction system. For this reason, we have implemented iSPPT in the COSMO code in a test branch and investigated whether an iSPPT scheme can improve COSMO-E forecasts.

The results of the iSPPT experiments are shown in detail in Füzér (2018). In summary, iSPPT does not reveal a consistent improvement of the COSMO-E forecast spread-error relationship as compared to SPPT experiments. The ensemble mean error of the forecast is hardly sensitive to iSPPT, and a positive effect on the spread is found for wind speed and humidity and in some setups only while the spread for temperature could not be increased. The flexibility provided by iSPPT to perturb the individual physical tendencies differently is not helpful to achieve better scores for COSMO-E. Best results with iSPPT are achieved with the same random number setup as for SPPT applied to all physical tendencies.

3.5 Perturbations based on analysis increments (André Walser and Linda Füzér, MCH)

Perturbations from both SPPT and iSPPT do not account for model errors different than the ones arising from the parametrization schemes. For a global EPS, Piccolo et al. (2018) thus propose model perturbations using analysis increments (AIs) of the data assimilation cycle, as they are not random quantities but rather include possible sources of forecast errors. Such perturbations could also be beneficial for a limited-area EPS like COSMO-E. However, the characteristics of the AIs from the KENDA system, which provides the initial conditions for COSMO-E, has not been investigated yet and is thus unknown.

Füzér (2018) shows a detailed analysis of the AIs from the operational KENDA system of MeteoSwiss. The considered time period is 1st June 2017 to 31st August 2018 to cover all seasons and to be able to compare the summer of two different years. In summary, the AI

dataset only shows notable biases for summer temperature and humidity. Between 8 and 16 UTC, a negative temperature bias of up to -1.5 K can be found in the lowest model levels. During the other seasons and variables, regional biases are visible. Both the absolute mean AIs and standard deviation show clear variability among the seasons and have a diurnal cycle that also varies with the seasons. The magnitude and variability of the AIs increase throughout the course of the day and reach a maximum at 12 UTC and a minimum at night time. The most pronounced diurnal cycle is visible for summer, followed by spring and autumn. A comparison of summer 2017 and 2018 leads to the conclusion that the AIs analysed in this thesis are representative for the respective seasons because the two years show very similar characteristics although they were different in terms of meteorology. The comparison of AIs and model verifications against radiosondes reveals that the magnitude of the AIs is in good agreement with the model first guess mean error. Additionally, as expected, the AIs have opposite signs compared to the mean error of the FG ensemble mean.

The results of the analysis point towards a possible suitability of the AIs as model perturbations. There is a variability within the data, therefore the individual members of the ensemble prediction system would be perturbed differently and lead to an enhanced spread in the result. The AI fields should be grouped by season and time of the day and drawn from the corresponding group when the perturbations are applied. As the AIs are in good agreement with the bias of the FG ensemble mean, perturbations generated using AIs have the potential of reducing the model error and local biases. Before using the AIs as model perturbations, the outliers in the AI data set should be further investigated. It might be useful to set a range for the AIs in order to avoid disproportionally large perturbations.

Even though the study confirms that model perturbations with analysis increments have a large potential to be beneficial for a high-resolution EPS too, it has not been implemented and tested yet due to missing resources.

4 Post-processing and interpretation of ensembles

4.1 Calibration (A. Mazur, W. Interewicz, IMGW)

The development and application of calibration methods at IMGW were initiated in the previous Priority Project SPRED, and here only the results and conclusions from the continuation of the research and method(s) development are presented. The research essentially focused on three basic methods of determining the ensemble mean.

- The most common procedure for calculating the ensemble mean is to use the arithmetic mean of values obtained for all particular members, here called "Simple" Average. Values obtained from the members affect the ensemble mean with the same weight. The simplicity of the method implies that no additional procedures or assumptions are required.
- An alternative approach can be described as (multi-) linear regression (MLR), where pre-made predictions of all (X) EPS members are compared with the observations during a learning phase. The weights of each member are then calculated to judge how "important" the selected member should be in the overall EPS average (or how large a member's share in the EPS average should be). The least squares method used for the computation of the weights can also take into account all potentially important factors such as geographic coordinates, altitude, hour of forecast start, current forecast hour etc. An additional condition is the normalization of weights to one.

- Finally, an artificial neural network (ANN) was investigated to see if this approach could be a valid substitute for a Simple Average or MLR Mean. The basic idea is that the weights, according to the same scheme as in the MLR calculation, are calculated (learned) using the concept of the neuron layer(s), appropriately activated during the learning phase. This approach uses the commonly used ANN back-prop method combined with the activation function of a hyperbolic tangent. During the research (and later in the operational application of the method), a system with two layers of neurons (input and hidden) was used. The first (input) layer contains six neurons, the second, hidden layer contains two neurons. Such a scheme is due to the fact that the EPS creates four sets of five members, corresponding to four neurons, while the other two input neurons are related to spatial (geographic coordinates, terrain height) and time constants (forecasts leadtime). In the hidden layer, two neurons are assigned to variables (forecast members) and constants.

The effectiveness and superiority of the ANN method compared to the Simple Average and MLR were proven (Fig. 22). After the tests and this comparison the ANN method was implemented in an operational mode.

Another calibration technique applied and tested was the VOD (Vector Of Displacement) procedure. The method based on the space-lagged (cross-) correlation technique was used in this respect.

The basic principle of the method is based on the assumption that the forecast value field (including the ensemble mean forecast) can be spatially shifted relative to the actual value field, maintaining the spatial "shape". To determine the size of this shift (i.e. VOD - Vector Of Displacement), these steps are followed:

1. Calculate the "centre of mass" of the two-dimensional field of forecast values
2. Calculate the "centre of mass" of the two-dimensional field of measured values
3. Define VOD as the vector connecting these two points
4. "Shift" the forecast field by the VOD vector

An example of the result of using this procedure is shown in the figure 23.

As the number of SYNOP stations in Poland is not quite large (61), the procedure has been modified for the elements measured at the stations. Instead of calculating the "centres of mass" of continuous fields, the procedure is as follows:

1. at each SYNOP station, find the grid point (in a specific vicinity) with the forecast value closest to the one measured at station;
2. calculate the displacement vector for single station as the difference between the station location and the location of this point in the forecast field;
3. calculate an overall VOD as the average over all the stations
4. displace every value of forecasts by the vector of displacement

An example of the result of using this procedure is shown in figure 24.

After finding an improvement in the quality of the forecasts, this procedure was also applied operationally. In the operational mode, VOD is being determined at the beginning of each calculation cycle for each forecasted meteorological element. It is assumed, that this value does not change in the current calculation cycle, but it is updated at the next model run.

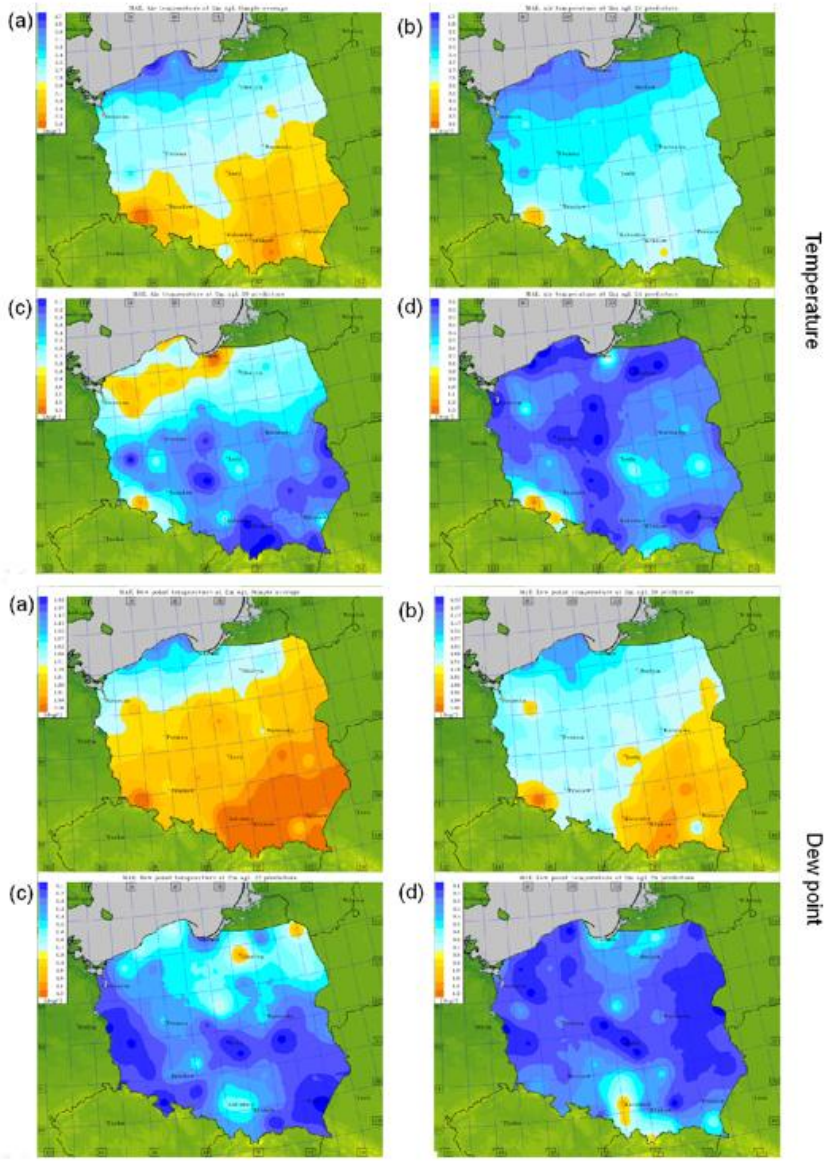

Figure 22: Skill comparison for different calibration methods, in terms of 2m air temperature (upper four panels) and dew point temperature (lower four panels). Panel (a) Simple average, (b) Multiline Regression (MLR), 24 predictors, (c) ANN, 20 predictors (ensemble values only), (d) ANN, 24 predictors (ensemble values + spatiotemporal coordinates). Results are for the years 2011-2015.

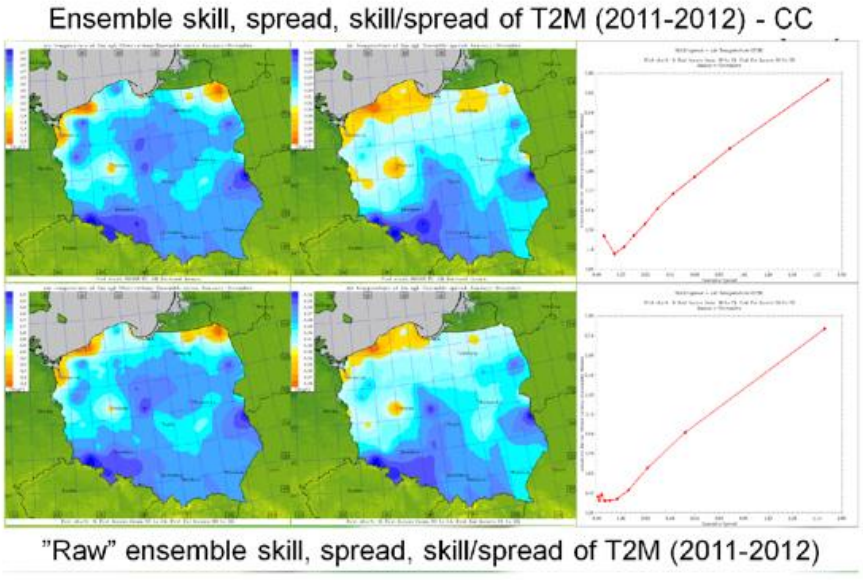

Figure 24: Same as Fig. 23 but for air temperature at 2m.

4.2 Specific products from ensemble outputs (R. Golino, F. Marcucci, COMET)

In the framework of the EUMETNET SRNWP-EPS project, a tool for thunderstorm forecasting has been developed. The algorithm combines different indices following the decision tree in Fig. 25 and evaluates for each grid point the suitable weather phenomenon according to the WMO table 4678.

The most important indices used in the code are: Cape, Cin, Total total index (TT), Showalter Index (SI), Updraft Helicy (UH), Lighting Potential Index (LPI), Integrated Graupel (QG), Cloud Physics Thunder Parameter (CPTP). Indices can be computed internally if

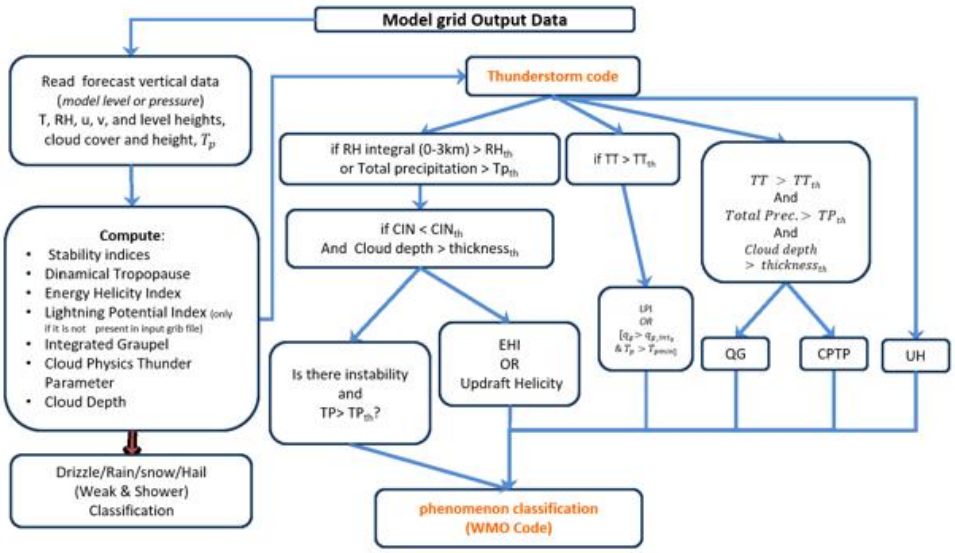

Figure 25: A schematic overview of the algorithm decision tree to evaluate the phenomenon assigned to a specific grid point.

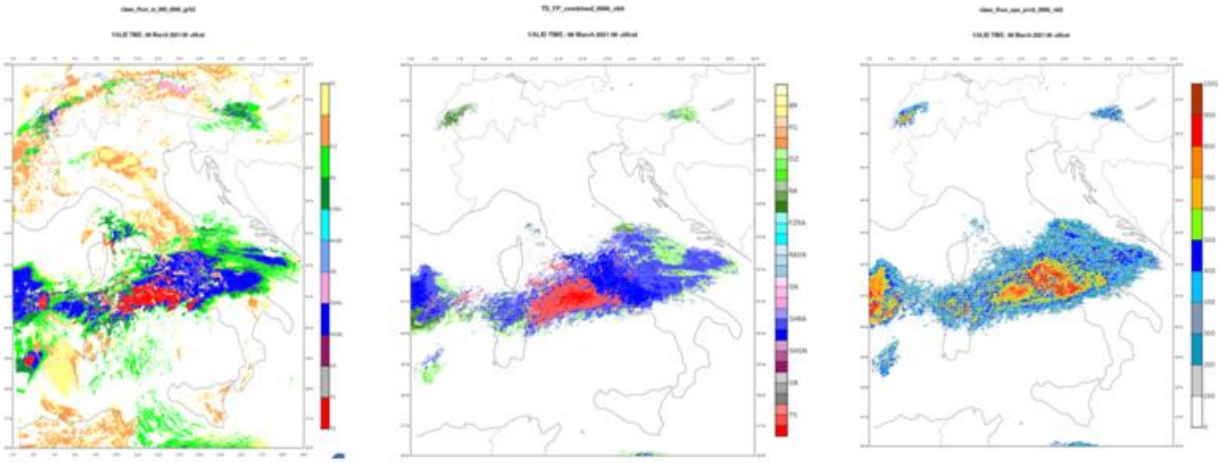

Figure 26: Output of the algorithm applied to deterministic COSMO-IT (left). Most probable phenomenon computed using the 20 outputs of the algorithm applied to the COSMO-IT EPS ensemble members (centre) and related probability (right). All pictures are referred to the 00UTC run of 08 March 2021, forecast step +6h.

not available as model output. The algorithm has been applied to deterministic outputs of COSMO-IT model and also to the 20 forecast members of the ensemble convection permitting system COSMO-IT EPS. In order to have a synthetic picture of the scenario predicted by the ensemble, the EPS outputs can be post-processed to obtain a single field (grib format) that represents the most probable phenomenon. For each grid point, the phenomena predicted by all the members are collected and clustered, then the most populated cluster is considered to decide the suitable phenomenon. The associated probability is computed taking also into account events from the most severe group. Low-probability phenomena (less than 20%) are discarded. An example of the algorithms output from different models (deterministic COSMO-IT and ensemble COSMO-IT EPS) is given in Fig. 26. In the ensemble outputs (two rightmost pictures) fog/mist events (BR/FG - yellow/orange in the colorbar) are not

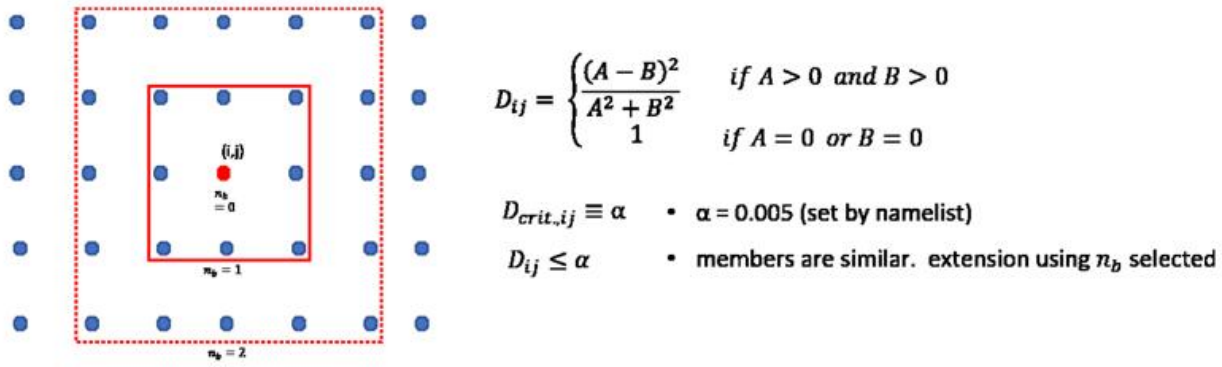

Figure 27: A schematic overview of the method proposed by Dey et al (2016).

considered. To enlarge the sample, a nearest neighbour post processing is applied using the similarity criterion proposed by Dey et al (2016). Namely, for each single grid point (i,j) the values of the EPS members are considered in pairs (190 independent comparison with 20 members) in order to assess if there is an agreement among the ensemble members. The value Dij is computed for all the pairs as shown in Fig. 27, where A and B are the values of the 2 chosen members at the grid point (i,j). If the averaged value Dij is greater than a given parameter (= 0.05 by default), there is no similarity and the agreement is further verified increasing the scale (stopping at nb-order of neighbourhood, 1 by default resulting in 3x3 box and 9x20 values to be compared). Finally, the most representative phenomenon is assigned to the (i,j) grid point. The similarity criterion, currently under evaluation, is expected to be able to filter out showers and drizzle if more significant weather is predicted by other members/neighbours, thus producing a more realistic output.

4.3 Specific products from ensemble outputs (A. Mazur, G. Duniec, IMGW)

Flashrate (as a storm indicator) and visibility range or visibility limitations (caused by fog, but also precipitation) are derived as non-standard products from the EPS.

Forecasts of visibility range were calculated from direct model output using an algorithm based on the forecast of the extinction parameter ext (calculated as a function of water/ice amount in the air, see Stoelinga and Warner, 1999, or Gultepe et al., 2006):

$$VIS = \frac{-\ln(0.02)}{\beta_{ext}}$$

Figure 28: Visibility range from extinction parameter.

These forecasts were verified against measurements at Polish SYNOP stations (see Fig. 29.

Overall conclusions drawn from this research were as follows:

- the average spread is two to ten times lower than the error measured as MAE: the ensemble FVIS is strongly under-dispersive;
- as far ad the spatial relations are concerned, the error is smaller for central and southern Poland, while spread is bigger in the southern and northern part of Poland;

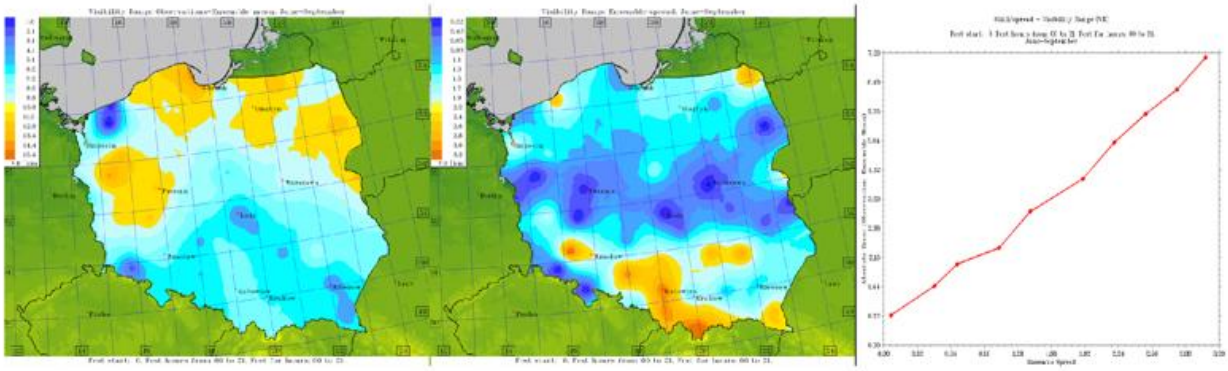

Figure 29: An example of skill (left), spread (middle) and skill-spread relation (right) of the VIS forecasts. Averaged values for June to September, 2011-2015.

- skill and spread are in general better (i.e., smaller and bigger, respectively) for "dry" months (June and September).

In the FLR calculation it is assumed that there is a relationship between the CAPE (from which the maximum updraft velocity W is calculated), the cloud top/base temperatures (CTT/CBT respectively) and the lightning frequency (FR, 1/minutes):

$$W = 0.3 \cdot \sqrt{2 \cdot CAPE}$$

$$FR = \left(\frac{W}{14.66} \right)^{4.54}$$

$$if \quad CTT > -15°C \quad FR = FR \cdot \left[\max\left(\frac{-CTT}{15}, 0.01 \right) \right]$$

$$if \quad CBT < -5°C \quad FR = FR \cdot \left[\max\left(\frac{CBT + 15}{10}, 0.01 \right) \right]$$

Figure 30: Flashrate forecasts calculated from CAPE and cloud top/base temperatures.

Additional filters were used to improve the quality of forecasts (see e.g. Wong et al., 2013).

Forecasts were verified against measurements at Polish lightning detection network PERUN (Fig. 31).

A general conclusion drawn from this part of the study was that the CAPE-based forecasts of flashrate intensity produce good skill values for central and north-western Poland, with the spread being bigger in central and western Poland. This algorithm, however, significantly overestimates flashrate intensity. A precipitation filter is applied, that is, it is assumed that flashrate intensity is zero in the absence of rainfall.

The Universal Tornadic Index (UTI, Taszarek and Kolendowicz, 2013) was a possible candidate for thunderstorm recognition and forecasts, to be verified against data from the lightning detection network:

In the above formula, CAPE is the surface based Convective Available Potential Energy, CAPE3km the Surface based CAPE released below 3 km, LCL the Surface based lifting condensation level height, AMR500 the Average mixing ratio below 500 m, LLS the 0-1 km wind shear, DLS the 0-6 km wind shear (magnitude of vector difference) and SRH1km the 0-1 km storm relative helicity. It is also assumed that SRH1kmis non-negative, and if

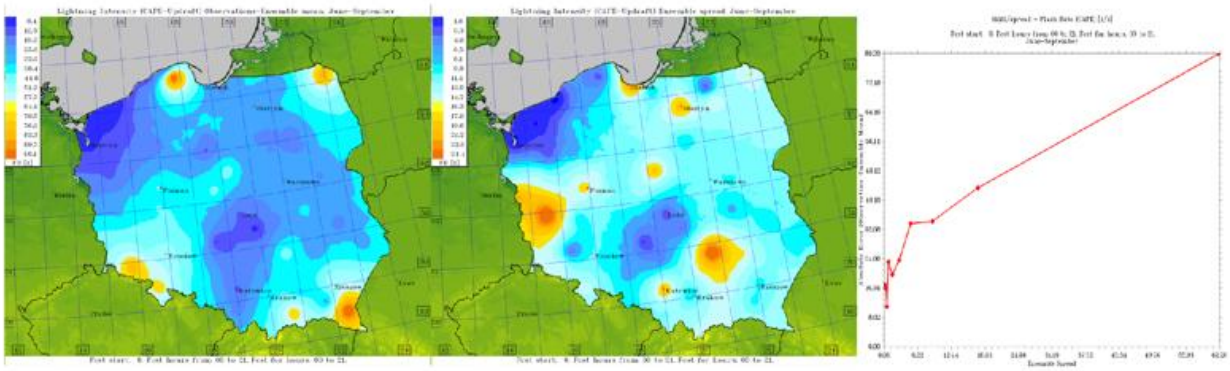

Figure 31: An example of skill (left), spread (middle) and skill-spread relation (right) of the FLR forecasts. Averaged values for June to September, 2011-2015.

$$UTI = \frac{CAPE \cdot SRH_{1km}}{200} \cdot \frac{5 \cdot (DLS - 20) + \left(\frac{200 - LCL}{10}\right)}{100} + CAPE_{3km} + \frac{SRH_{1km}}{4} \cdot \frac{LLS}{12} \cdot \frac{AMR_{500}}{100}$$

Figure 32: Universal Tornadic Index as a possible indicator of thunderstorm occurrence.

LCL is greater than 1500m or CAPE is equal to zero or convection precipitation is less than 2mm/h, then UTI becomes zero. UTI increases with the probability for a significant tornado. For Poland, the operational significance of UTI should attract attention when greater than 0.5-1.0. It should however be kept in mind, that these (climatologically obtained) values do not guarantee that if a forecaster uses threshold values in real-time data, he will be able to specify whether a tornado will occur. Results rather suggest that tornadoes can (may) be formed at all. Universal Tornadic Index was assumed as an indicator of the occurrence of a extreme convective phenomenon. Since it contains many factors (CAPE, storm relative helicity, convective precipitation, wind shear etc.), it may be useful in forecasting not only tornadoes, but also thunderstorms or squall lines. The ensemble mean value of the UTI is comparable to the one calculated in a deterministic run, however significantly less amount of "noise signal" is observed. Further research was carried out to determine any climatological connection between UTI and FLR values. Still, this index did not meet the expectations, in the sense that no significant correlation of this kind was detected. It was perhaps due to a different spatial range of the predicted convective phenomena, namely tornadoes (basic scale of tens to hundreds of meters) vs. "regular" thunderstorms (hundreds of meters to few kilometres).

5 Transition to ICON-LAM

The COSMO Consortium is moving towards the model ICON. This means that the convection-permitting ensemble systems must be converted to the ICON-LAM model. In order to be able to perform a transition to ICON-LAM in the current ensemble configurations, two ingredients are needed: (i) data assimilation for ICON-LAM based on LETKF and (ii) a model perturbation method for ICON-LAM. The first issue is addressed by the data assimilation projects and plans, the second is addressed in the present PP.

For tackling the issue of model perturbation with ICON-LAM, in addition to the technical

adaptations, it has to be examined whether the previous approaches to the representation of the model uncertainties can also be used with ICON-LAM. Due to the change in the characteristics of the model, modifications of the applied methods are likely to be required. The migration of the CP ensemble systems to ICON-LAM will require: forecast experiments for different test periods to explore the properties of the new systems, identification of further development requirements, adaptation of ensemble generation methods.

During the APSU Priority Project, all the ensembles were still running based on the COSMO model, and the model perturbation methods were developed in COSMO. The only exception was DWD, where the transition was more advanced. Here, experiments on the Parameter Perturbation in ICON-LAM (ICON-D2-EPS configuration) were carried out. This work is described in the next subsection.

At the time of writing, a new Priority Project on ensemble development is ongoing (PROPHECY), where model perturbation methods are developed, implemented and tested in ICON in several COSMO members.

5.1 Randomly perturbed parameters in ICON-D2-EPS (C. Gebhardt, DWD)

Coinciding with the lifetime of PP APSU, the ICON-D2-EPS has been prepared as operational EPS application of the ICON limited area mode at DWD. ICON-D2-EPS replaces COSMO-D2-EPS as ensemble prediction system on the convection-permitting scale.
On the one hand, the general methodological approach for member generation in COSMO-D2-EPS is transferred to ICON-D2-EPS, i.e. local ensemble transform Kalman filter for the initial conditions, forecasts of ICON-EU-EPS as lateral boundaries, and randomly perturbed parameters representing model uncertainties. The EPS set-up is identical for the first phase after the transition, with 20 members running every 3 hours for up to 27 hours lead time (45 hours for the 03 UTC run) on a similar domain with a grid spacing of ca. 2.1km.
On the other hand, some of these methods require adjustments to fit to the characteristics of the ICON model in a beneficial manner. Within the PP APSU, the adjustments and the effects of the method of randomly perturbed parameters (RPP) in ICON-D2-EPS are of particular interest and can provide valuable information for the COSMO community. This section reports about the adjustments made to both the range of perturbed values of certain parameters as well as to the technical implementation of the perturbation approach. This implementation is now fully controlled via the ICON namelists and applied within the model. There is no need for preparatory processing scripts in contrast to the procedure for COSMO-D2-EPS.
The general approach remains the same, i.e. for each parameter to be perturbed a value is selected randomly from the default and one or two pre-defined perturbed values in each member. This selection is done at forecast start and the selected parameter values are fixed for the entire forecast range of an EPS run. This selection from a *limited number* of possible values is different from approaches with a random choice of *any* parameter value within the given range.

Most aspects of the physics parametrizations do not substantially change between COSMO-D2 and ICON-D2, which means that many parameters of RPP for COSMO-D2-EPS can be perturbed analogously in ICON-D2-EPS, subject to minor re-tuning. Some parameters have to be adjusted to changes in the parametrization (i.e. the dependence of the vertical diffusion on the Richardson number affects the appropriate range of values for `tkhmin` / `tkmmin`). There are a few replacements (i.e. `radqc_fact` vs. `box_liq` for radiation/cloud cover) and some new parameters are added. More details are listed in Table 2 together with the default values and perturbation ranges for ICON-D2-EPS resulting from preparatory

sensitivity studies.

For the sensitivity studies, 14 days of deterministic ICON-D2 00 UTC runs are performed for each potential perturbation of a parameter with only this perturbation applied for the entire forecast range of 24 hours and all other parameters set to the default value. This procedure is, of course, different from the application in the EPS with its daily randomized mixture of perturbations, but it turned out to be very efficient in detecting which perturbations have a potential for leading to outliers in terms of verification scores. The sensitivity studies aim at a selection of parameter perturbations leading to similar forecast quality without outliers (neither 'better' nor 'worse'). The starting point for the perturbation ranges for ICON-D2 are based on experiences with perturbations for COSMO-D2-EPS (acting on the same scale) and for the global ICON-EPS (using the same model). Note that differences in the scale can lead to differences in the appropriate perturbation ranges between ICON global/EU and ICON-D2. Fig. 33 exemplifies the results of the sensitivity study for the initial set of perturbations for selected variables and for mean error only (other scores were tested as well but they are not shown).

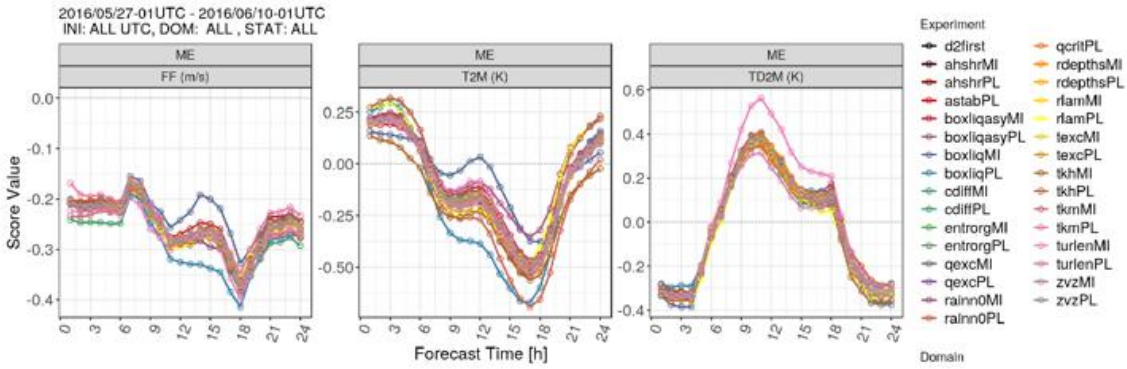

Figure 33: Mean error of 10m wind speed (left), 2m temperature (middle), and 2m dewpoint temperature (right) as a function of the forecast lead time averaged over 14 days of 00 UTC deterministic ICON-D2 runs. Each coloured line corresponds to exactly one parameter being perturbed in just one direction (see legend with 'PL' for 'increased' and 'MI' for 'decreased') keeping all other parameters at their default values. The fully unperturbed run ('d2first') is contained as well but overlaid by the other runs.

Most of the mean errors are very similar among the different runs for the three variables 10m wind speed, 2m temperature, and 2m dewpoint temperature. Just a few parameter perturbations are considered to produce outliers, e.g. the perturbation in both directions of `box_liq` (blueish lines) for wind speed and 2m temperature and `rain_n0_factor` for 2m temperature or the reduction of `tur_len` for the 2m dewpoint temperature. The parameter perturbations pointing at possible outliers with this quite conservative test have been adjusted for the first experiments with ICON-D2-EPS and table 2 lists the accordingly selected perturbation set-up.

Note that these perturbation ranges are subject to change in light of further developments of the parametrizations and of the ICON-D2-EPS. An up-to-date list of perturbations used in operational set-up can be found online in the ICON database reference manual (Reinert et al., 2021, latest version).

In the following, verification results of the pre-operational ICON-D2-EPS in comparison to the operational COSMO-D2-EPS are presented for a winter (December 2019 to February 2020) and summer (June to August 2020) period. Fig. 34 shows verification scores of the winter period for 2m temperature, 2m dewpoint temperature, hourly precipitation, and

CD2	ID2	meaning	def-	−	+
a_stab	a_stab	stability correction of turbulent length scale	0	none	1
c_diff	c_diff	length scale factor for vertical diffusion of TKE	0.2	0.1	0.4

Table 2: Perturbed parameters in COSMO-D2-EPS (**CD2**) and in first experiments with ICON-D2-EPS (**ID2**). The default (**def.**) and perturbed values (decreased: −; increased +) refer to ICON-D2-EPS. The updates to operationally used parameters, default values, and perturbation ranges in ICON-D2-EPS are available online (Reinert et al., 2021) together with information about the perturbation being additive or multiplicative for a given parameter (e.g. rlam_heat changes from multiplicative to additive with ICON-D2-EPS).

hourly 10m wind gusts as a function of the forecast lead time for 00 and 12 UTC runs combined.

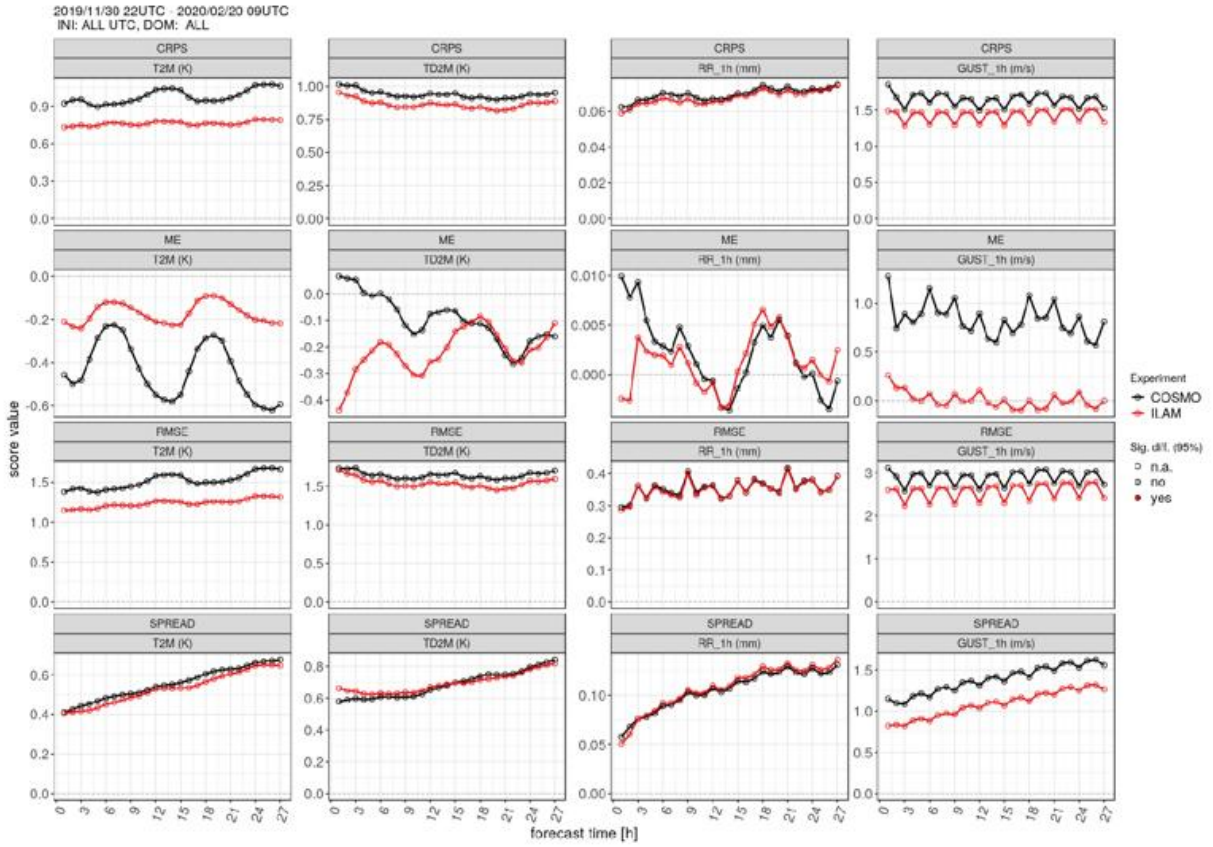

Figure 34: Continuous ranked probability score (CRPS), mean error and root mean squared error of the EPS mean, and EPS spread (from top to bottom) for 2m temperature, 2m dewpoint temperature, hourly precipitation, and hourly 10m wind gusts (from left to right) as a function of the forecast lead time of the pre-operational ICON-D2-EPS (red) and the operational COSMO-D2-EPS (black) for winter 2019/2020. Scores of 00 and 12 UTC runs are combined.

Comparing ICON-D2-EPS with COSMO-D2-EPS an improvement of CRPS is evident for all variables. The mean error for 2m temperature is clearly improved both in terms of magnitude as well as reduced daily cycle. The reduction of the daily cycle of the bias supports the beneficial use of ICON-D2 compared to COSMO-D2 in forecasting. It is observed for other variables as well (not shown, e.g. 10m wind speed). The dewpoint temperature shows a dry bias at forecast start of ICON-D2-EPS compared to COSMO-D2-EPS which extends up to forecast hour 15. This problem has been overcome in the further development of the system by different measures, of which the most important is the incorporation of 2m temperature and 2m relative humidity observations in the data assimilation.
The bias of the hourly precipitation in the early forecast hours is reduced in ICON-D2-EPS. Very remarkable is the reduction of the mean error for 10m wind gusts to nearly 0 m/s over most parts of the forecast range.
The RMSE of the EPS mean is reduced by ICON-D2 for most variables and neutral otherwise (hourly precipitation) and is similar to changes in CRPS. It should be noted here, that changes in mean error and RMSE for winter and summer for the variables shown here, as well as for other variables, closely follow the changes of the deterministic run from COSMO-D2 to ICON-D2 (not shown).

The EPS spread does hardly change from COSMO-D2-EPS to ICON-D2-EPS except for a reduction for the 10m wind gusts (as well as mean wind, not shown). The reason for this reduced spread is not clear yet and subject to further research. Overall, the threshold-based forecast of 10m wind gusts benefits from the step to ICON-D2-EPS according to the Brier skill score plotted in Fig. 35 for different thresholds. The improvement affects both the reliability as well as the resolution component of the Brier score (not shown).

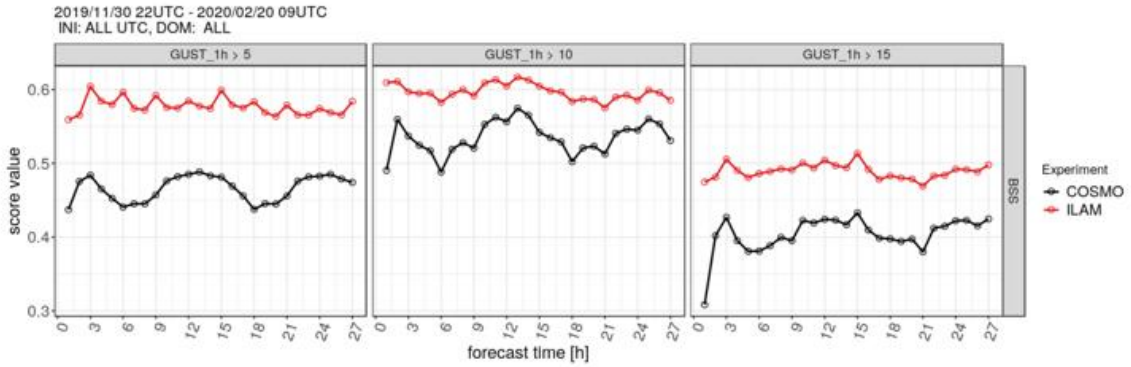

Figure 35: Brier skill score of hourly 10m wind gusts for thresholds of 5 m/s, 10 m/s, and 15 m/s (from left to right) as a function of the forecast lead time for the pre-operational ICON-D2-EPS (red) and the operational COSMO-D2-EPS (black) for winter 2019/2020. Scores of 00 and 12 UTC runs are combined.

The selection of verification scores for the summer period is shown in Fig. 36 in analogy to the scores for the winter period.

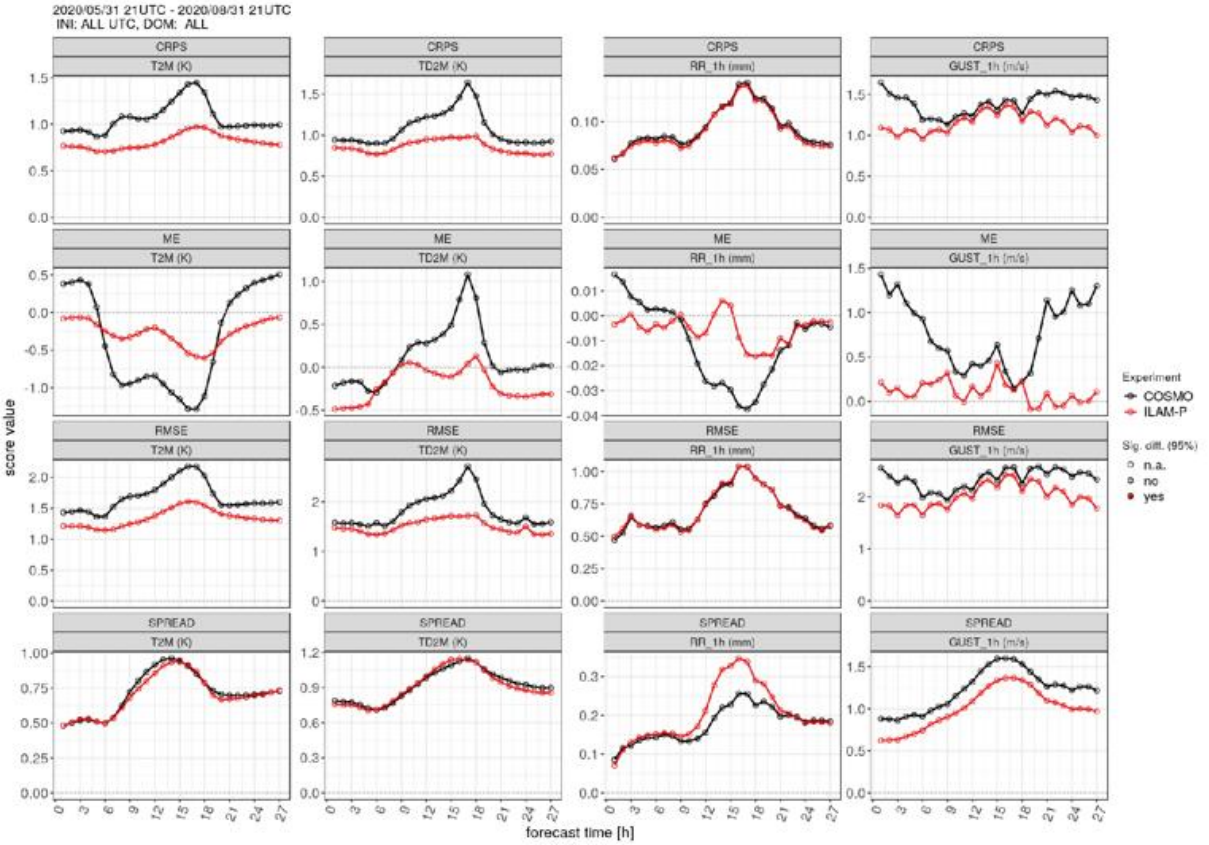

Figure 36: Continuous ranked probability score, mean error and root mean squared error of the EPS mean, and EPS spread (from top to bottom) for 2m temperature, 2m dewpoint temperature, hourly precipitation, and hourly 10m wind gusts (from left to right) as a function of the forecast lead time of the pre-operational ICON-D2-EPS (red) and the operational COSMO-D2-EPS (black) for summer 2020. Scores of 00 and 12 UTC runs are combined.

The main features seen for winter also hold for the summer period. Main differences are the remarkable quality gain by ICON-D2-EPS in the mean error of 2m dewpoint temperature and hourly precipitation and the more pronounced reduction of RMSE for 2m (dewpoint) temperature around mid-day as compared to the winter period. For 10m wind gusts, the quality of ICON-D2-EPS in summer and winter is similar. This in turn results in a moderate improvement in summer around mid-day compared to COSMO-D2-EPS, which itself shows better scores for the wind gusts in summer than in winter. The improvement in Brier skill score by ICON-D2-EPS in summer is qualitatively similar to the results for winter and is not shown here.
One effect to mention here is the increased spread of hourly precipitation during mid-day in summer which is not observed for winter. However, it should be kept in mind that increased spread of precipitation tends to be linked to increased mean values. A threshold-based verification with the Brier skill score for hourly precipitation in summer points at moderate improvements when using ICON-D2-EPS (Fig. 37).

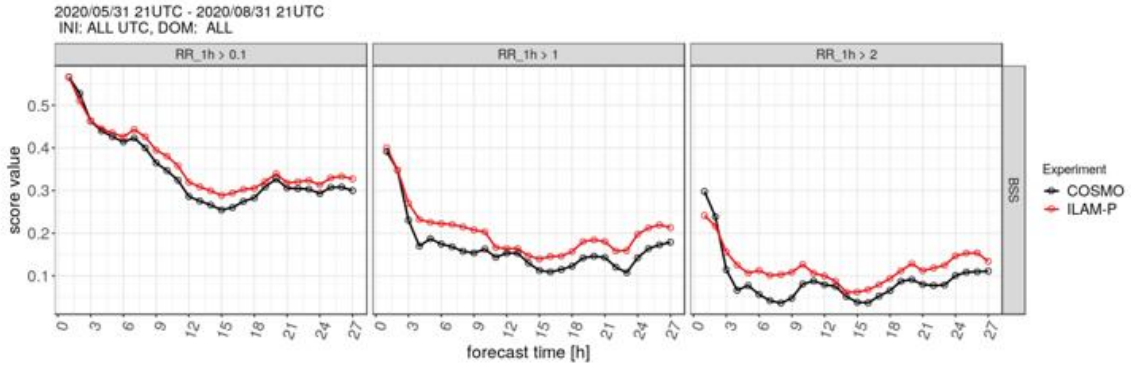

Figure 37: Brier skill score of hourly precipitation for the thresholds 0.1 mm/h, 1 mm/h, and 2 mm/h (from left to right) as a function of the forecast lead time for the pre-operational ICON-D2-EPS (red) and the operational COSMO-D2-EPS (black) for summer 2020. Scores of 00 and 12 UTC runs are combined.

The last part of this section covers the technical implementation of the parameter perturbations in ICON-D2-EPS. While the perturbation approach for COSMO-D2-EPS requires the perturbed parameter values to be set explicitly in the namelist for each member separately as a pre-processing step, including the randomization, the ICON-D2-EPS just needs general information about the parameters to be perturbed and the relevant ranges provided via the namelist. The randomization is done during the model run and there are additional namelist parameters to control a few options of the randomization and parameter selection.
Fig. 38 is a flow chart of the procedure.

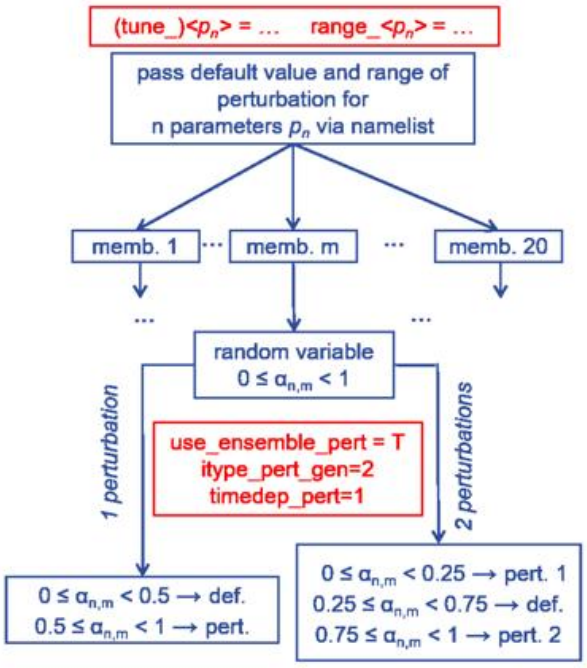

Figure 38: Technical implementation of the parameter perturbations in ICON-D2-EPS.

The default values of the parameters (tune_)$< p_n >$ are set in their respective namelists as for the deterministic run. A range for perturbations is set as (range_)$< p_n >$ in the ICON namelist `ensemble_pert_nml`. There is only one entry for the range which has to be given

as deviation from the default value. Therefore, only symmetric perturbations (in an additive or multiplicative sense depending on p_n) are possible in ICON-D2-EPS. There are also restrictions for a few parameters to be perturbed only in one direction.
The namelist `ensemble_pert_nml` contains the important switch `use_ensemble_pert` to be set to `.TRUE.` to activate the parameter perturbation. A random variable $\alpha_{n,m}$ is then generated in ICON from a uniform distribution between 0 and 1 for each parameter p_n and member m. By setting the parameter `itype_pert_gen=2` in `ensemble_pert_nml`, the random variable $\alpha_{n,m}$ leads to the value of p_n being one of default or perturbed value, as indicated in Fig. 38. A choice of `itype_pert_gen=1` would lead to a perturbed value somewhere within the perturbation range according to $\alpha_{n,m}$ taken at face value as implemented for the global ICON-EPS and its nest over Europe.
Another important control switch for the perturbation procedure is the namelist entry `timedep_pert` in `ensemble_pert_nml`. A value of 1 causes the randomization to depend on forecast start time as it is done in ICON-D2-EPS. The global ICON-EPS uses a value of 0 leading to a dependence on the member ID only. Some details about these namelist entries can be found in Reinert et al. as well. They provide for more options to generate EPS members than just in the way it is presented here for ICON-D2-EPS.
There might be slight drawbacks in the described implementation of the perturbation procedure in ICON-D2-EPS compared to COSMO-D2-EPS, like the symmetric perturbation ranges and the methodological aspect that each parameter is no longer perturbed exactly in 50% of the members of a model run, but only statistically. However, the namelist-based approach makes it more feasible to run the RPP and makes the approach more portable between different machines and exchangeable among COSMO partners compared to COSMO-D2-EPS.

6 Conclusions

Like most of the WG7 Priority Projects, the activities of APSU covered a quite broad range of ensemble development topics. This allows us to carry out ensemble development in a coordinated way between the different COSMO partners, while preserving the specificity of the different ensemble implementations and needs (different domains, focus on somehow different weather phenomena, different computing capabilities and human resources). However, thanks to the APSU Priority Project, the activities about ensemble development of the different COSMO members were focused on specific high-priority themes, benefiting from each others' work and avoiding duplications and dispersion of efforts.

Some conclusions can be drawn from this work, highlighting the impact of the Project activities on the ensemble development and operational usage, and identifying the next steps needed to perform the transition of the ensembles to the ICON model.

- The new stochastic approaches to model the model error (SMME and AMPT) are promising methods to describe the model error and incorporate it into ensemble design. However, their complexity and the difficulty of objectively representing the model error require a long development phase, which is not concluded in the time frame of APSU. It is important to keep these developments linked to each other, in order to benefit from each others' results and experiences. Due to the transition of the Consortium to the ICON model, it is now suggested to implement the two methods in ICON and continue their development in the new model.
- The SPPT method is successfully used at MCH as operational model perturbation method. Therefore MCH will invest resources in implementing SPPT in ICON, in

view of the future transition to the ICON model for their ensembles. The proposed iSPPT variant, even if it did not prove to be more beneficial than the classical SPPT in COSMO, will be considered for implementation, in order to permit its usage and further assessment in the new model framework. The study performed on the analysis increments, to be possibly used as source of model perturbation, lead to positive results. However, the development of this method would require time and resources, and this has to be taken in account in planning future actions.

- The implementation of model perturbation methods in ICON will also permit to the COSMO partners to start working on the new model system and to contribute to the development of the ICON model
- The application of soil/surface perturbations proved to be successful and lead, in combination to the perturbation of the atmospheric fields, to promising results. Therefore these perturbations will also be adopted in the ICON-based ensembles.
- In order to apply the parameter perturbation method in ICON it is needed to study the sensitivity of the ICON model to its parameters, as it was done at DWD during APSU. Therefore this activity will be repeated for the other domains where ICON-based ensembles need to be developed. This will also permit to gain a deeper knowledge of the model and its behaviour, which is in the interest of all the COSMO partners.
- The tasks related to the development of new ensemble products and ensemble output calibration lead to an operational usage of the new products and of the calibrated outputs. Therefore this task will be continued in the future, by expanding to new products and improving the calibration methodology.

Concluding with a poetic note, the APSU PP was like the underground fresh water reservoir of the Sumerian and Accadic culture, after which the project is named, from which fertilising quality the future work will benefit.

7 Acknowledgements

We are grateful to the COSMO Consortium, which gives us the opportunity to work together and benefit from mutual exchanges and discussions. The Project leader would like to thank the members of Working Group 7 for their continuous and active engagement.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

For any comments and questions, please contact the editor:

1 Introduction

In 2006, the STC approved the development of a common, unified verification 'library' through the VERSUS project, which was followed by the PP-VERSUS2 in 2009. The objective of this strategic decision was to develop a common COSMO verification software package that would enable the production of homogeneous and comparable statistical results. In recent years, partly due to technical limitations of VERSUS and the ceasing of further development, the WG5 members considered the possibility of utilizing multiple verification modules that would not necessarily be linked to one software package (e.g. VAST software for spatial methods). For the CP activity, it is essential to maintain a software as a common tool for their production as this will ensure the adoption of the same verification practices that will allow for the easier long-term monitoring of the derived results.

Before the start of PP CARMA, Common Plot verification activities were carried out using the VERSUS verification software environment. Because of the technical limitations of VERSUS and lack of further development, it has been decided within the consortium that this should be replaced with the MEC-Rfdbk software. The MEC-Rfdbk system uses small files for fast calculation of verification scores, while the results can be browsed interactively online. The verification is based on the use of feedback files (FF), that hold information on observations (including meta-data) and their usage in data assimilation, as well as the corresponding model analysis, first-guess and past forecasts, in NetCDF format. These files are relatively small, being produced for each valid time / observation type and can be used for various verification tasks.

The Model Equivalent Calculator (MEC) software for the production of Feedback Files, and verification scripts based on the R package Rfdbk, are tools that were developed and are in operational use at DWD for the verification of both COSMO and ICON model chains.

1.1 Goal of PP

The goal of the CARMA Priority Project (2018-2021) was to replace the existing VERSUS verification software environment with the MEC-Rfdbk software developed by DWD, as a Common Verification Software (CVS), in order to perform part of the verification activities in the consortium. The main use of the new CVS is be the production of the Common Plot (CP) verification while spatial verification should rather be performed with other available tools (VAST, etc.) in each service. MEC-Rfdbk is also suitable for EPS verification, but this type of application was not be included in the current project as EPS verification is not part of CP activity, but can be considered in a next phase. The CVS that is based on MEC-Rfdbk is chosen with the intention of being a useful user-friendly tool for the entire COSMO community. It addresses the need to perform traditional point verification both for the surface and the upper air using conventional methods, which arise from operational and research activities. Moreover, a centralized transfer and visualization of CP statistics on COSMO web server will facilitate the easier analysis of the outcome of this activity and is one of the main goals of this project.

The most striking advantages of the new verification system adopted for CP preparation activity, are the shortfall of data pre-processing (all data in one place, observation and forecast correctly assigned to each other, quality control done by data assimilation, small files), the fast and simple calculation of standard verification scores and the interactive visualisation and online production of results.

PP CARMA was also linked with the following COSMO tasks:

- Support Activities – NWP Test Suite: the MEC-Rfdbk system is currently installed and used on the ECMWF platform for the evaluation of new model versions before they are officially released.
- PP C2I Task 3 for the evaluation and comparison of COSMO and ICON-LAM forecasts: the MEC+Rfdbk system was used to produce verification results included in the ICON Report "Verification of ICON in Limited Area Mode at COSMO National Meteorological Services" (Rieger et al., 2021) published as part of the Priority Project
- Support Activities – Common Plot verification (SPRT).

1.2 Brief Description of System Design

The MEC-Rfdbk verification system is based on the use of feedback files (FF) that hold information on observations and their usage in the data assimilation (DA) system. FF and are available for each observation system used in DA and contain information regarding the observations (including meta-data) and corresponding model analysis, first-guess and past forecast (also ensemble) in the NetCDF format. These files have a relatively small size (e.g. 4.8Mb SYNOP for COSMO-7km run for the NWP Test Suite domain covering the entire Europe) and are produced as one file for each valid-time (time window), model and observation system. A detailed description of FF can be found here (http://cosmo-model.org/content/model/documentation/core/default.htm).

The FF are produced by the Model Equivalent Calculator (MEC; Potthast, 2019) within the data assimilation system or as stand-alone. Information from FF can be used for verification tasks (e.g. name, location, level, weight in DA, ensemble spread, Talagrand index and so on). Further on, these files are used by the Rfdbk (Fundel, 2021) package to perform some convenience functions like data adjustment, re-labelling, binning etc. and then calculate the verification scores. Finally, the verification scores in Rdata format are visualized on the dedicated COSMO web page, using the R shiny server (Chang et al., 2020).

A schematic diagram of the system is presented in Fig. 1, followed by short descriptions of the main system components. **For more detailed presentations of the MEC-Rfdbk system and its components, including information regarding installation and use, please check the dedicated documents referenced in Section 6.**

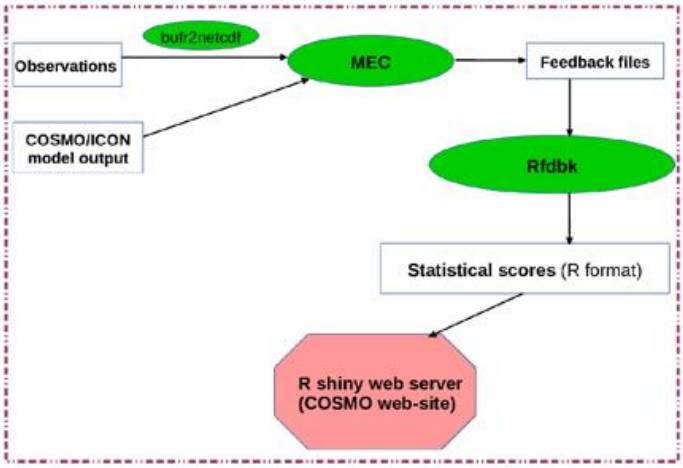

Figure 1: Schematic representation of the MEC-Rfdbk system.

1.2.1 The Model Equivalent Calculator (MEC)

MEC applies the observation operators from the data assimilation scheme (Nudging, 3Dvar, Ensemble Kalman Filter) to model forecasts (COSMO, ICON) and stores the results in verification files (NetCDF feedback file format). The software can use as input observations, model runs (deterministic or ensemble), analysis runs or even another MEC run, depending on the user needs and can be applied to interpolate between two or more time periods. Observation operators are either those implemented in the DWD global data assimilation code (3dvar/EnVar/LETKF) or those implemented in the COSMO model, as used in the nudging and the KENDA/LETKF data assimilation scheme. Alternatively, the fof-files (feedback file format as well) written by COSMO (in the nudging mode or in the first guess run for KENDA) may be taken as input for MEC. A further option is to use the original observational data (CDFIN, i.e. BUFR format converted to NetCDF). In these cases verification files will be generated separately for each observation type (TEMP, PILOT, SYNOP, etc).

For this project (as well as for the permanent Common Plot Activity), this second approach was adopted by using a common set of observations retrieved in bufr format from the MARS archive. These observations are converted in NetCDF format with the bufr2netcdf software (Patruno and Cesari, 2011) and used as input in MEC. The results of MEC are stored in the NetCDF feedback file format.

The advantages of using the MEC software as part of the verification system for CP activities are related to data pre-processing (all data in one place) and ensuring observation and forecasts are correctly assigned to each other, with quality control done by data assimilation.

MEC characteristics and requirements:

- produces feedback files
- namelist based

Installation

- Sources: Fortran 2003/2008 and C (Makefile for gfortran provided)
- Dependencies: NetCDF, CGRIBEX (MPI Hamburg), GRIP-API (ECMWF), (MPI recommended), Fortran compiler, C compiler
- Sufficient memory to hold one model state (1 ensemble state)

IO specifications

- model in Grib2 format – COSMO or ICON-LAM
- parameters - PS, T, U, V, P, Q (mandatory, all model levels); T2M, TD2M, CLC, CLCT, CLCL, CLCM, CLCH, CLC, H_SNOW, TOT_PREC, VMAX_10, TMIN_2M, TMAX_2M
- observations (CDFIN: BUFR converted by bufrx2netcdf to NetCDF)
- output: ver-files, NetCDF feedback files including past forecasts

MEC can produce feedback-files for any model, which can then be used as input to produce verification statistics using Rfdbk. Some mandatory parameters from the model of interest must be available on all model levels: PS, T, U, V, P, Q, while others are optional, depending on the available observations and user needs (T2M, TD2M, PS, N, FF, DD, Gust, RR, etc).

The production of IFS FF using the Common Plot set of observations (cdfin files) is at the moment on-going, due to some limitations of the MEC software that need further investigation. This activity is included in the COSMO-SPRT Common Plot one for 2021-2022.

1.2.2 The Rfdbk package

This is an R interface that aims to exploit the information contained in the feedback files and can be used to perform feedback file-based verification. Rfdbk uses as input the feedback files obtained from MEC (one file for each validity date and observation type) and outputs score files (again, for each validity date and observation type). Rfdbk exploits the functionality of the R data.table format and can therefore handle huge data tables efficiently with a concise syntax that allows to apply functions on sub-categories. Rfdbk itself is not a verification package but an assortment of R functions (libraries). Based on Rfdbk libraries, R scripts exist to quickly and reliably produce verification results. These scripts can be modified and adjusted according to the needs of each particular system that will be linked to.

Rfdbk characteristics and requirements:

- R interface for COSMO feedback files
- main purpose is to load feedback file content with R
- additional functionalities useful for verification implemented as well
- namelist based verification scripts using Rfdbk do the verification

Installation

- Sources: R language
- Dependencies: NetCDF library and R with additional R packages: RNetCDF, data.table, parallel, strings, survival, grid, verification, reshape2, pcaPPIO specifications
- input - feedback files obtained previously with MEC - one file for each validity date and observation type
- output - score files for each validity date and observation type

Verification can be done for various types of observations (SYNOP, radiosondes, radio occultation, aircraft, wind profiler and so on). Continuous scores are computed for various types of observations, while categorical scores are also available for SYNOP observations. Verification can be performed for deterministic runs (forecast or hindcast) or ensemble, for any model (COSMO, ICON, IFS, etc.), while cross model verification (e.g. COSMO vs. ICON vs. IFS) is also possible. The package allows the handling of large data tables that facilitate the loading of feedback file content, data adjustment, binning, calculation of basic verification scores and so on. Rfdbk -based scripts can be used for:

- domain average verification (function of forecast lead-time for a user defined verification period), including domain stratification,
- time series (function of valid time in the verification period or as a function of the forecast lead-time)
- station based verification (function of observation station).
- aggregation on sub-domains, height bins, levels or periods

Rfdbk is a user-friendly package that can be employed in R-based scripts in order to perform point verification for either surface or upper air parameters using various types of observations and model runs. The advantage of using Rfdbk based verification scripts is their flexibility, which means they can be modified and adjusted according to the needs of each user and (UNIX) system.

1.2.3 R Shiny web server

On top, an interactive (R based) tool for the online visualization of verification results has been developed and will be also adopted in this project. This is based on the R Shiny web server that is currently setup on the COSMO web-site for the NWP Test suite needs. Through this capability it is possible to have on demand interactive plot web browser application, plot and arrange scores, summary score charts and browse data, with separate web-based apps for each observation and verification type.

This centralized, online and interactive visualization of the results on the COSMO web-site using the R Shiny server is meant to enable an easier evaluation of the results.

1.3 Overview of System Implementation

PP CARMA has obtained the successful results. The main outcome was the implementation of the new CVS in most countries of the COSMO consortium, with the system already in use for various operational implementations of both COSMO and ICON, as can be seen from tables 1 and 2.

	IMPLEMENTATION		**PRODUCTION**		**Visualization**
	DACE/MEC	**Rfdbk**	**FF**	**SCORES**	**(optional)**
NMA	yes	yes	yes	yes	yes
HNMS	yes	yes	yes	yes	-
DWD	*(yes)	*(yes)	*(yes)	*(yes)	*(yes)
MCH	*(yes)	*(yes)	on-going	on-going	
COMET	yes	yes	yes	yes	
IMGW-PIB	yes	yes	yes	yes	yes
RHM	yes	yes	on-going		
IMS	yes	yes	yes	yes	yes
ArpaE-SIMC	yes	on-going			

Table 1: Status of implementations for the MEC+Rfdbk system in each centre. *denotes that the system was installed and in use before the start of the project.

	NMA	HNMS	DWD	IMGW-PIB	COMET	MCH	RHM	IMS	ArpaE-SIMC
COSMO	x	-	x	x	x	x	-	-	x
ICON	x	x	x	x	x	-	x	x	-

Table 2: Overview of models verified by each centre using the MEC+Rfdbk software.

First results using the MEC+Rfdbk output for some CP activities started in the 2020 spring season (MAM 2020). The number of model scores computed with the new CVS has gradually increased until present (15 models expected for JJA2021), as will be shown in Section 3, dedicated to presenting the PP results.

2 Description of Tasks

2.1 Task 1: First Level Support Implementation and Training

Goal: The first level support implementation and training of the Project Support Team (PST) were included. In turn, the PST ensured and supported the implementation of the system for all the other partners.

2.1.1 Subtasks

1.1 Documentation review (MEC-Rfdbk), analysis of resources required. Preparation of a document for verification task specifications (common areas, models, parameters, statistical indices, representation) included in CP activity.

1.2 Documentation preparation (MEC-Rfdbk) with all the necessary installation and use notes for the PST training.

1.3 Preparation of a complete example set of data (one season, one model) to be used during the training and testing period. Model output as a test bed, including parameters that are part of CP requirements prepared. Adaptation of observations in NetCDF format (with bufr2netcdf COSMO software).

1.4 Training provided by DWD experts for first level support to the PST. During this training, a "clean" installation of MEC, Rfdbk and Shiny routines for visualization of results will be performed on a test machine. A complete cycle of model evaluation for a test case (outcome of Task 1.3) over CP area will be performed (observation preparation, run of MEC for Feedback files preparation, run of Rfdbk for extraction of statistical indices for both continuous and dichotomic parameters, visualization of results with Shiny).

1.5 Implementation of the MEC-Rfdbk system at NMA and HNMS (PST), in order to set up the MEC+Rfdbk system in all participating countries (with support from DWD experts where necessary).

1.6 Adaptation of scripts to produce the necessary statistical information for the production of the CP requirements, on a seasonal basis. Preparation and testing of scripts for semi-automatic use of the system.

1.7 Setup of web interface with the use of Shiny R routines on COSMO server to host CP activity outputs once the system becomes operational.

2.1.2 Deliverables and Preliminary Results

- Written instructions for installation and use of MEC-Rfdbk system.
- Installation of the MEC-Rfdbk system at NMA and HMNS (PST) and first tests of the implementation.
- Scripts for semi-automatic use of the system, available to project participants through common WG5 repository.
- Dataset (forecast/observation) to be used for test period of MEC-Rfdbk system.
- Completion of test period experiment and production of statistics (PST).
- Web interface to host Common Area plots for all countries.

The observations necessary for CP activity are prepared and disseminated to the participants operationally, on a daily basis.

Together with the daily observations, three sets of scripts are available for:

- production of FF with MEC from various model specifications (COSMO, ICON-LAM native or regular grid), on different platforms (local machine, ECMWF)
- production of scores using Rfdbk
- templates for plotting the results using the shiny server

The web interface to host Common Area plots for all countries is available on the COSMO web-site: http://www.cosmo-model.org/shiny/apps/carma/.

2.2 Task 2: Second Level Implementation and support+

Goal: Implementation of the MEC-Rfdbk system by all the member countries in the consortium, with support from PST (DWD support provided only when necessary and always through the PST).

2.2.1 Subtasks

2.1 Remote training PST for users from each centre. Dissemination of instructions, mailing list creation for problems solving, videoconferences, etc.

2.2 Implementation of MEC-Rfdbk system in each participating centre with support of PST

2.2.2 Deliverables and Preliminary Results

MEC-Rfdbk system installed by all project participants with support from PST. An overview of implementation status for each system component was shown in tables 1 and 2 (Section 1.3).

2.3 Task 3: Cross-validation of implementation

Goal: Testing of the verification system implementation and training through practical use.

Requirements from the participating scientists with regards to their verification needs led to the necessity of shifting the initially main task of the project from COSMO to ICON, in the view of the COSMO to ICON migration. As a consequence, two additional sub-tasks were included after the start of the project. The first additional sub-task was directly related to the COSMO to ICON migration and the need to test the new verification system for ICON-LAM implementations, rather than continue to invest much effort in adapting it for COSMO needs. Apart from this, an optional sub-task was also proposed, which was not foreseen at the beginning of the project. With the shiny server (COSMO web) used for both CP activities and the NWP Test Suite verification platform and due to the interest of the participants to use the MEC+Rfdbk system for verification requirements additional to CP activities, set-up of individual shiny servers was advised, in order to avoid loading the COSMO shiny server unnecessarily.

2.3.1 Subtasks

3.1 Performance of a test with all the necessary output for the CP reports. This task included development/adaptation of automatic procedures (scripts adaptation to local DBs) for seasonal CP activities based on the MEC-Rfdbk system by all services. Preparation of MEC output files for seasonal CP.

3.2 Transfer to statistical output to COSMO web server and visualization of results through installation of Shiny server (capability developed in Task 1.6) for comparison purposes.

3.3 Optional comparison of test output with VERSUS system or any other "home" verification system.

3.4 Set-up and testing of MEC+Rfdbk capabilities for ICON-LAM
Set-up of system and performance of a test with all the necessary output of ICON-LAM for the CP reports. This task was added due to the requirements of the participants, in view of the new ICON implementations. Some centres were unable to verify COSMO because of MEC model data requirements and lack of storage resources (e.g. not all required model data are archived). This additional sub-task also took into consideration the migration from COSMO to ICON.

3.5 (optional) Set-up of individual shiny server for visualization
At the start of the project, the shiny server on the COSMO web-site was used for visualization of results from Rfdbk (CP verification as well as NWP test suite). However, this can only be a solution for the CP activities, since verification activities of the users from the MEC+Rfdbk system vary and also include other type of individual verification. For future use (optimal) of the MEC+Rfdbk system, the set-up of individual shiny servers for each interested centre was suggested, to facilitate the visualization of the verification results. Similar to the implementation of the MEC+Rfdbk system, the shiny server was first set-up for the PST team who would, in turn help the other participants set-up their own systems.

2.3.2 Deliverables and Preliminary Results

- Evaluation of MEC-Rfdbk system for CP production based on an example dataset. Comparison with results from other verification software.

- Implementation of CP seasonal output with the MEC-Rfdbk system.

2.4 Task 4 Elaboration of guidelines for CARMA (MEC-Rfdbk) system use

Goal Preparation of documentation on the use of the MEC-Rfdbk system (including CP activities specifications).

2.4.1 Deliverables and Preliminary Results

Guidelines on the implementation, use and application of the MEC-Rfdbk system for CP production. ***An overview of the PP documentation (including Guidelines) is available in Section 6.***

2.5 Overview of Issues and Remaining Discussion Points

Remaining Discussion Points
Following the finalization of the project, a few remaining issues are at the moment still on-going, due to some limitations either of the software or specific problems of some users. These activities are included in the COSMO-SPRT Common Plot activities for 2021-2022 and refer to:

- IFS based FF
- installation and user support
- inclusion of all models in the new verification system

As Common Plot activities are a continuous and evolving task, some features of the current requirements might differ to the ones envisioned at the beginning of the project. As a consequence, follow up activities will also aim to incorporate the new requirements included in this year guidelines of the CP activity, such as:

- upper air verification
- 6h precipitation in all time intervals
- conditional verification
- update of the system with new versions of Rfdbk and distribution of new MEC versions for FF production

3 Timeline of Activities and Results

For the various results presented in the sections bellow, the following models were employed:

ICON GLOBAL (DWD)
ICON-EU (DWD)
COSMOPL7 / COSMO-PL(IMGW-PIB)
COSMO_ME (COMET)

ICON-D2 (DWD)
ICON_IT2 (COMET)
ICONGR (HNMS)
ICON_IMS / ICON-IL2p5 (IMS)
ICONPL (IMGW-PIB)
COSMO-CE-PL (IMGW-PIB)
COSMO_IT2 (COMET)
COSMO-1E (MCH)
COSMO-2E (MCH)
COSMO-RO_2p8 (NMA)
ICON-RO_2p8 (NMA)
COSMO-D2 (DWD)
COSMOP2k8 (IMGW-PIB)
COSMO-RO (NMA)

Standard Verification (seasonal) is generally performed for the following continuous parameters: 2-meter temperature – T2M (deg K), 2-meter dew point temperature - TD2M (deg K), surface pressure - PS (Pa), total cloud cover - N (octa), 10-meter wind speed - FF (m/s), wind direction - DD (deg) and wind gust - Gust (1 hour, m/s). Categorical scores are also computed, for the following parameters: 6 hour accumulated precipitation - RR_6h (thresholds: 0.2, 1, 5, 10, 15, 20 mm/6h), total cloud cover (thresholds >= 1, >= 4 and >= 7) and 10-meter wind gust (thresholds: >= 12.5, >= 15, >= 20 m/s).

Scores for continuous parameters include the mean error (ME) and root mean squared error (RMSE), mean absolute error (MAE), standard deviation (SD) and so on (only ME and RMSE will be discussed in the following examples). Dichotomic scores include the probability of detection (POD), false alarm rate (FAR), equitable threat score (ETS), frequency bias (FBI). Other scores based on the number of hits, misses, false alarms and correct negatives respectively are also available, but will not be shown. For all scores, the number of observations used in computations (LEN) is also available.

For the purpose of the project and future Common Plot Activities, scores were performed either for national domains or for the two domains used in the Common Area Verification Activities (see Figs. 2, 3 and Table 3).

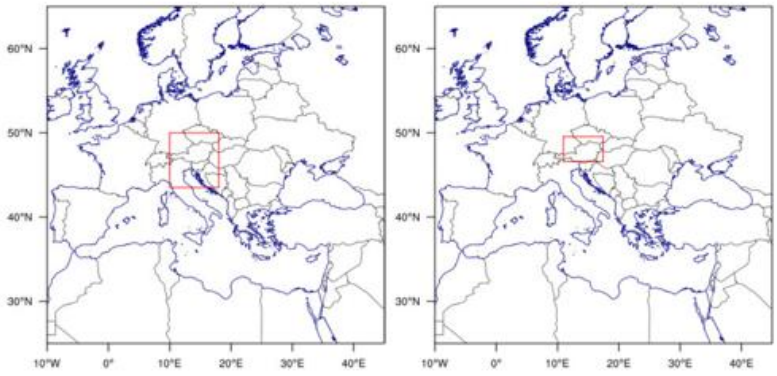

Figure 2: Common Areas: CA1 (left) and CA2 (right) used for the verification.

The two common areas for which the scores are computed include parts of Northern Italy, Austria, Slovenia, Croatia, Germany, Bosnia and Herzegovina, Hungary, Slovakia, and the Czech Republic. For Common Area 1, 96 stations were selected, with altitudes between 0m and 753 meters. Although slightly more restricted geographically, Common Area 2

included a larger number of stations than CA1. The stations in CA2 also cover a greater range of altitudes compared to CA1 (maximum altitude 3114m in CA2 compared to 753m in CA1). Table 3 offers an overview of station distribution for the two areas. The two areas were defined according to the list of stations previously used in verification activities with VERSUS. The results are computed taking into account all stations of interest. However, results are also available stratified by station altitude.

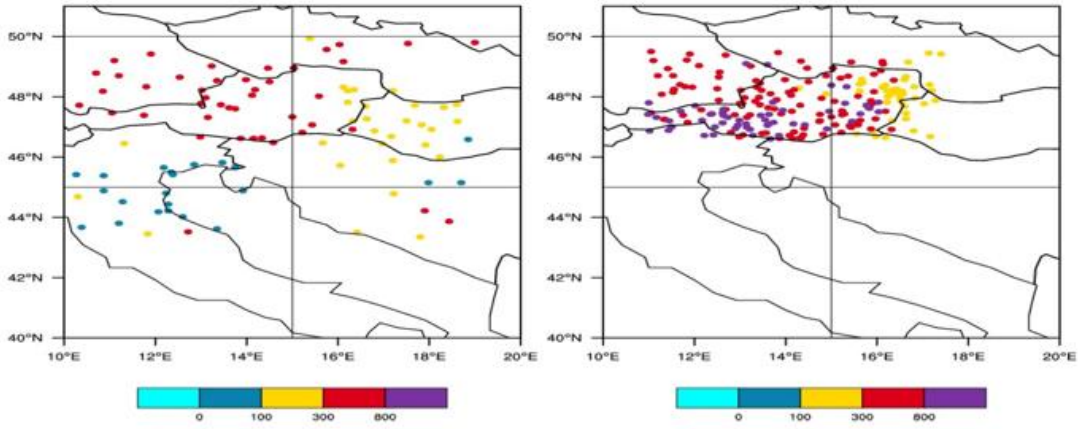

Figure 3: Location and altitude of synoptic stations in CA1 (left) and CA2 (right) used for the verification.

Common Area	Number of stations					Altitude	
	Total	$alt < 100m$	$100m < alt < 300m$	$300m < alt < 800m$	$alt > 800m$	Min	Max
CA1	96	23	30	43	0	0m	753 m
CA2	205	2	41	107	55	0m	3114m

Table 3: Overview of stations distribution for the 2 Common Areas, depending on altitude.

The verification results presented in the following sections are a sample of the derived statistics that were gradually obtained following the implementation of the MEC+Rfdbk system in more participating institutes. Complete sets of statistical scores obtained with the MEC-Rfdbk verification system for the models considered here are either available on the COSMO shiny server (http://www.cosmo-model.org/shiny/apps/carma/) or detailed in various papers referenced hereafter, including the Common plot annual reports available on the COSMO web site (http://cosmo-model.org/content/tasks/verification.priv/default.htm). For a detailed description of the Common Area Verification Activities, we refer to the document by

The following type of graphs produced with the MEC-Rfdbk system are exemplified below:

- Categorical scores for Gust (Fig. 4), RR_6h (figure 6) and N (figure 8);
- Scores for continuous parameters (Figs. 5 and 7);
- Scores for upper air parameters (figure 9);
- Comparison between two models showing reduction in ME and RMSE (Fig. 5).

3.1 MAM 2020: First Results

The first results of a cross model verification (with the MEC-Rfdbk software) for the Common Plot activities were performed for the 2020 spring season (MAM 2020) and detailed in Iriza-Burcă, Linkowska, and Fundel (2020). For these results, a set of three COSMO model runs were considered: COSMO-D2 (DWD), COSMO-PL (IMGW) and COSMO-RO (NMA). Only COSMO 00 UTC model runs were evaluated, with forecast step every 3 hours. The integration domains for COSMO-D2 and COSMO-PL were the operational ones (also included in the official Common Plots activities), while the COSMO-RO integration domain differed from the operational set-up of the model employed in NMA (in order to cover the Common Areas). The scores were computed for the two common areas presented before. Selective results obtained with the MEC+Rfdbk system for CA1 are presented below.

Categorical scores for 10-meter wind gust (1 hour) computed for CA1 (exemplified in Fig. 4) show a generally higher probability of detection for the 12.5m/s threshold than for the 15m/s one. For the first threshold, highest POD values are obtained during the day, with lower values starting with +21 hours anticipation, especially for COSMO-D2. A high false alarm rate from all three models can be seen for the 15m/s threshold, especially from COSMO-RO for CA1 in the second part of the considered forecast interval. For this threshold, a slightly better behaviour is exhibited by COSMO-RO for the first hours of forecast, while for the 12.5m/s threshold, the behaviour of the three models is similar for both areas. For both areas, the behaviour of the model (mainly for the 12.5 m/s threshold) is more similar between COSMO-D2 and COSMO-RO. For a detailed analysis of all the results for MAM 2020, we refer to the paper by Iriza-Burcă, Linkowska, and Fundel (2020).

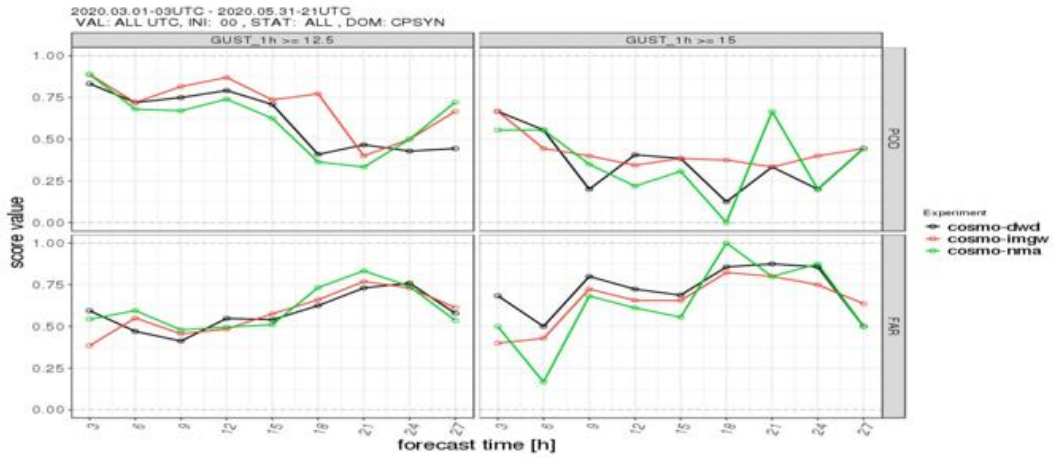

Figure 4: MAM2020 - Categorical scores for Gust (CA1); POD (top) and FAR (bottom): threshold >= 12.5 (left) and >= 15 (right). COSMO-D2 (black), COSMO-PL (red) and COSMO-RO (green).

3.2 SON2020: Verification of ICON in Limited Area Mode at COSMO National Meteorological Services

Some verification results using the MEC+Rfdbk system were included in the ICON Report "Verification of ICON in Limited Area Mode at COSMO National Meteorological Services (Rieger et al., 2021) published as part of the Priority Project 'Transition of COSMO to ICON' (PP C2I). The aim of the project was to ensure a smooth transition for the COSMO national meteorological services to the ICON model and the report offered the first published

verification results on this subject. For this report, verification results were obtained either entirely using the MEC+Rfdbk system (e.g. COSMO-RO_2p8 vs. ICON-RO_2p8) or with the VERSUS verification software and translated to Rdata in order to visualize them using Rfdbk/Shiny server (COSMO-CE-PL vs. ICON-PL and Common Area Verification Results).

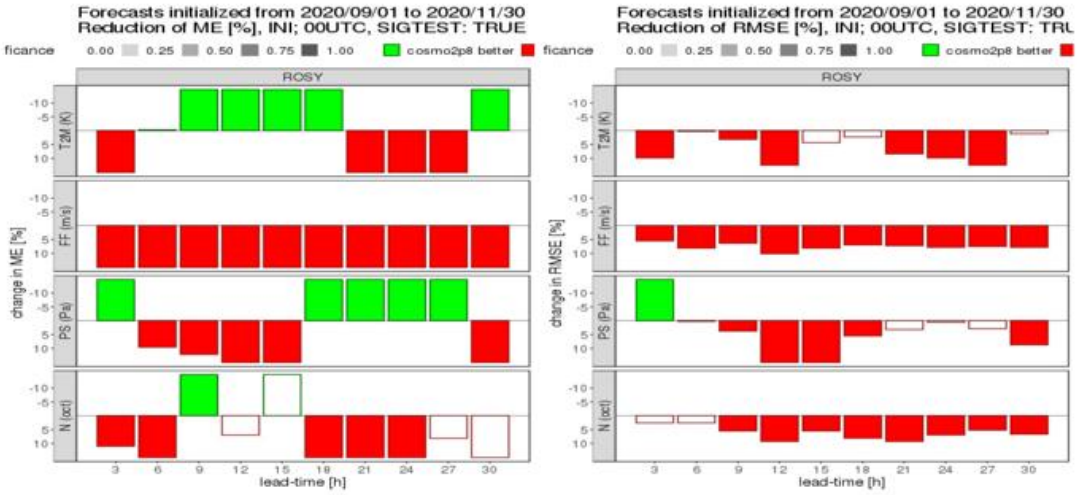

Figure 5: SON2020 - Comparison between ICON-RO-2.8km and COSMO-RO-2.8km: changes in ME (left) and RMSE (right) for all Romanian synop stations; top to bottom: T2M (K), FF (m/s), PS (Pa), N (octa); green - COSMO-RO-2.8km better, red - ICON-RO-2.8km better.

Comparison between ICON-RO-2.8km and COSMO-RO-2.8km **showing reduction in ME and RMSE** is exemplified in Fig. 5. The results obtained with MEC+Rfdbk suggested a good performance of the ICON-LAM model integrated for Romanian territory for the season of interest (up to 78 hours), with a small systematic increase in errors for the later forecast times (+60 hours) for T2M, FF, PS and N (Fig. 5). The comparison between COSMO-RO-2.8km and ICON-RO-2.8km showed a better performance from ICON for most continuous parameters, for the first 30 hours of forecast, visible especially from the reduction in the amplitude of errors.

3.3 DJF2021: First Common Activity Applications

Starting with the 2021 winter season (2021), the first results obtained with MEC+Rfdbk were included in the Common Verification Results (Fig. 6). For the DJF2021 season, FF were produced from the following models:

CA1: ICON-EU, COSMOPL7, COSMO_ME
CA2: ICON-D2, ICON_IMS / ICON-IL2p5, ICONGR, ICONPL, COSMO-1E, COSMO-2E, COSMO-D2, COSMOP2k8
National domains: ICON-RO_2p8, COSMO-RO_2p8

Selective Results for CA2 are shown in Fig. 6 (categorical scores RR_6h). ETS (Equitable Threat Score) and FBI (Frequency Bias) computed for 4 thresholds ($>= 0.2mm/6h$, $>= 1mm/6h$, $>= 10mm/6h$ *and* $>= 20mm/6h$). Results suggest a better performance of the models for the lower thresholds ($>= 0.2\ mm/6h$, $>= 1mm/6h$), with a general tendency to over-forecast. For the higher thresholds, this tendency is mostly shown by COSMOP2k8 and ICONPL.

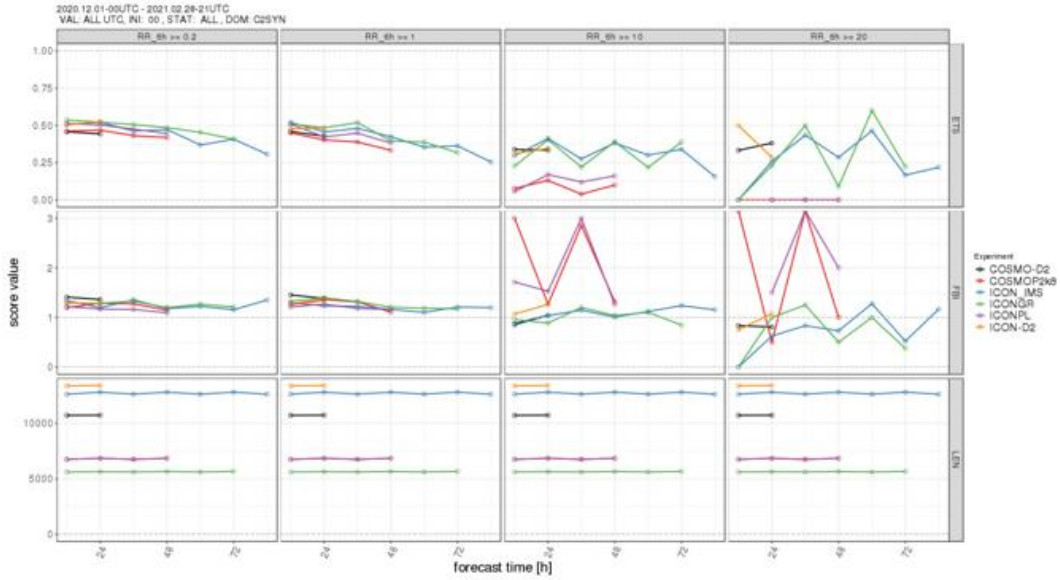

Figure 6: DJF2021 - Categorical scores for RR_6h (CA2): ETS (top), FBI (middle) and number of observations (bottom) values for CA2; thresholds (left to right): $>= 0.2mm/6h$, $>= 1mm/6h$, $>= 10mm/6h$ *and* $>= 20mm/6h$. COSMO-D2 (black), COSMOPk28 (red), ICON_IMS / ICON-IL2p5 (blue), ICONGR (green), ICONPL (purple) and ICON-D2 (orange).

3.4 MAM2021: Extended Common Area Activities

For the MAM2021 season, FF were produced from the following models:

CA1: ICON-GLOBAL, ICON-EU, COSMO_ME, COSMOPL7
CA2: ICON-D2, ICON_IMS / ICON-IL2p5, ICONPL, ICONGR, ICON_IT2, COSMO-CE-PL, COSMO-1E, COSMO-2E, COSMO_IT2
National domains: ICON-RO_2p8, COSMO-RO_2p8

Selective Results for CA1 are presented in Fig. 7, exemplifying scores computed for continuous parameters. For this season and area, in general, lowest ME values are obtained from ICON-EU, that also displays the smaller amplitude of errors for all parameters. The difference in number of observations is given by the fact that ICON-EU is only integrated for a period of 48 hours.

Selective Results for National Domains can be seen in Fig. 8. **Categorical scores for cloud cover** are computed for 3 thresholds (in octa): $N >= 1$, $>= 4$ *and* $>= 7$), taking into account all Italian stations (**national domain**). These results show a similar behaviour of all three evaluated models (COSMO_ME, COSMO_IT2 and ICON_IT2), especially for the first two thresholds, with high POD and a relatively small FAR. Slightly larger values of FAR can be seen for the highest threshold.

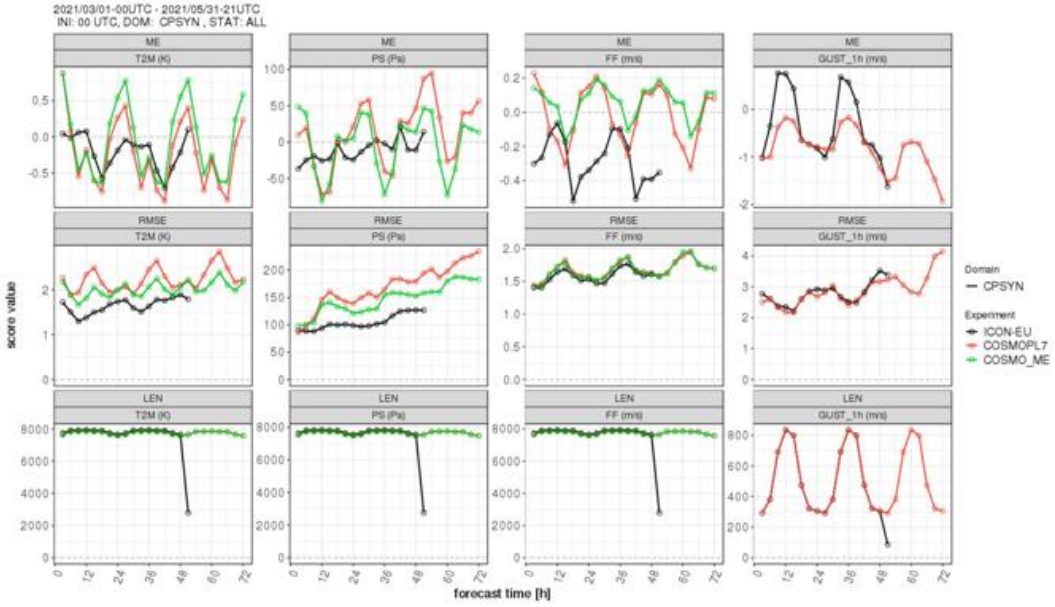

Figure 7: MAM2021 - ME (top), RMSE (middle) and number of observations (bottom) values for CA1; left to right: T2M, PS, FF and GUST (1h). ICON-EU (black) (black), COSMO-PL7 (red) and COSMO_ME (green).

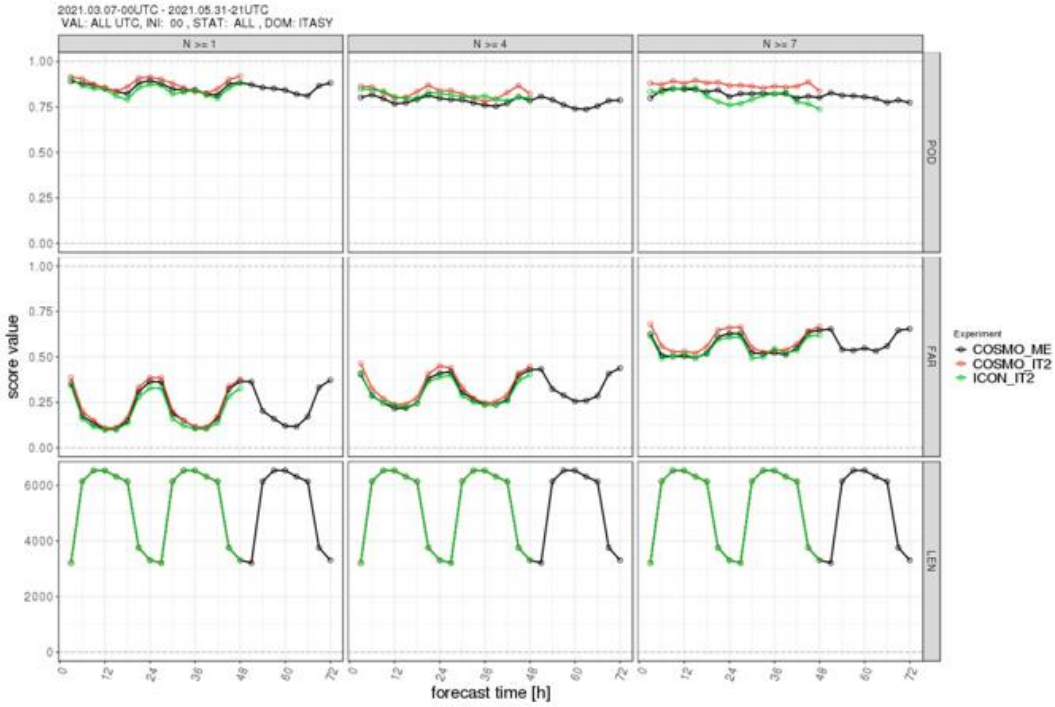

Figure 8: MAM2021 - Categorical scores for Cloud Cover: POD (top) and FAR (bottom) values from: COSMO_ME (black), COSMO_IT2 (red) and ICON_IT2 (green) for Italy national domain (all Italian stations); thresholds (left to right): $>= 1$, $>= 4$ *and* $>= 7$ (octa).

3.5 JJA2021: Ongoing Activities

Compared to the previous season, starting with JJA 2021, it was decided to employ a polygon description for the verification area instead of the previously used station lists. Also starting with the JJA2021 season, TEMP verification scores obtained with the MEC+Rfdbk verification system will be gradually included in the Common Plot activities. An example of the derived statistics obtained for upper air parameters is presented in Fig. 9.

For the JJA2021 season, FF are expected to be produced from the following models:

CA1: ICON-GLOBAL, ICON-EU, COSMO_ME, COSMOPL7
CA2: ICON-D2, ICONGR, ICON_IMS / ICON-IL2p5, ICON_IT2, ICONPL, COSMO_IT2, COSMO-CE-PL, COSMO-1E, COSMO-2E
National domains: All as CA1 and CA2, ICON-RO_2p8, COSMO-RO_2p8

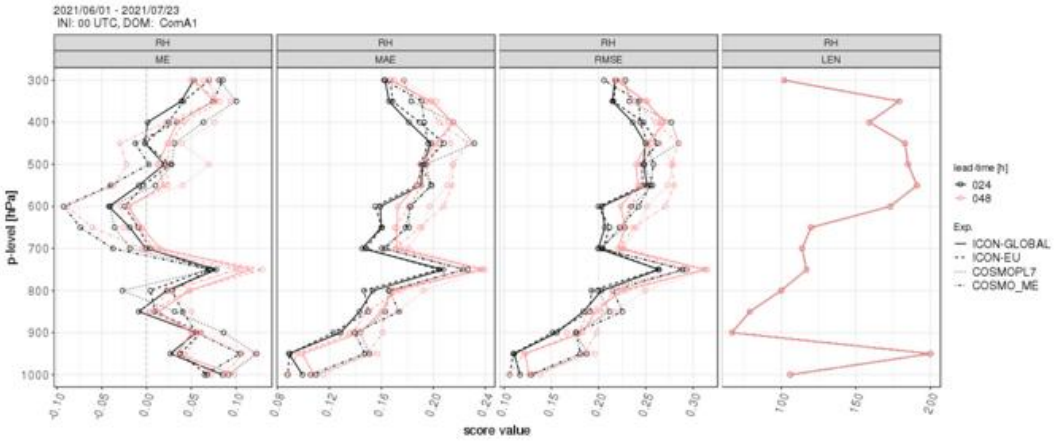

Figure 9: JJA2021 – Upper air relative humidity: ME, MAE, RMSE and LEN (left to right), values from: ICON-GLOBAL (continuous line), ICON-EU (dashed line), COSMOPL7 (dotted line) and COSMO_ME (dotted and dashed line), for +24 h (black) and 48 h (pink) lead time; scores computed for CA1.

4 Conclusions and Outlook

Following the finalization of the project, the MEC-Rfdbk system is implemented and runs operationally in IMGW-PIB, IMS, NMA, HNMS and COMET for various configurations of the ICON and COSMO models. As previously mentioned, the system was already in use before the start of the project in MCH (surface verification only) and DWD.

The following type of graphs can be produced with the MEC-Rfdbk system for Common Plot Activities:

- Categorical scores for Gust, RR_6h and N;
- Scores for continuous parameters;
- Scores for upper air parameters;
- Comparison between two models showing reduction in different scores.

All the remaining open issues that concern MEC-Rfdbk adaptation in some services and implementation of new features, will be performed through WG5 SPRT Common Plot activity.

Detailed documentation and templates for the use of the MEC-Rfdbk system are available for usage both for CP and national verification activities.

For more detailed presentations of the MEC-Rfdbk system and its components, including information regarding installation and use, documentation is available in the COSMO repository (PP CARMA Branch): http://cosmo-model.org/view/repository/wg5/PP-CARMA .

5 Meetings

- 20th COSMO General Meeting, Saint Petersburg (Russia), 3-7 September 2018
- ICCARUS 2019 (ICON/COSMO/CLM/ART USER SEMINAR), Offenbach, Germany, 18 – 22 March 2019
- COSMO-CARMA TRAINING for PST, Offenbach, Germany, 9 – 11 April 2019
- 21st COSMO General Meeting, Rome (Italy), 9-13 September 2019
- ICCARUS 2020 (ICON/COSMO/CLM/ART User Seminar), 2 – 6 March 2020 / PP CARMA web-meeting, 1st April 2020 (Minutes)
- 22nd COSMO General Meeting, 1-11 September 2020, teleconferences
- ICON/COSMO/CLM/ART User Seminar (ICCARUS) 2021, virtual seminar 8 – 19 March 2021 (Minutes)
- PP CARMA virtual discussion (PL and WG5c, 1st July 2021 (Minutes)
- 23rd COSMO General Meeting, 14-17 September 2021, teleconference

6 Documentation

The documentation for the installation and use of the MEC+Rfdbk verification system is available in the COSMO repository (PP CARMA Branch):

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

For any comments and questions, please contact the editor:

1 Introduction

The ICON model development originally was a joint effort between the Deutscher Wetterdienst (DWD, Offenbach) and the Max-Planck Institute for Meteorology (MPI, Hamburg) with the aim to get a common modeling framework for global weather forecast and climate simulations. Later on, the Deutsches Klimarechenzentrum (DKRZ, Hamburg) and the Karlsruhe Institute for Technology (KIT, Karlsruhe) joined this model development. ICON became operational as a global model for NWP at DWD at 20 January 2015.

Although being a global model, ICON (Zängl et al., 2015) should be able to do simulations on the regional scale, too, first by two-way nesting (at 21 July 2015, the ICON-EU nest replaced the former COSMO-EU at DWD), and later on as an externally coupled limited-area model. In consequence, currently and in the following years the COSMO-Consortium (Consortium for Small-Scale Modelling) also joins the ICON-model development and the member states will replace the regional model COSMO (www.cosmo-model.org) (Doms and Baldauf, 2018; Baldauf et al., 2011) by the limited-area setup of ICON during the next years. The same holds for the COSMO licensee countries.

To support and to supervise this migration process and to maintain quality assurance at the several weather services for the replacement of a regional-scale NWP model, a few priority projects have been defined in the COSMO consortium. The goal of the priority project 'Comparison of the dynamical cores of ICON and COSMO' (PP CDIC) is an objective as possible assessment of the dynamical cores of both models. It was carried out mainly during the two year period 2016-2017. The need for such a comparison stems from the fact that it is not a priori clear if the triangle grid of ICON and some properties of its dynamical core (e.g. there is no time-splitting between slow and fast processes in the pure non-hydrostatic Euler equations), although being beneficial on the global scale, will be beneficial on the small (or regional) scale, too.

Section 2 gives a brief overview and comparison of the main properties of the dynamical cores of ICON and COSMO. Their assessment is mainly done by the evaluation of several (idealized) test cases that are typical for limited area models. Physical parameterizations are switched off as much as possible. These idealized test cases and their comparison of ICON and COSMO are discussed in section 3. Strong scaling properties on massively parallel computers are presented in section 4.

2 Brief overview and comparison of the dynamical core formulations of ICON and COSMO

In this section, a brief comparison between the dynamical cores of COSMO and ICON is given, more details can be found in Doms and Baldauf (2018) and Zängl et al. (2015), respectively. The dynamical cores of both models are based on the compressible, non-hydrostatic Euler equations (this holds for the new COSMO-EULAG development (Kurowski et al., 2016; Ziemiański et al., 2021), too. However, in the following only the operationally used so-called 'Runge-Kutta-version' of COSMO is considered). For operational setups, both models use the shallow atmosphere approximation (together with the traditional approximation for some Coriolis and spherical metric terms in the advection).

The prognostic variables of COSMO are pressure p', temperature T' (both perturbations from a reference state) and the 3 spherical velocity components u, v, w. ICON uses density ρ, either density weighted virtual potential temperature $\rho\Theta_v$ or Exner pressure Π (the latter for

easier vertically implicit time integration), vertical velocity w and the triangle edge normal component of the horizontal velocity v_n as prognostic variables (of course u and v can be diagnosed from v_n for each triangle and vice versa). To increase numerical accuracy, ICON again uses the deviations from a reference state of the thermodynamic variables (ρ', $(\rho\Theta_v)'$, or Π') in the dynamical core.

A basic difference between ICON and COSMO lies in the horizontal grid and the related discretizations. COSMO uses a structured (i.e. a rotated lat-lon) grid, whereas ICON uses a triangular grid based on successive subdivision of the triangles of an icosahedron. Horizontal discretizations use a staggered C-grid and vertically a Lorenz-grid: scalar variables (like ρ, T, p, ...) are positioned in the cell center; in the center of a cuboid in COSMO and in the center of a prism in ICON (more precise: this center is determined as the circumcentre of a triangle). In contrast, each edge normal velocity component sits in the center of the edge face. In spite of this formal similarity in the staggering, though one can apply simple finite-difference formulas in the case of COSMO, the discretizations in ICON merely must be constructed via the integral theorems of Gauss and Stokes. However, the application of the Gauss theorem in the continuity equation (i.e. a finite-volume approach) allows exact mass conservation in ICON. This is not possible in COSMO, since ρ is not a prognostic variable there.

In particular for the advection of these 'dynamic' variables, COSMO can use higher order schemes (although one-dimensional, direction-split) in the horizontal direction due to the simple finite-difference approach. In the convection-permitting setups, usually a fifth order scheme (Wicker and Skamarock, 2002) is used. In contrast, ICON has to use again second order discretizations. However, this is at least consistent to the other second order discretizations.

Concerning the time integration of the Euler equations, both dynamical cores use the horizontally explicit, vertically implicit (HEVI) approach. This treats the fast vertically expanding sound and gravity waves in an implicit manner, to avoid too small time steps. However, COSMO uses a split-explicit scheme to treat the remaining horizontal directions: the fast waves (sound and gravity waves) are integrated with a small time step, whereas the slower advection terms are treated with a larger time step. Both processes are combined by so-called partial operator splitting, which couples these processes better than complete operator splitting (Skamarock and Klemp, 1992) and to achieve at least second order in time a 3-stage Runge-Kutta scheme is used. This approach was first developed for the WRF model by Wicker and Skamarock (2002), and its stability properties for COSMO have been proven in Baldauf (2010). In contrast, ICON avoids the split-explicit method but integrates both the fast waves and the advection of the above mentioned dynamic variables with the same small time step (Zängl et al., 2015). The motivation stems from the fact that in a global model with higher model tops, the maximum advection velocities are not so far away from sound velocity, therefore, a split-explicit approach is obviously less advantageous for a global model than for a pure limited-area model like COSMO. To achieve second order in time a two-time-level predictor-corrector scheme is applied.

Apart from these fundamental discretization approaches, each dynamical core needs more or less additional measures for stabilization. For the vertically implicit integration both dynamical cores use some off-centering in the coefficients weighting the previous and the actual time level. In COSMO, quasi-3D divergence damping is indispensable to stabilize the split-explicit approach. In contrast, divergence damping is not essential for stability in ICON (however, to calculate diffusion on the longer fast physics time step, a weak 3D and 2D divergence damping is used, too). On the other hand, ICON needs a mechanism to stabilize artificial modes that arise due to the C-grid discretization on triangles. Here, a higher order

velocity reconstruction solves the problem (Zängl et al., 2015). Furthermore, additional fourth order hyperdiffusion and Smagorinsky diffusion are applied in both models mainly to suppress non-linear instabilities. However, the detailed strength of these mechanisms may be differently implemented in both models.

Finally, although not directly part of the Euler solver, the tracer advection schemes should be compared. COSMO uses the second order Bott (1989) scheme for the transport of the water variables and turbulent kinetic energy (Förstner et al., 2006), and potentially also for other variables e.g. arising in the ART module. Although this scheme is mass-conserving, this property is unfortunately slightly weakened due to a mass-consistency fix, which is needed for a proper moisture treatment (see also the discussion in Baldauf (2019)). ICON uses the third order scheme by Miura (2007) for the transport of water vapour ρ_v, and the corresponding second order variant for the other tracers. This scheme is mass-conserving, too, for every single tracer. The additional mass-consistency does not destroy mass-conservation because ICON itself is already mass-conserving.

These whole bundles of different discretization strategies make it quite difficult to answer in advance which dynamical core is superior over the other. Only a comprehensive simulation study with several tests can try to assess and compare these approaches.

3 Idealized test cases

In this main section, several idealized test cases that are relevant for small-scale models are performed. During the last decades, a certain set of such standard test cases for the non-hydrostatic flow regime has been established in the community of dynamical core developers for atmospheric models. These include linear wave expansion, linear and nonlinear flows over mountains, and highly nonlinear falling or rising of bubbles to test the solver for the Euler equations. These tests are designed to indicate e.g. possible problems with the terrain-following coordinate or with well-balancing properties. Additionally, there exist several test cases for the pure tracer advection.

Since the focus of the project lies on the capability of limited-area modeling, all tests use flat domains (i.e. they are not defined on a sphere). Technically, mainly the use of the alternative torus grid generator (by Leonidas Linardakis) instead of the standard ICON grid generator is a new aspect. It allows the use of either single periodic BCs (in y-direction only) of of double periodic BCs (in both x- and y-direction). Most of the test cases use a 2D $x-z-$ vertical slice setup. To this purpose four (double) rows of triangles with periodicity in y-direction have been placed along the 'equator' (along the x-axis) of the torus grid (side remark: two (double) rows of triangles should be sufficient to achieve periodicity, but a few internal calculations of metric coefficients require a larger grid).

A comparison by idealized test cases seems to be a very objective evaluation method. Nevertheless, some ambiguities remain; some broader discussion about such an evaluation can be found in Theis and Baldauf (2019). In the case of ICON and COSMO especially the different horizontal grids (triangle and quadrilateral, respectively) complicates the comparison of accuracy and efficiency. Whereas in COSMO Δx, Δy and Δz are just given by the quadrilateral dimensions of each grid cell, we use here for ICON Δx as the length of those triangle edge that goes around the 'equator' of the torus grid. Note, that in contrast Zängl et al. (2015) define the ICON grid spacing as the square root of the average grid cell area $\Delta x_A = \sqrt{A}$. The difference is just $\sqrt{A} \approx 0.658 \Delta x$. In COSMO, the time step Δt means the advective time step, whereas the fast waves time step is a factor of 6 smaller. In ICON, Δt denotes the 'fast-physics' time step, whereas the dynamics time step is a factor of 5 smaller.

For most of the idealized tests the COSMO version 5.4b.1 from 18 July 2016 was used and for ICON a version around September 2016. At this time the ICON dynamical core was settled enough and didn't changed since then. Nearly all tests have been performed on the Cray XC40 (Broadwell) at DWD, with the exception of the Weisman, Klemp-Test of section 3.6 performed on the operational Linux cluster (Sandy Bridge) at IMGW.

3.1 Linear gravity and sound wave expansion

This test case considers the expansion of gravity and sound waves, which are generated by the small vertical oscillations of a weak warm bubble in a stably stratified atmosphere, possibly with a horizontal background flow of constant velocity. The whole configuration is limited to a 2D channel with the horizontal length L and the height $H = 10$ km. Consequently, the test exercises every term of the Euler equations (but with the exception of all terrain-following metric correction terms) together with the time integration scheme. This setup was originally proposed by Skamarock and Klemp (1994), who delivered an approximated analytic solution. Later on, the test was slightly modified by Baldauf and Brdar (2013), in particular by using an isothermal background atmosphere with constant T_0, with the goal to deliver an (apart from linearization) unapproximated analytic solution. With such an analytic solution convergence properties can be investigated.

The test is performed in two setups: a 'small scale' setup with channel length $L = 300$ km, where all Coriolis terms have been switched off, and a 'large scale' setup with $L = 6000$ km and with Coriolis terms. Both tests use a background temperature of $T_0 = 250$ K.

3.1.1 Small scale test

Fig. 1 demonstrates the expansion of the wave pattern after 30 min. for the variables $T - T_0$ and w. The bubble initially was set in $x = 100$ km, and the whole field is advected by a constant background velocity of 10 m/s to the right. The comparison with the analytic solution of Baldauf and Brdar (2013) (blue lines) shows a good agreement already for the coarse horizontal grid spacing of $\Delta x = 1000$ m and an even better one for the finer grid spacing $\Delta x = 250$ m.

This convergence behavior is further examined in a dedicated convergence study shown in Fig. 2, which compares the standard error measures L_1, L_2, and L_∞ of the simulation against the analytic solution. Simulations with grid spacings of $\Delta x = \Delta z = 2000, 1000, 500, 250, 125$ m have been performed. COSMO used time steps of $\Delta t = 10, 5, 2.5, 1.25, 0.625$ s, respectively, and ICON used $\Delta t = 6, 3, 1.5, 0.75, 0.375$ s, respectively. Both models converge in all measures and both variables $T - T_0$ and w, however the convergence rate of COSMO is clearly below second order for w, and nearly second order for T only for coarser resolutions. In contrast, ICON shows an almost perfect second order convergence. An explanation for the slightly reduced convergence of COSMO due to the split-explicit approach is given in Baldauf (2010) (as a side remark: the convergence rate of COSMO shown in Baldauf and Brdar (2013) is even smaller. The reason was, that the distance for the application of periodic BCs was unfortunately chosen slightly smaller than $L = 300$ km; this happened due to the special treatment of periodic BCs in COSMO).

One should mention, that the second order convergence of ICON is only achievable, if the off-centering parameters in the vertically implicit integration are set to zero (i.e. a purely centered Crank-Nicholson scheme). This is not possible in the combination with physical parameterizations due to stability problems.

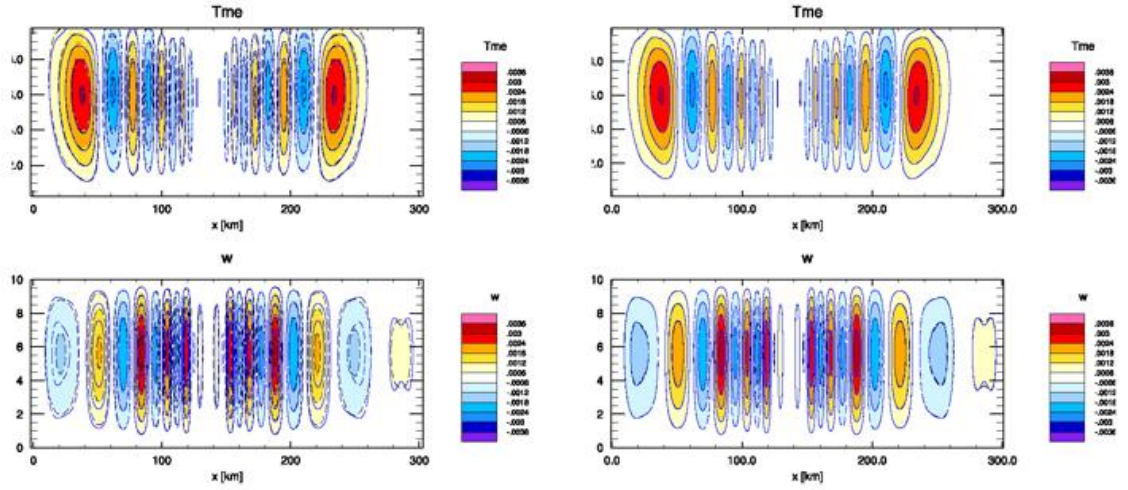

Figure 1: Linear gravity and sound wave expansion test. Small scale setup. COSMO simulation (colors and dashed, black, lines) after $t = 30$ min. Temperature deviation T' from background state (top) and vertical velocity w (bottom) for the grid spacing $\Delta x = \Delta z = 1000$ m (left) and $\Delta x = \Delta z = 250$ m (right). Analytic solution in blue lines.

3.1.2 Large scale test.

In the large scale test, the background velocity is set to zero; this is necessary for the proper comparison with the analytic solution in the case of a non-vanishing Coriolis force. Fig. 3 shows the wave pattern after 8 hours for the variables $T - T_0$ and w. In this large scale setup both models show a proper second oder convergence (Fig. 4), with slightly smaller errors for ICON (however, this also depends on a proper definition of grid spacing in ICON, see above).

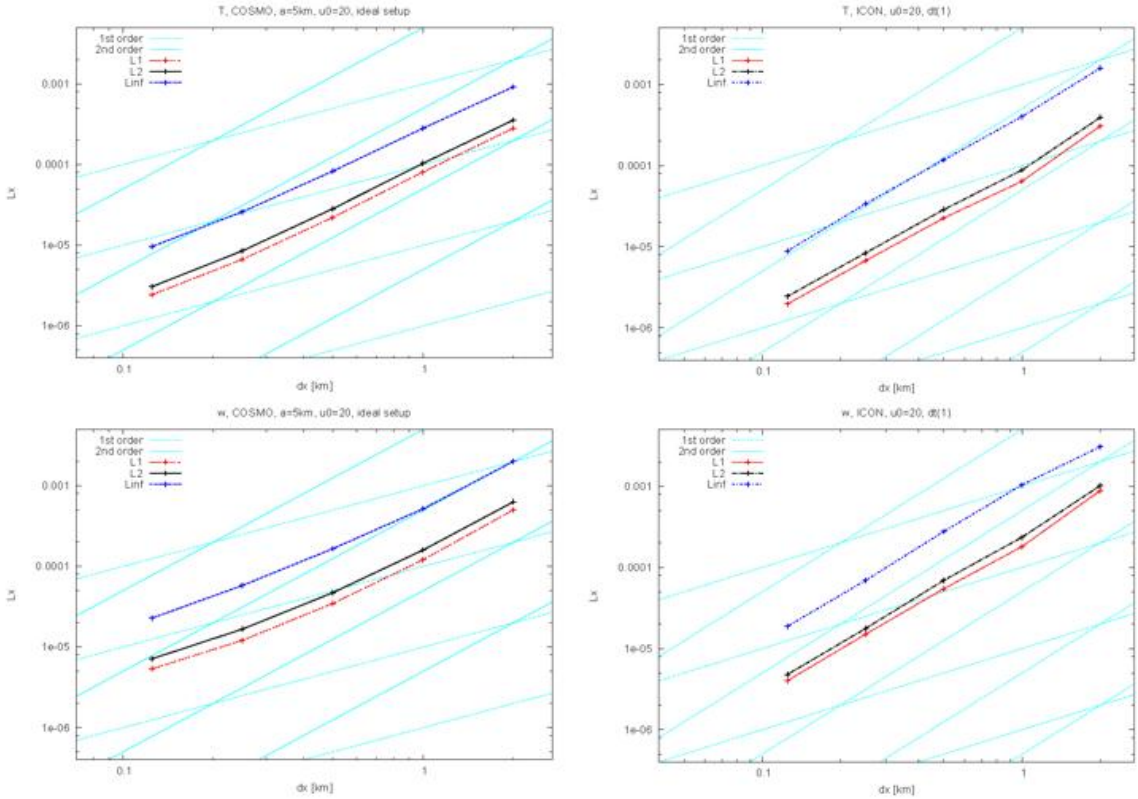

Figure 2: Linear gravity and sound wave expansion test. Small scale setup. Error measures L_1 , L_2 and L_∞ over the grid spacing for temperature deviation T' from background state (top) and vertical velocity w (bottom). Comparison between COSMO (left) and ICON (right).

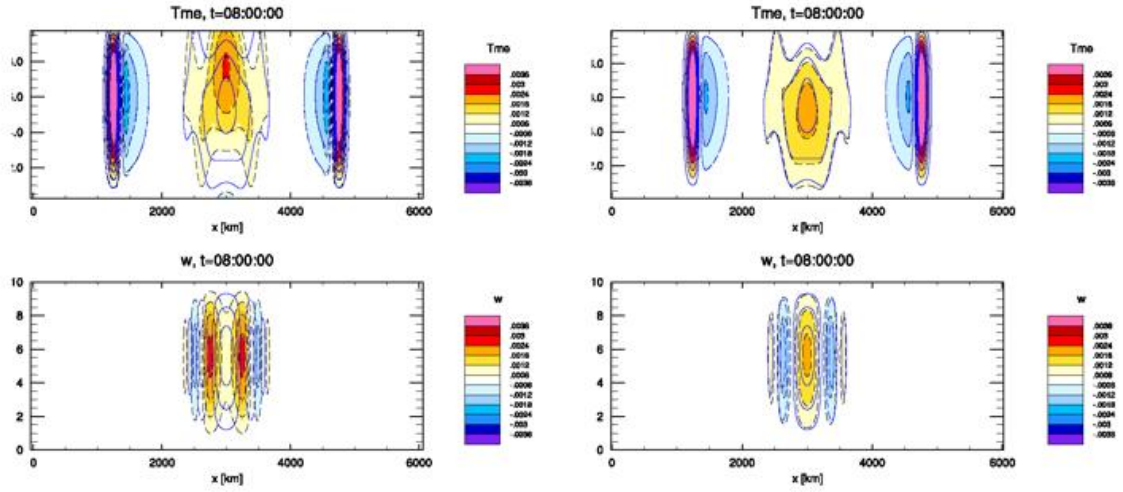

Figure 3: Linear gravity and sound wave expansion test. Large scale setup. COSMO simulation (colors and black, dashed lines) after $t = 8$ h. Temperature deviation T' from background state (top) and vertical velocity w (bottom) for the grid spacing $\Delta x = 20$ km (left) and $\Delta x = 5$ km (right), and $\Delta z = \Delta x/40$. Analytic solution in blue lines.

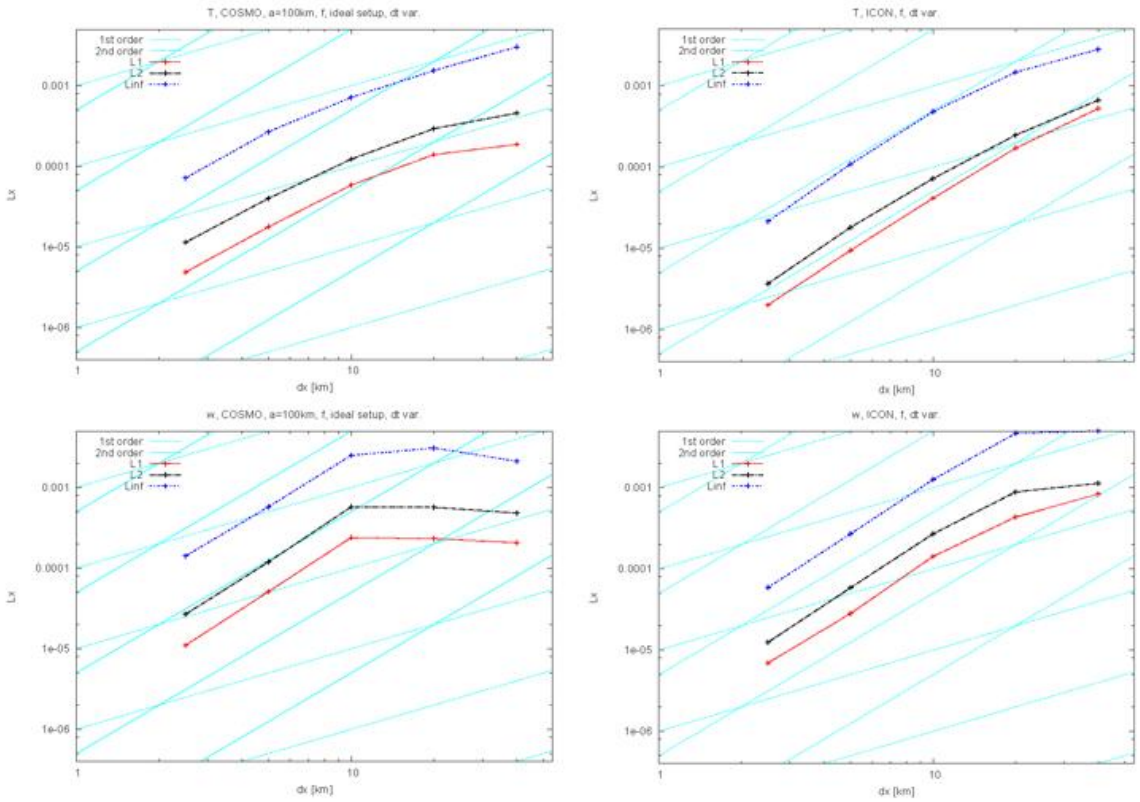

Figure 4: Linear gravity and sound wave expansion test. Large scale setup. Error measures L_1 , L_2 and L_∞ over the grid spacing for temperature deviation T' from background state (top) and vertical velocity w (bottom). Comparison between COSMO (left) and ICON (right).

3.2 Atmosphere at rest

This test consists of a single mountain of Gaussian shape with a maximum height of 1000 m and a half width of 5000 m analogous to Zängl et al. (2004). The atmosphere is at rest with a prescribed stratification with constant Brunt-Vaisala frequency of $N = 0.01$ 1/s and a temperature of $T = 288$ K at mean sea level. The other thermodynamic variables are in hydrostatic balance. Such a configuration should remain stationary for arbitrarily long times. However, at least for models that use terrain-following coordinates, a numerical imbalance between differently discretized terms will induce a flow after some time. Obviously, as smaller these disturbances are, as better the model formulation. In principle, this test cases inspects two properties of the model: first, the accuracy of the pressure gradient in vertical direction and along coordinate surfaces and its balance with the buoyancy term. Second, it tests the accuracy of the initial hydrostatic balance (a piecewise polytropic atmosphere was initialized and the new exponential reference atmosphere was used in both models). A further discussion about this test case can be found in Zängl et al. (2004).

Figure 5 demonstrates that ICON (bottom) induces much less disturbances than the standard setup of COSMO (top): COSMO induces vertical velocities w that reach about ± 4 m/s, whereas ICON induces maximum values of less than ± 1 m/s and spatially more limited to the vicinity of the mountain. Both models use the same vertical grid spacing, relatively close to operational settings ($\Delta z \approx 19.8$ m near the bottom until 780 m at the model top). After about 17 hours, the COSMO run broke. One can reduce the disturbances of COSMO and prevent the model crash by using third order implicit vertical advection. However, this version decouples the vertical advection process a bit more from the other dynamical processes and therefore was never used operationally.

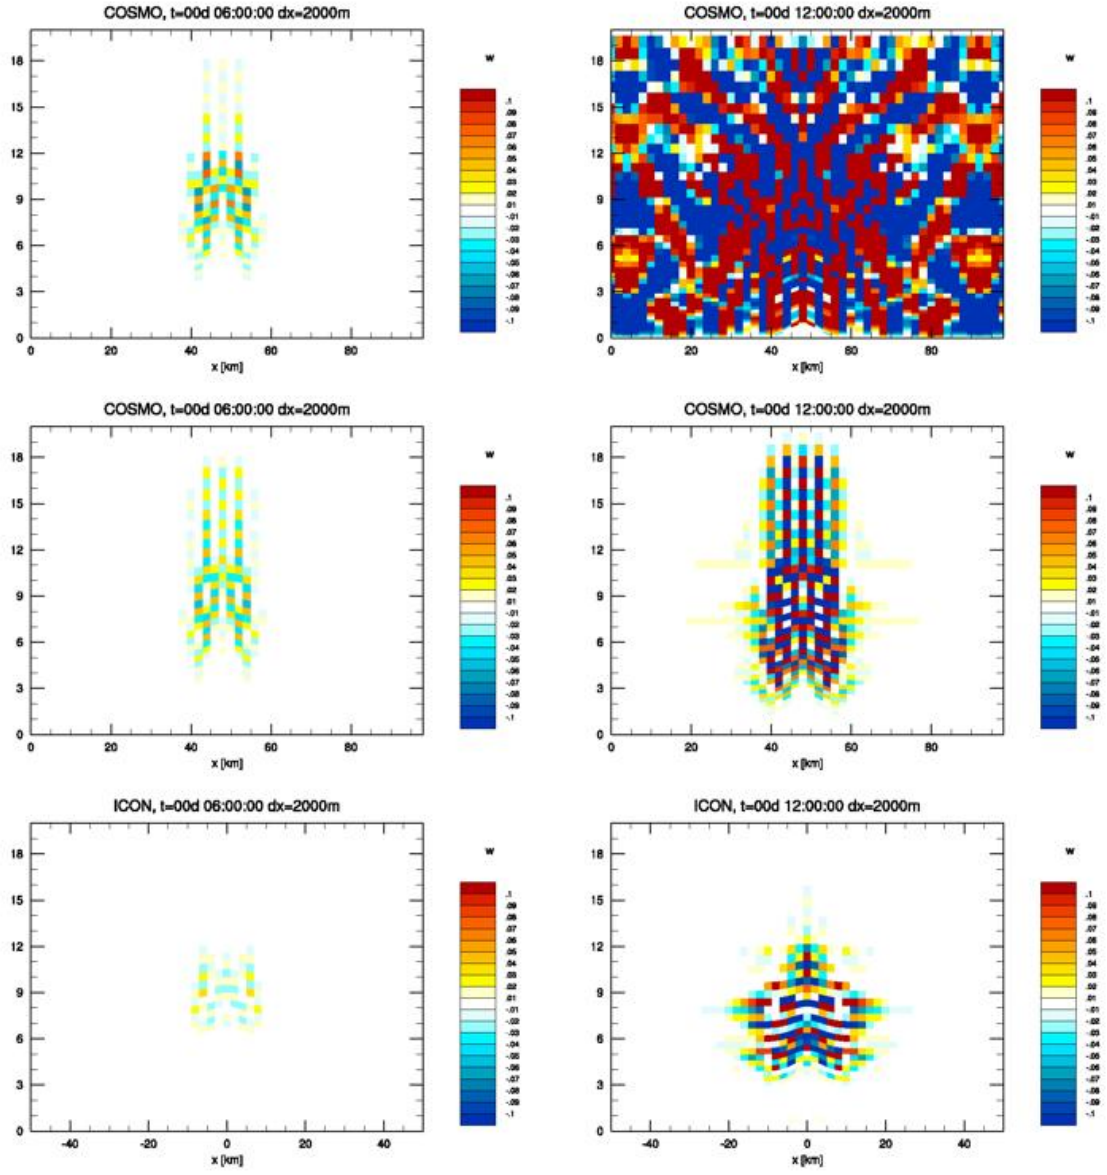

Figure 5: Atmosphere at rest. COSMO with operational setting (top), COSMO with third order vertical implicit advection (middle), and ICON (bottom). w after $t = 6$ h (left) and 12 h (right).

3.3 Linear flow over mountains

A further standard test case is the linear flow over flat mountains. Such a test investigates many of the spatial discretizations of a model including the metric terms of the terrain-following coordinate formulation. Their correct implementation and numerical behavior again can be assessed by the comparison with the linearized analytic solution, which is applicable due to the quasi-linearity of the setup. Here, the analytic solution of Baldauf (2008) is used, which is virtually identical to the slightly more approximated solution by Smith (1980).

The whole setup is adapted from Schär et al. (2002) (section 5b), which defines a series of mountains with the orography function

$$h(x) = H_0\, e^{-x^2/a_e^2}\, \cos^2 \pi \frac{x}{a_c}$$

with the two length scales $a_e = 5$ km and $a_c = 4$ km. The inflow velocity is $u_0 = 10$ m/s, the temperature is stably stratified with a constant Brunt-Vaisala frequency of $N = 0.01$ 1/s, and the surface temperature is $T_s = 288$ K.

3.3.1 2-dimensional flow

The vertical grid is chosen as equidistant. The maximum mountain height is $H_0 = 25$ m, which results in a vertical Froude-number of $Fr_H = u_0/(NH_0) = 40 \gg 1$. Therefore, this setup can be considered as linear in a good approximation. The horizontal Froude-number $Fr_a = u_0/(NL)$ lies in the range 0.1...0.5, i.e. in the range of almost hydrostatic to nearly non-hydrostatic flow over mountains. As can be seen in Fig. 6, both models reproduce the analytic solution quite well, perhaps with a minimal advantage for ICON. Note, that a proper convergence study is difficult due to the influence of the artificial damping layers and therefore was not performed (this problem does not exist in the test case of section 3.1). Beyond this, both models use different formulations: whereas COSMO uses a relaxation scheme towards the large scale values for all prognostic variables, ICON uses the damping layer formulation for w alone by Klemp et al. (2008). At least, a comparable damping height starting in about $z = 14$ km was used both in COSMO and ICON.

3.3.2 3-dimensional flow

The setup for the 3D flow uses a vertically stretched grid with a cell thickness of 24.7 m near the ground and 976 m at the model top. This vertical grid spacing and the background temperature profile is shown in Fig. 7. For the horizontal grid spacing the coarser value $\Delta x = 500$ m has been chosen for these 3D simulations. Now a circular symmetric Gaussian mountain $h(x, y) = H_0\ 2^{-(x^2+y^2)/a^2}$ is used with $H_0 = 1$ m (leading to $Fr_H = 2000$) and $a = 5$ km (leading to $Fr_a = 0.4$). The inflow velocity is $u_0 = 20$ m/s and the stratification again uses a constant $N = 0.01$ 1/s. The damping layers are chosen as for the 2D case, and Fig. 8 demonstrates that both damping layers behave relatively similar near the model top. Both models reproduce the analytic solution quite well (Fig. 9), now perhaps with a minimal advantage of COSMO. This demonstrated in particular that all metric correction terms are correctly implemented in both models.

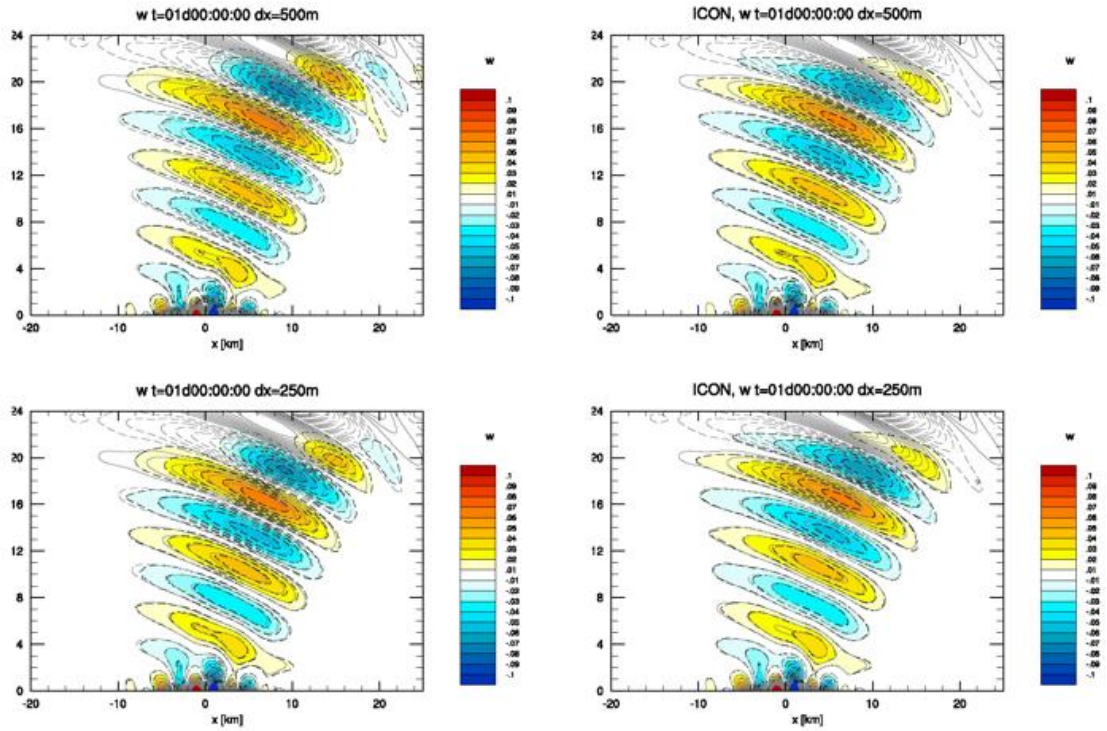

Figure 6: 2D linear flow over mountains. Vertical velocity w of COSMO (left) and ICON (right) for the two resolutions $dx = 500$ m (top) and $dx = 250$ m (bottom). Colors and dashed, black lines: simulation; grey lines: analytic solution.

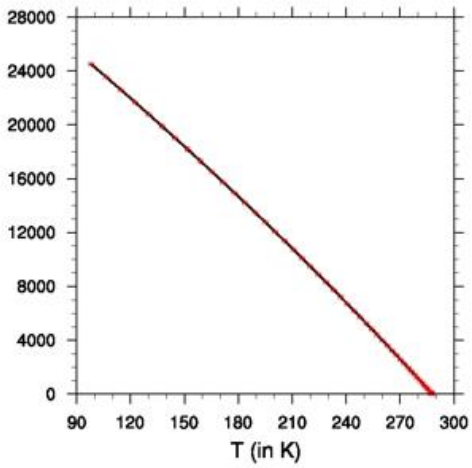

Figure 7: 3D linear flow over mountains. Initial temperature profile and vertical grid spacing (stars).

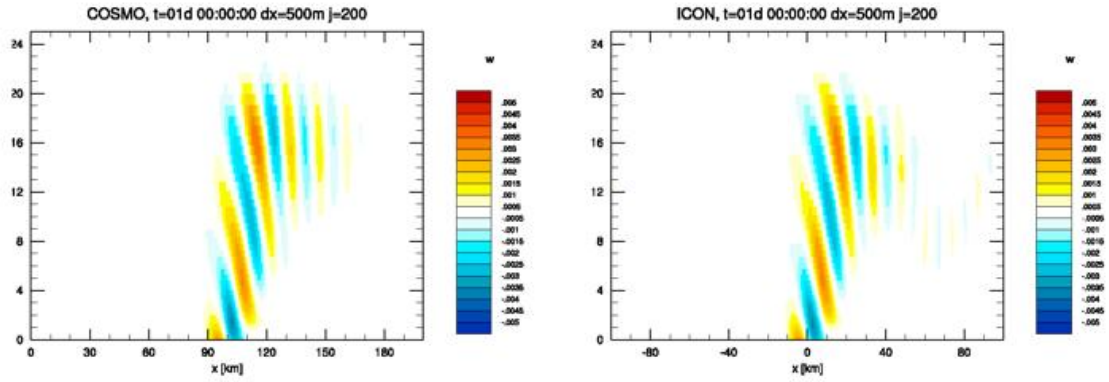

Figure 8: 3D linear flow over mountains. COSMO (left) and ICON (right). Vertical cross section of vertical velocity w through the symmetry axis.

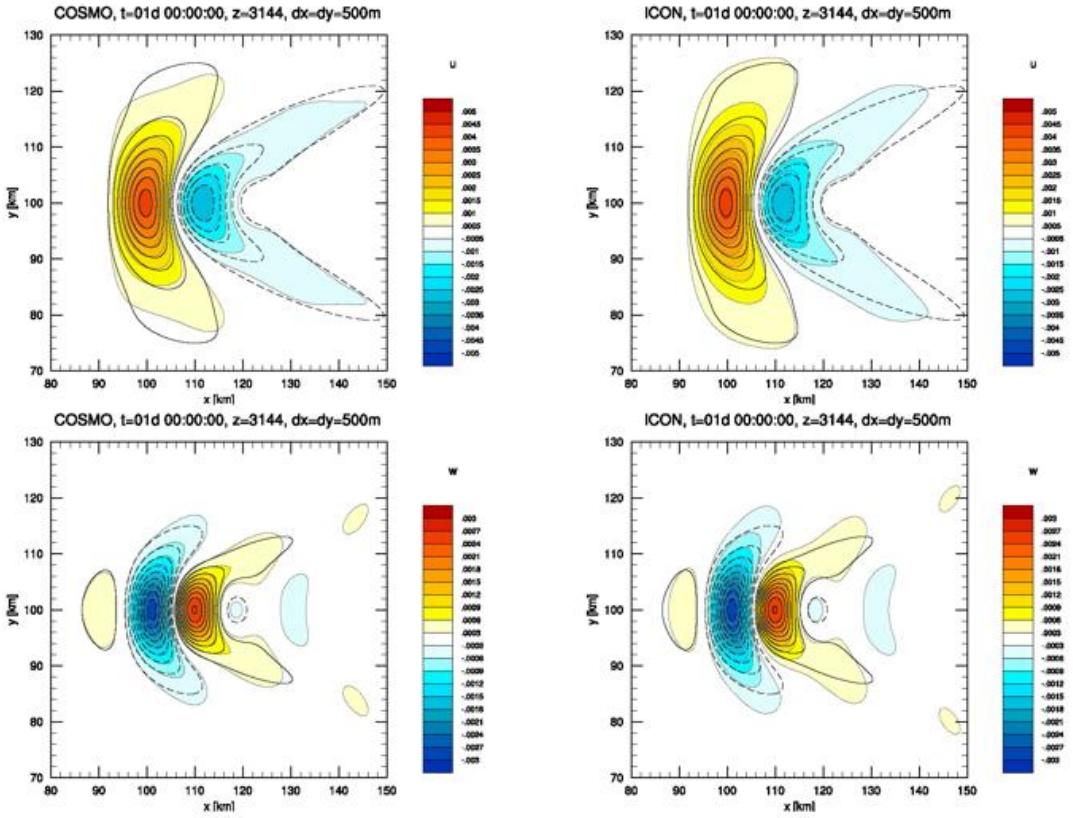

Figure 9: 3D linear flow over mountains. COSMO (left) and ICON (right). Horizontal cross sections of horizontal velocity u (top) and vertical velocity w (bottom) at height $z = 3144$ m above MSL. Colors and grey lines: simulations; black lines: analytic solution.

Table 1: Some characteristic values for the Gaussian mountain $h(x, y) = H_0\ 2^{-(x^2+y^2)/a^2}$ with $a = 3$ km in the 3D non-linear case: the maximum mountain height H_0, the maximum orography step max Δh between two neighboring grid cells, and the maximum slope angle max α.

H_0	max Δh	max α
1000 m	234.9 m	13.2°
3000 m	704.7 m	35.2°
4000 m	939.6 m	43.2°
4500 m	1057 m	46.8°
4700 m	1104 m	48.0°
5000 m	1174 m	49.6°
6000 m	1409 m	54.8°
7000 m	1644 m	58.9°
8000 m	1879 m	62.0°

3.4 Nonlinear flow over steep mountains

We use the same setup as for the linear 3D flow in section 3.3.2, with the exception that the Gaussian mountain is bit narrower ($a = 3$ km) and the mountain heights H_0 are much higher to reach the strongly non-linear regime with steep mountains. Furthermore, an even coarser horizontal grid spacing of $\Delta x = 1000$ m has been chosen to again increase the height step Δh between two neighboring grid points (the vertical grid stretching is the same as in section 3.3.2). Additional to the slope angle, Δh has a stability limiting influence, too. Table 1 gives some characteristic properties for these mountains and the setup. To prevent model breaks by unphysical gravity wave breaking, turbulent diffusion was switched on (each model uses its 'standard' turbulence scheme for this purpose).

Fig. 10 shows the comparison between COSMO and ICON for relatively moderate mountain heights up to $H_0 = 3000$ m. To keep the model domain small enough to perform larger series of tests, a periodic boundary condition has been chosen. Its effect is visible by the entrance of the mountain lee wave again on the left side of the domain. This might have a certain influence to the mountain inflow (e.g. some sort of blocking), however, these effects seem tolerable for this more qualitative study.

Fig. 11 shows the COSMO model for the maximum heights $H_0 = 4000$ m (in comparison with ICON), and 4500 and 4700 m. These COSMO simulations are only stable with the Mahrer discretization of the pressure gradient term (Baldauf, 2013).

Fig. 12 shows the ICON model for mountain heights H_0 between 5 km and 8 km; COSMO is no longer stable for such high values of H_0, whereas ICON tolerates very steep mountains. This very positive property is due to a modified version of the Mahrer discretization by Zängl (2012).

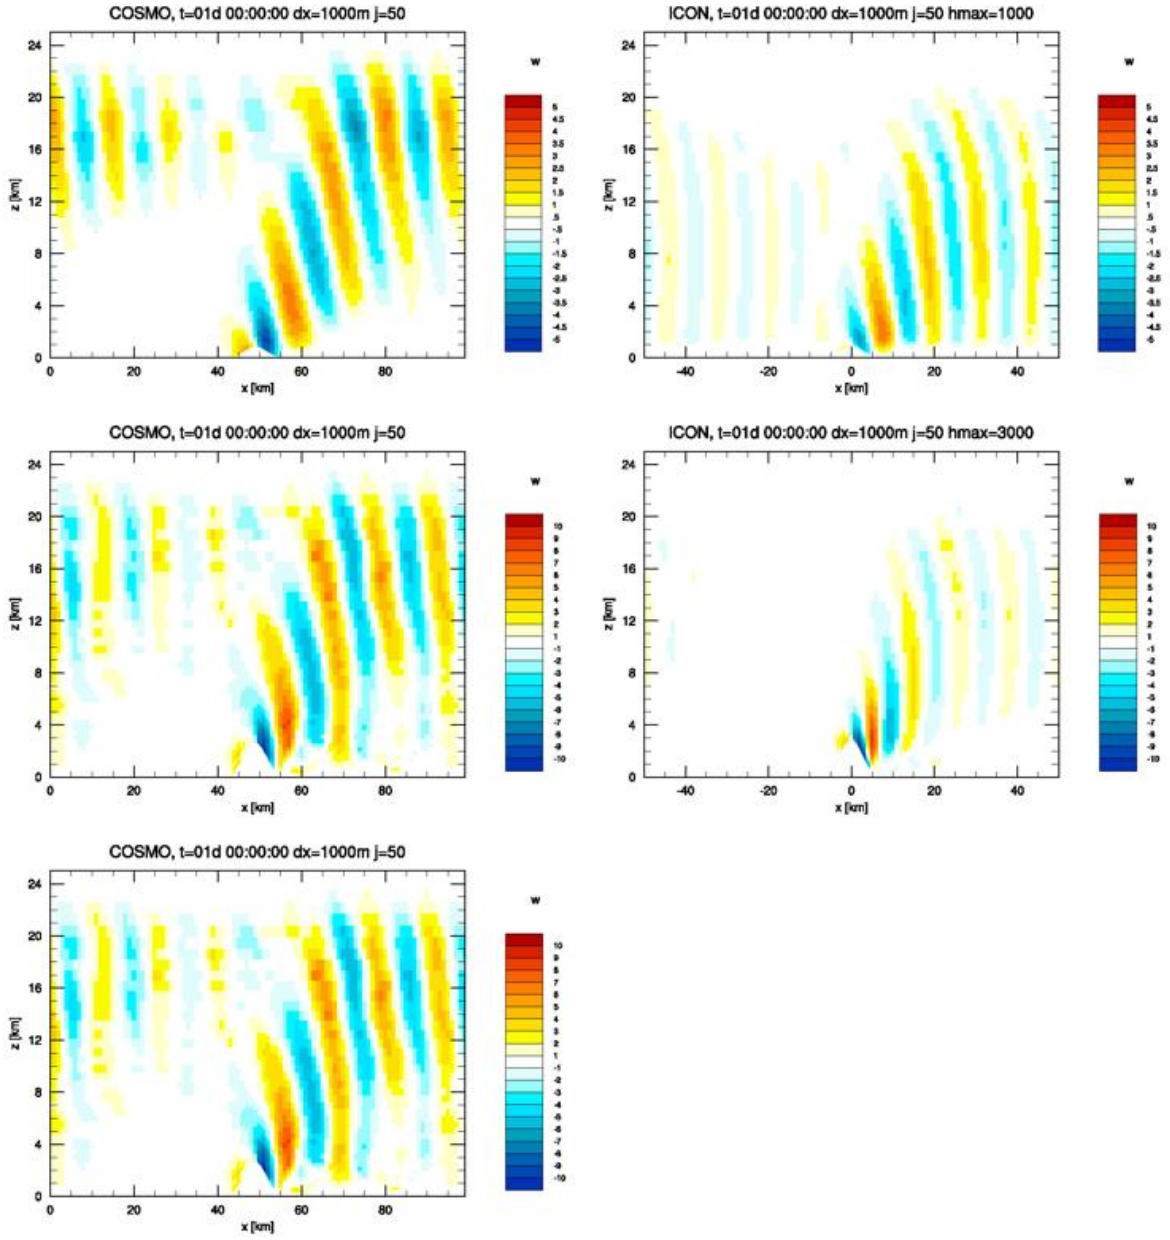

Figure 10: 3D flow over steep mountains. Cross section through the symmetry axis of COSMO (left) and ICON (right) for maximum mountain heights $H_0 = 1000$ (top) and $H_0 = 3000$ m. The bottom figure shows COSMO but with the alternative Mahrer-discretization in the fast waves solver.

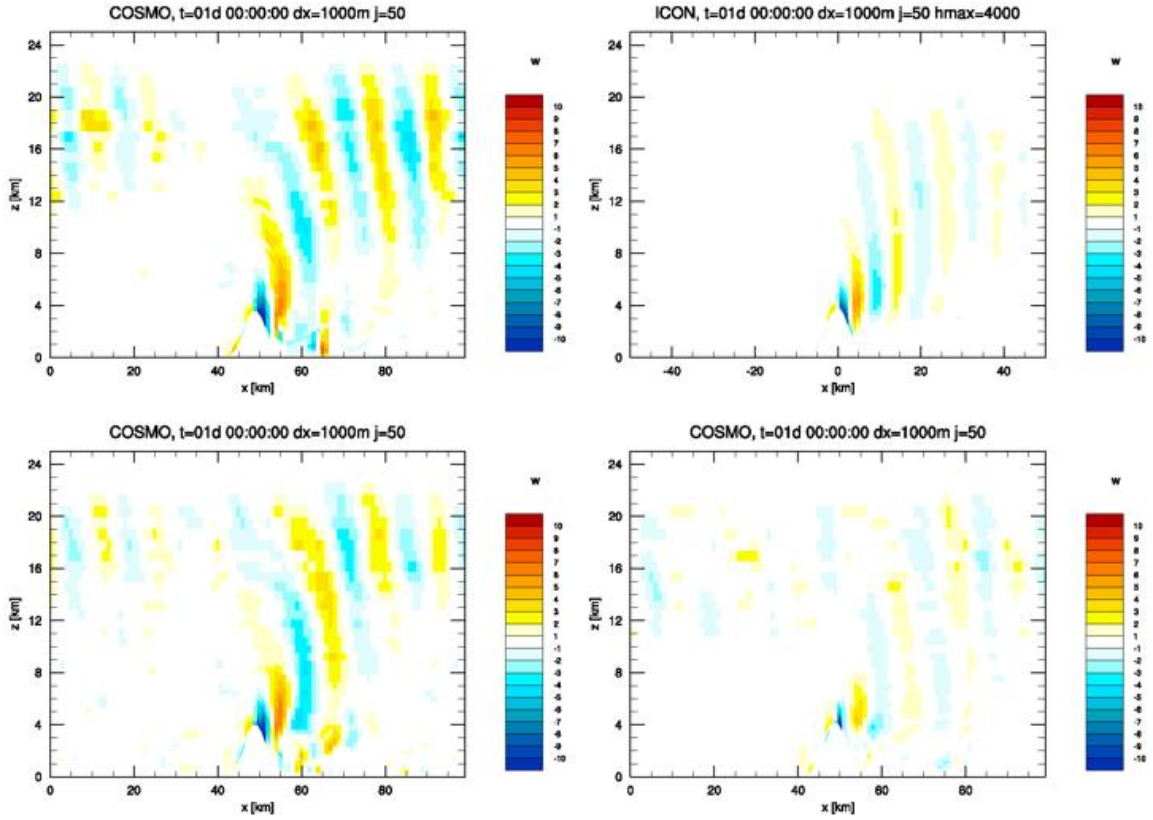

Figure 11: 3D flow over steep mountains, COSMO and ICON for maximum mountain heigh $H_0 = 4000$ (top row). COSMO for $H_0 = 4500, 4700$ m (bottom row).

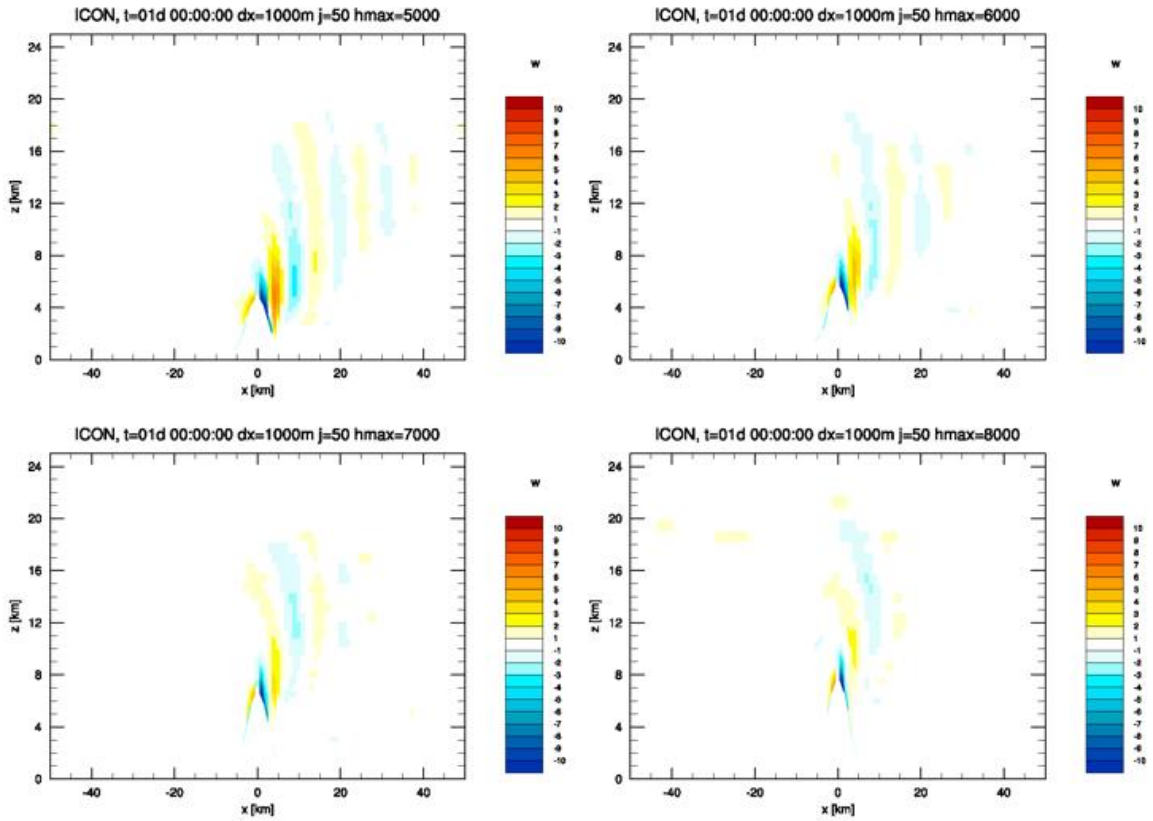

Figure 12: 3D flow over steep mountains with the ICON model for maximum mountain heights $H_0 = 5000$, 6000, 7000 and 8000 m (top, left to bottom, right).

3.5 Falling cold bubble

This highly non-linear test case is defined in Straka et al. (1993). A bubble that is up to 15 K colder than the neutrally stratified surrounding atmosphere is set 3 km above the ground in a 6.4 km high and 51.2 km wide 2D channel. This initial situation is shown in the left, upper panel in Fig. 13 (only a part of the right half of this horizontally symmetric setup is shown) The bubble falls down and after hitting the ground, bow fronts on both sides evolve. Due to a Kelvin-Helmholtz instability, several vortices are generated. To prevent the simulation to develop too fine-scale structures and to allow convergence, diffusion with a constant diffusion coefficient of $K = 75m^2/s$ is used both for heat and momentum. Coriolis force is switched off.

Fig. 13 shows the evolution of the potential temperature for the grid spacing $\Delta x = \Delta z = 25$ m with the COSMO model. For this fine resolution one can expect an almost converged solution; in fact the agreement with the reference solution given in Straka et al. (1993) (their Fig. 1) is very good (note that Fig. 13 and 14 use the same isolines as this reference figure).

Fig. 14 shows a comparison between COSMO and ICON for the different grid spacings $\Delta x = \Delta z = 200, 100, 50, 25$ m, where for COSMO time steps of $\Delta t = 2.0, 1.0, 0.5, 0.25$ sec. have been used, and for ICON $\Delta t = 1.44, 0.72, 0.36, 0.18$ sec., respectively. One easily recognizes the convergence of both models for finer resolutions. However, the final state of ICON (i.e. after 15 min.) is not exactly identical to the reference solution of Straka et al. (1993). (e.g. the second vortex overlaps the third one a bit more). Until now, the reason for this behavior is not yet clear. One only can speculate that the diffusion might work slightly different, but further investigation seems to be necessary.

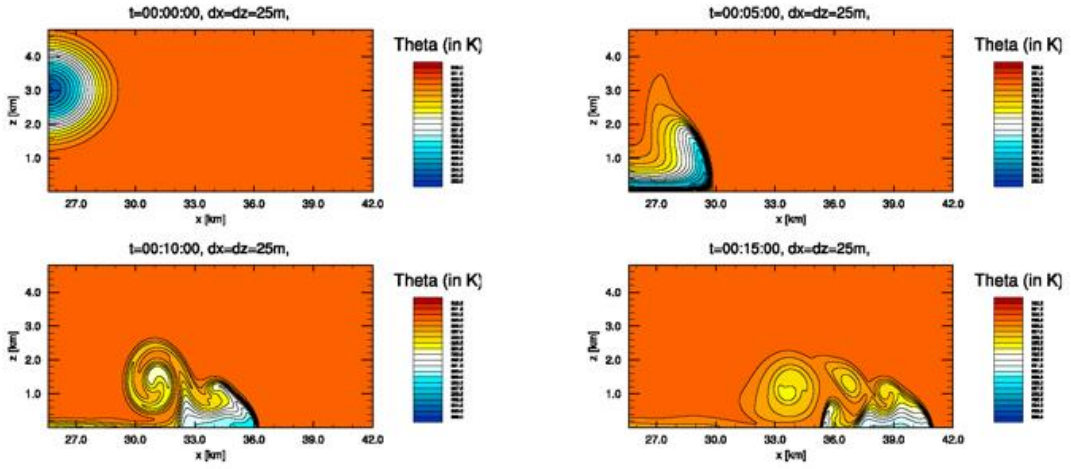

Figure 13: Falling cold bubble test. COSMO, $\Delta x = \Delta z = 25$ m, Θ after t=0, 5, 10, 15 min., `y_vert_adv_dyn='impl2'`. Only parts of the right half of the domain is shown.

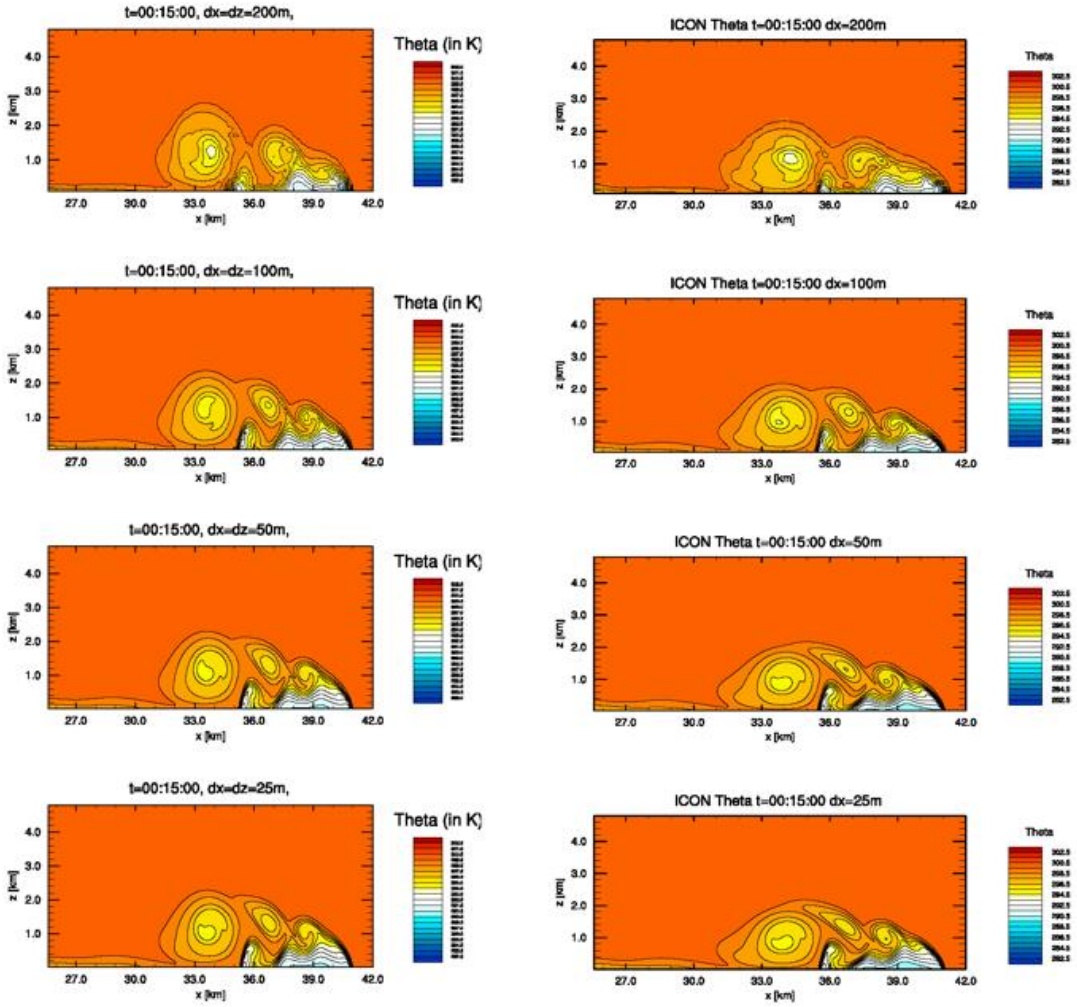

Figure 14: Falling cold bubble test. Θ after t=15 min., comparison between COSMO (left) and ICON (right) for different grid spacings $\Delta x = \Delta z = 200, 100, 50, 25$ m.

3.6 The Weisman and Klemp (1982) test case

This section reports results from the idealized moist deep convection test case of Weisman and Klemp (1982) carried out for the ICON model. The test requires from the model a capability to handle nonhydrostatic flows, triggered by latent heat release and rain water evaporation. The ICON model results are compared with references provided by the COSMO model (Baldauf et al., 2011) and Weisman and Klemp (1982) model. Symmetry of solutions allows limiting comparisons to the southern part of the computational domains.

3.6.1 Experimental setup

Definition of the environmental atmospheric profiles of potential temperature, moisture, and wind predominantly follows the setup of Weisman and Klemp (1982) (theirs Equations 1, 2, and 4). The qv_0 parameter of the moisture profile is set to 14 g/kg. Subsequent simulations differ by the environmental wind shear parameter U_S, while the other parameters are kept unchanged. A constant wind profile is added to the original environmental wind profile in the ICON simulations ($0.45 \cdot U_S$) to keep developing convective systems near the centre of the computational domain. Convection is initiated by an ellipsoidal thermal having the horizontal radius $r_h = 10$ km, vertical radius $r_v = 1.4$ km, and maximum temperature excess $+6°$C.

The computational domain of the ICON model utilizes a horizontally-unstructured grid equivalent to a cartesian 100 x 100 grid points periodic grid with the grid length equal 2 km. The vertically-structured grid has 90 levels, with stretching, and spans up to 40 km height above the surface. The sponge layer is between 25 km height and the top of domain. The simulations are carried out using a 3-category ice Kessler-like microphysical scheme, with snow, cloud ice, and graupel. The turbulence parameterization utilizes a TKE-based mixing scheme. The integration time is limited to 120 minutes. The Coriolis force is not included in the model equation set.

Configuration of the reference COSMO simulations is based on the ARTIFCTL module of Blahak (2015) and approximately follows the ICON model test case configuration. A few important differences are listed below:

- the horizontal grid of the COSMO model is structured,
- the original environmental wind profiles are used,
- the COSMO domain is elongated to 300 km in the X-direction,
- the vertically-structured grid has 74 levels between the surface and 25 km height, sponge layer starts at 15 km height, and levels are colocated with the ICON levels.

Data visualisation is based on the NCL environment[1]. The ICON native-output data were used for visualisation. Data regridding to the cartesian grid was carried out using tools the Earth System Modeling Framework[2] tools.

3.6.2 Results of simulations

Three types of experiments were performed with the wind shear parameters (U_S) equal 15, 25, and 35 m/s. A few principal convective phenomena are observed in each simulation: (i) formation of an updraft in result of the convection initiation, (ii) formation of rain shafts, (iii) subsequent formation of precipitation-driven downdrafts, and (iv) a cold pool growth at the surface. For example, all these phenomena are observed in the ICON $U_S = 15$ m/s simulation (Figure 15), as well as in the reference Weisman and Klemp (1982) (Figure 16) and COSMO (Figure 17) simulations.

Growth of 4 convective cells is observed in the low-shear ICON simulation ($U_S = 15$ m/s; Figure 15). Those cells live relatively short and feature relatively moderate vertical velocities and vorticity within the mid-tropospheric updrafts (Figure 15 and Figure 18, left). That suggests that those cells are likely not supercellular.

Convective cells that develop at the gust front in the ICON simulation with $U_S = 15$ m/s (e.g., cell II) tend to move slower than the gust front and are prone to decay once cut off from CAPE-rich air. A qualitatively similar solution is observed in Weisman and Klemp (1982) (Figure 16). A rather contrasting solution is observed in the COSMO simulation (Figure 17). In that simulation, a long-lived cell develops with a stronger updraft encompassing increased vertical vorticity (around 0.006 s^{-1} in the COSMO versus 0.004 s^{-1} in the ICON; Figure 19, left), and that cell sticks to the gust front.

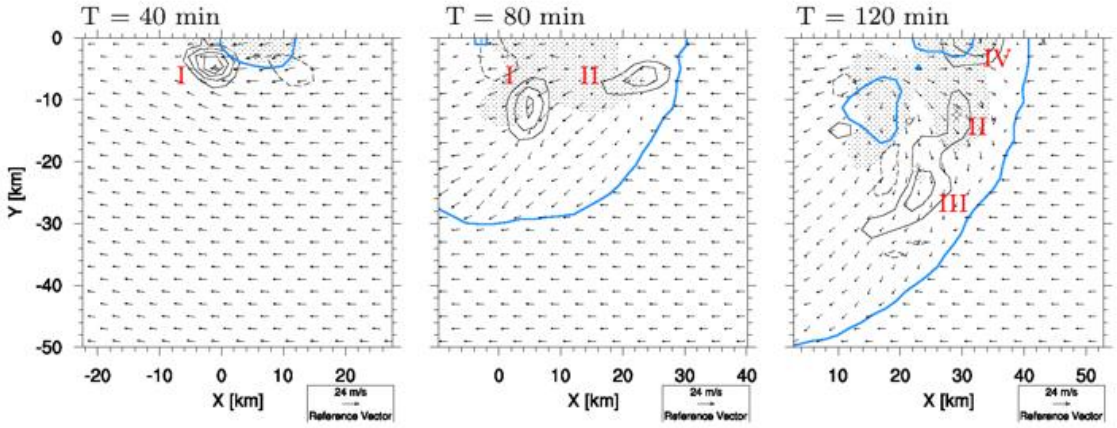

Figure 15: Convective cells and low-level flow field developing in the ICON simulation with $U_S = 15$ m/s. The arrows denote approximately storm-relative flow at 147 m height above the surface ($\overline{U} = 12$ m/s was subtracted from the flow field). The blue line denotes the meso-cold front position at 10 m height. The contours denote vertical wind speed at 4677 m height (contours shown for -8, -6, -4, -2, 5, 10, 15, 20, 25, 30 and 35 m/s; negative values dashed). The shading (hatching) denotes the rain water mixing ratio exceeding 1 g/kg (4 g/kg) at 10 m height. Individual convective cells are marked with the red roman numbers.

The ICON simulation with $U_S = 25$ m/s is shown in Figure 20. Here, two convective cells develop by 80 minute of simulation and subsequently merge around 120 minute. At least three differences arise in comparison to the previous ICON simulation. First, the mid-level vertical vorticity within the first cell (I) reaches around 0.008 s^{-1} (Figure 18, middle), that is, a value close to the threshold defining the mid-level supercellular mesocyclone (0.01 s^{-1}). Second, the cell I is long-lived and has a rather compact updraft. Finally, the cell I propagates around 36 km to the south after 120 minutes of simulation. Those observations suggest that the cell I represents to some extent the supercellular convection. A quite similar convective

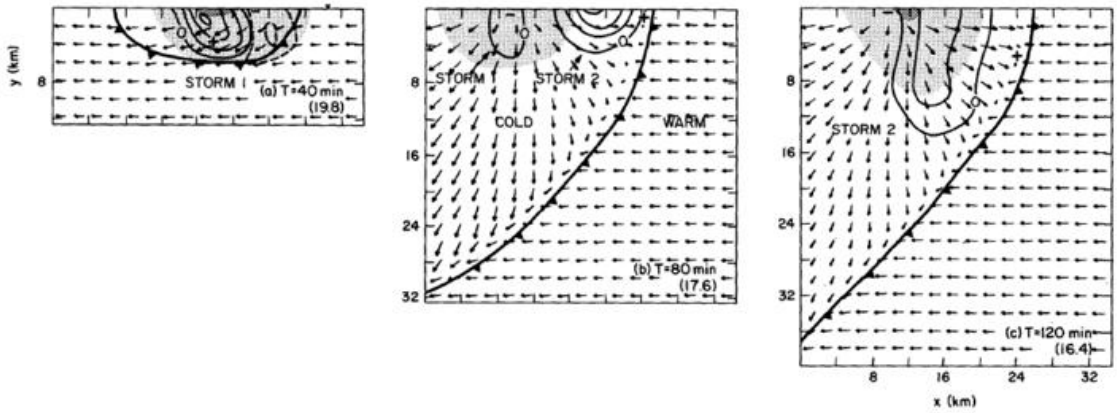

Figure 16: The reference Weisman and Klemp (1982) simulation for $U_S = 15$ m/s (theirs Figure 4).

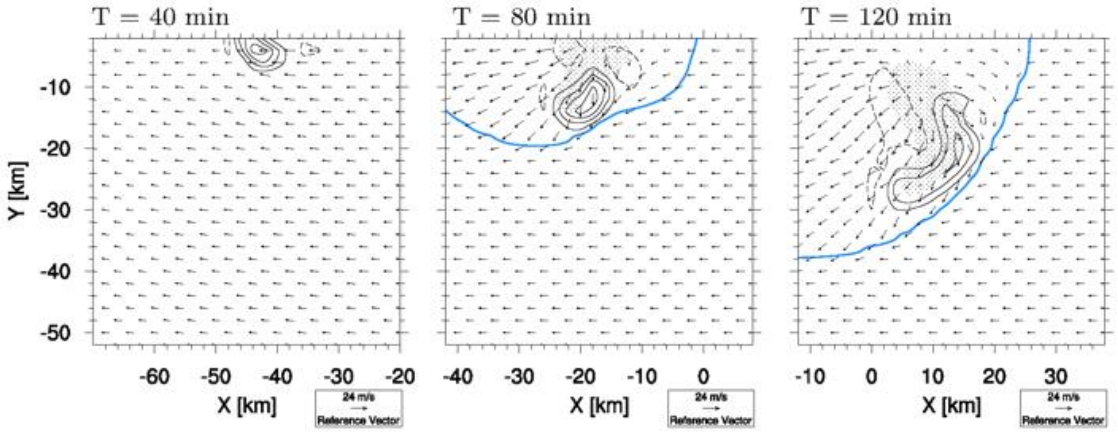

Figure 17: The reference COSMO simulation with $U_S = 15$ m/s, and $\overline{U} = 12$ m/s. Data is depicted as in Figure 15.

cell with the vertical vorticity of around 0.008 s^{-1} (Figure 19, middle) is observed in the COSMO simulation as well (Figure 21).

Figure 22 shows a convective cell developing in the ICON simulation with the strongest environmental wind shear ($U_S = 35$ m/s). At 80 minute, the maximum mid-level vertical vorticity of the cell exceeds 0.012 s^{-1} (Figure 18, right), a value in the range of supercellular mesocyclones. The cell moves to the right of the environmental winds and departs around 42 km to the south (120 minute), while remaining in proximity of the gust front. The updraft and precipitation shafts seem to be almost separated. Therefore, that cell likely represents the supercellular convection. The reference COSMO (Figure 23 and Figure 19, right) and Weisman and Klemp (1982) simulations (Figure 24) show development of quite similar supercellular storms. In those simulations, the maximum vertical vorticity is slightly weaker (around 0.008 s^{-1} and 0.01 s^{-1}, respectively).

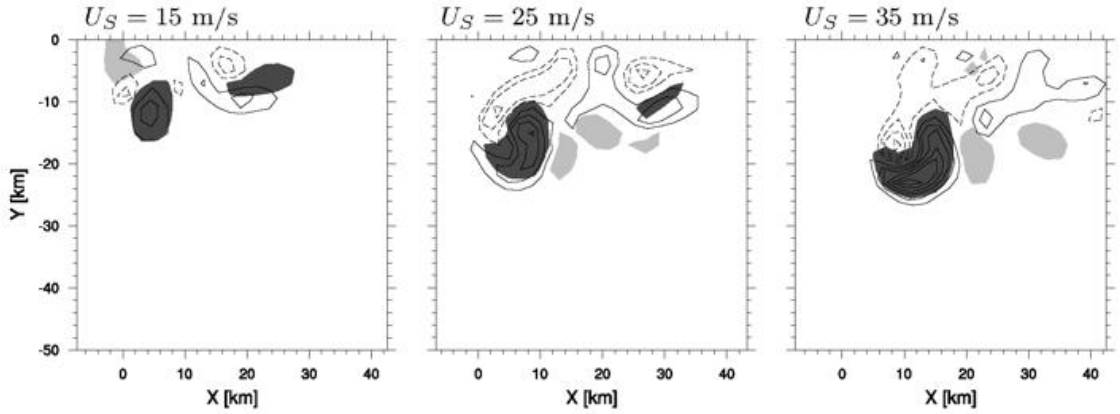

Figure 18: Vertical vorticity at 4677 m height (negative values dashed; contour interval 0.002 s^{-1}; the zero contour not shown) after 80 minutes of the ICON simulations. Light (dark) shading denotes vertical velocities lower than −2 m/s (larger than 5 m/s) at the same height.

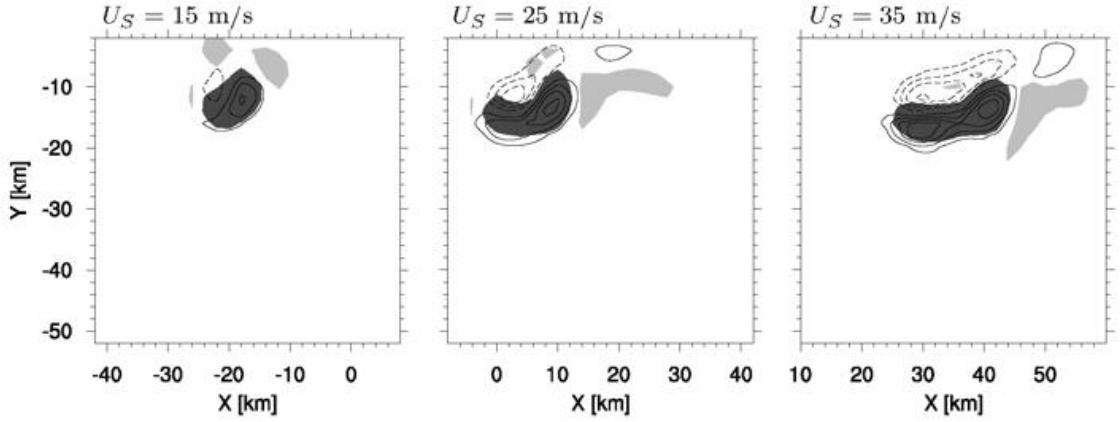

Figure 19: Vertical vorticity at 4677 m height (negative values dashed; contour interval 0.002 s^{-1}; the zero contour not shown) after 80 minutes of the COSMO simulations. Light (dark) shading denotes vertical velocities lower than −2 m/s (larger than 5 m/s) at the same height.

3.6.3 Summary

This experiment was intended to verify whether the nonhydrostatic ICON model is capable to simulate deep moist convective flows, and in particular the supercellular convection. Although the scope of analysis was limited, results indicate that this model consistently simulates convective flows in differently-sheared environments. The long-lived supercellular convection begins to develop in the moderate-shear environment and is further enhanced in the large-shear environment. When evolution of morphological flow features is concerned, convection observed in the ICON simulations is more similar to the one in the Weisman and Klemp (1982) simulations than in the COSMO simulation (especially for the low-shear experiment). The results do not indicate presence of any basic error in the coupling between the ICON nonhydrostatic dynamical core, saturation adjustment scheme, and parameterizations of the moist and turbulent processes.

4 Scalability aspects

In such a basic comparison between two models, computational efficiency of course also plays a big role. In general, one can say, that ICON runs definitely faster than COSMO on most platforms. In this section, we want to investigate in particular the scaling behaviour of both models for larger numbers of processors on massively parallel computers. Here we concentrate on the strong scaling properties, i.e. the reduction of wall-clock time by running on an increasing number of processors for *the same* simulation setup (i.e. same domain, same number of grid points, same time step, ...). The strong scaling property is important to assess how large a machine must be to tackle a given problem (by the way, strong scaling is a bit easier to investigate than weak scaling with different setups for different processor numbers). We have investigated only CPU based machines, more precise the experiments for both COSMO and ICON have been run on the Cray XC40 (Broadwell) of DWD (i.e. neither GPU based computers nor vector computers have been used).

It is important to mention a difference in the parallelization strategy: COSMO uses only distributed memory parallelization based on the MPI library, In contrast, ICON uses both distributed memory (with MPI) and shared memory parallelization (using openMP).

Fig. 25 shows the strong scaling behavior of COSMO for a COSMO-D2 setup: a simulation over 27 h covering the area of Germany and parts of the surrounding countries. The experiment was carried out with COSMO version 5.4d.4 from 29 May 2017. The strong scaling behavior of the dynamical core (green line) and the physical parameterizations (light blue line) is almost perfect (i.e. linear decrease of wall-cock time) up to about 1000 processors and is still satisfactory at least up to about 10000 processors. The bad scaling of the 'additional computations' is mostly due to the RTTOV library (remark: U. Schättler could cure this problem later on, so that the scaling of these computations now is also quite good). Both the input as also the output don't scale at all: wall-clock times even slightly increase with increasing number of processors.

Fig. 26 shows the analogous strong scaling behavior of ICON for an ICON-D2 setup: it is quite similar to the COSMO-D2 setup, it also runs over 27h and covers roughly the same domain (the output on the regular lat-lon grid is exactly the same horizontally, however the triangle grid covers a slightly larger area). The experiment was carried out with an ICON version from May 2017. As for COSMO, the scaling for the dynamical core and the parameterizations is perfect for up to about 1000 processors. Note that the absolute wall-clock time for the sum of dynamics and physics calculations is smaller than for COSMO. The scaling becomes worse for higher numbers of processors, which is mainly caused by the input of boundary data. Remark: this problem could be largely improved in the meanwhile, in particular by reducing latency by collecting all levels before communication. Moreover, it is worth to mention that ICON allows to optimize the use of the cache by the choice of the so-called `nproma` parameter, i.e. to adapt the length of data blocks to the size of the cache. However, in these tests the value of `nproma` was not changed.

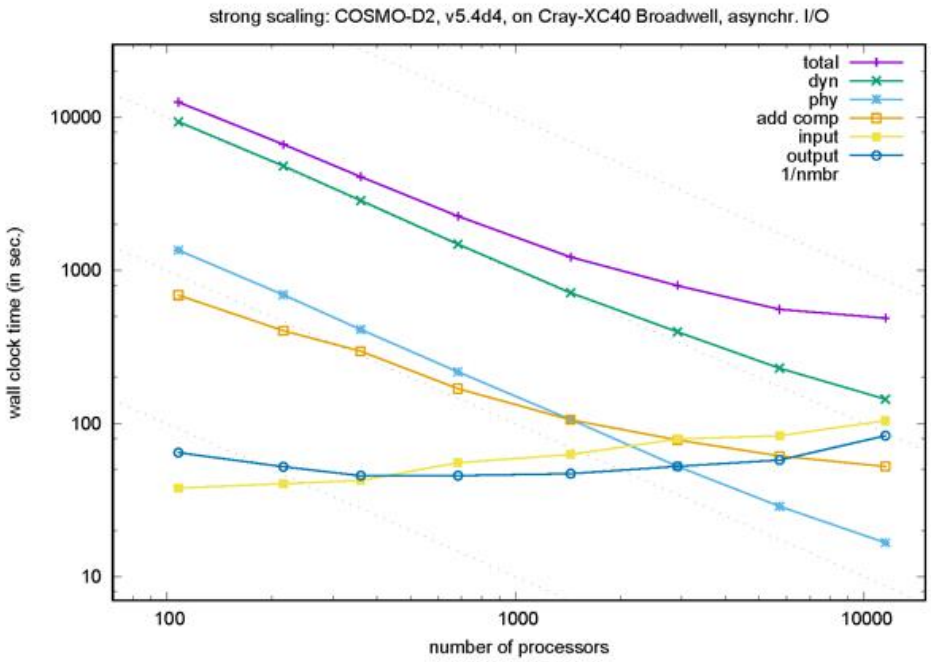

Figure 25: Strong scaling test for COSMO with a COSMO-D2 setup.

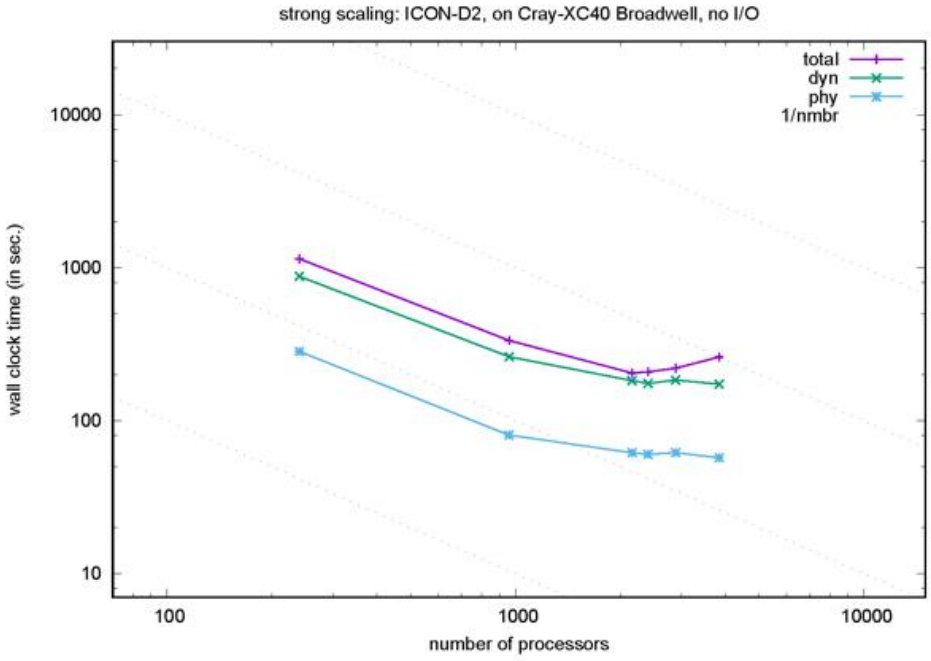

Figure 26: Strong scaling test for ICON with an ICON-D2 setup.

Table 2: List of requirements to the ICON model from climate modelers at DWD.

Issues	Status (around 2017)
Read in LBC Data from frame grid for ICON-LAM does not work yet with NCDF files.	Daniel Reinert and Günther Zängl were already informed.
After restarting, ICON still read the LBC data from the first month.	Already solved in new version.
ICON creates itself a symbolic link to the restart file.	This does not hurt. But just does not look nice and not necessary for us because we have different directories to store data and run the model. One can create the link by a run script and link to wherever
Need to decide a standard input data that iconremap can treat. All GCM data should be transformed to this format.	Task for CLM community.
Soil must be deep enough ($>$ 12 m) that the temperature at the bottom is constant throughout the year (should be the case in Terra).	Will be checked in our long simulation.
Less frequently updated SST.	(addendum: higher frequent updates are now implemented)

5 Application for special purposes (Climate, environmental appl.)

One task in the project was to identify possible obstacles for the use of ICON for other limited-area applications besides pure NWP. First, these are all kind of environmental simulations for several sort of pollutants like pollen, volcanic ash, and radioactive substances. Furthermore, the transport of aerosol or mineral dust in particular for the estimation of the mitigation of solar irradiation for renewable power generation is of interest. In the meanwhile the ART module is well established, so that the applicability of ICON for these purposes is out of question.

Another large application is regional climate simulation. During the project, mainly technical problems have been reported by the climate modelers listed in table 2 (reported by Christian Steger and Trang Van Pham (DWD)). These were mainly assessed as of minor priority, have already been solved in the meanwhile or probably can be solved with relatively low effort. In any case, no basic obstacle could be named for the application of ICON in this field.

6 Conclusions

To assess the ability of the dynamical core of ICON to be applicable for limited-area modeling and to possibly replace the COSMO model, a series of idealized test cases have been performed for both models. These test cases in particular are designed for small scale applications. It may be summarized that ICON delivers in most cases solutions that have similar or even slightly better quality (compared either to analytic solutions or at least to established reference solutions) as COSMO. The only exception is the Straka test case, where ICON delivers a slightly weaker solution; a fact that should be inspected further.

One main strength of ICON is its tolerance of much steeper mountains than COSMO without an additional orography smoothing. Furthermore, it is exactly mass-conserving both for the dry dynamical core and also for the tracers.

The scaling experiments show that ICON runs well on current parallel computers (at least CPU based ones) and its parallelization strategy and implementation is well suited for future massively parallel computers. In practical applications the wall-cock time of ICON is smaller than of COSMO. Remark: more recent results show also an efficient behavior of ICON on vector computers (here in particular on NEC SX Aurora). A GPU port, mainly done at MeteoSwiss, CSCS (Swiss National Supercomputing Centre) and at the DKRZ is widely advanced, too. This efficiency advantage of ICON towards COSMO should also be seen as an indicator, beyond this pure comparison of two particular models, that the split-explicit approach might be less superior to a pure 'single time step' approach than expected.

To summarize, from the viewpoint of the dynamical core, there is no visible obstacle for the replacement of the COSMO model by the ICON model.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction

In 2008, the COSMO steering committee (STC) established a new Priority Project named 'Conservative Dynamical Core' (CDC). The motivation for such a project stems from the fact that the three currently available dynamical cores of COSMO (called 'leapfrog', 'Runge-Kutta' and 'semi-implicit') don't have any conservation properties concerning the dynamical variables mass, energy or momentum. However, conservation of these variables is one of the fundamental guiding principles in the development of dynamical cores in many branches of fluid dynamics. The aim of the project was to investigate possible candidates for a new dynamical core with conservation properties (at least mass conservation) and to deliver prototypes that are already implemented into the COSMO model.

Considering the different proposed dynamical core formulations of the first draft project plan, the STC decided to concentrate the project on two branches: on the one hand to the EULAG model ('anelastic branch'), which is already well established in the fluid dynamics community, and on the other hand to the CONSOL solver ('compressible branch'), which stems from the aerodynamics community. EULAG is based on an anelastic approximation of the Euler equations. It uses a finite volume approach, which per se guarantees certain conservation properties. CONSOL is based on the compressible Euler equations and also uses a finite volume approach. Both solvers use implicit time integration methods: CONSOL for the whole dynamical core, EULAG at least for the fast, quasi-linear processes. This solution strategy in general helps in solving another issue which should be tackled by the project, namely to improve the ability of the dynamical core to be stable in steep terrain. This requirement is caused by the future applications of COSMO which will cover more and more horizontal resolutions of 1 km and less, where one can expect increasingly steeper slopes.

During the project, the properties of the two proposed solvers should be inspected. For this purpose, a 'decision tree' was defined at the beginning starting from a set of well accepted idealized tests until more complex semi-realistic tests which should be simulated by the prototypes.

Therefore, the first 2 papers (sections 2 and 3) deal with idealized tests consisting of stationary flow over mountains, expansion of linear gravity waves, strongly nonlinear and unstationary falling bubbles, and convection containing cloud microphysics, simulated with the EULAG model. The ability of the EULAG dynamical core to simulate meteorologically relevant flow fields is demonstrated in section 4. Finally the functionality of the COSMO-prototype with the implemented EULAG dynamical core is demonstrated with semi-realistic model setups in section 5.

Whereas the EULAG model has been used for some meteorological simulations before, this was not the case for CONSOL, for which a great challenge was the introduction of the buoyancy term into the existing pure hydrodynamical solver. Therefore, only a reduced test set could be inspected with this solver. Section 8 describes the solver and the idealized tests performed with it.

Apart from the pure dynamical core (the solver of the EULER equations), tracer advection is an important aspect of the numerics of a model, too. Section 6 investigates the basic advection scheme of EULAG, the MPDATA, for its usability as an alternative tracer transport scheme in COSMO.

The accompanying section 7 compares wave expansion properties of the several anelastic approximations with the compressible equations and the basic divergence damping mechanism used in the current COSMO dynamical core.

After a lifetime of about four years (end of 2012), the overall status of the project is an available prototype of COSMO-EULAG, ready for further testing in real case applications. Due to constraints in man power resources, the CONSOL solver couldn't achieve a similar stage. Therefore, the COSMO Science Management Committee and STC decided to finish the CDC project and to establish a folluw-up project, which concentrates on the 'COSMO-EULAG operationalization' (CELO).

2 Dry benchmark experiments with the anelastic EULAG model

Bogdan Rosa, Marcin J. Kurowski, Michał Z. Ziemiański

Institute of Meteorology and Water Management - National Research Institute, Poland

2.1 Introduction

This chapter describes results from dry idealized benchmark experiments performed with the anelastic model EULAG. The goal of the study is to test the feasibility of an anelastic approach for very high-resolution (kilometer and sub-kilometer) operational numerical weather prediction. The choice of tests draws on experiences with analogous problems Skamarock et al. (2004) and is based on widely accepted benchmark solutions. The experiments were performed in the framework of the COSMO Priority Project Conservative Dynamical Core.

The first experiment concerns the evolution of a two-dimensional density current induced by a large bubble of cold air descending to the ground Straka et al. (1993). The second experiment considers two interacting bubbles with different temperatures Robert (1993). Both problems are strongly non-linear and do not have analytical solutions. The third test examines the propagation of inertia-gravity waves in a periodic channel (Skamarock and Klemp, 1994) of different length. The last problem regards the evolution of gravity waves generated by a flow over a single Agnesi mountain (Bonaventura, 2000). Several flow regimes (linear / nonlinear hydrostatic and linear / nonlinear non-hydrostatic), are examined. The results are validated against the reference solutions obtained using compressible models.

2.2 Cold density current test

The simulations of a cold density current are based on a setup described in Straka et al. (1993). This experiment is one of the well-known benchmarks often employed for testing numerical models.

2.2.1 Experiment setup

As defined in Straka et al. (1993), the two-dimensional density current is initiated as a cold bubble of air that subsequently descends to the ground in a homogenous and isentropic atmosphere. After reaching the ground, the bubble spreads laterally and rotors induced by a Kelvin-Helmholtz instability form on its upper boundary. The basic set of parameters and configuration of the model are as in Straka et al. (1993). This involves constant potential temperature of the basic hydrostatic state $\theta_0 = 300$ K and diffusion coefficient $K = 75$ m^{2}s^{-1}. The appropriate environmental density profile is given by the Ogura-Philips formula Ogura and Phillips (1962). The bubble is located at the center of the model domain which extends from $x = -25.6$ km to $x = 25.6$ km. The vertical domain size is $z = 6.4$ km. In the original experiment Straka et al. (1993) the lateral boundary conditions were set as $u = w_x = p_x = \theta_x = 0$ and similarly the vertical ones, namely $w = u_z = p_z = \theta_z = 0$ Here, the lateral boundary conditions are periodic. A free-slip and rigid boundary conditions are imposed at the ground and at the top of the computational domain, respectively. The numerical calculations in Straka et al. (1993) exploit the symmetry of the problem about the vertical line $x = 0$, which is not the case for the current simulations.

2.2.2 Results

The study, following Straka et al. (1993), is focused on the first 15 minutes of the evolution of the density current. Time evolution of potential temperature field and a process of formation of the vortical structures is presented in Rosa et al. (2011). Because the problem is symmetric with respect to the vertical axis it is sufficient to visualize and analyze evolution in only half of the domain. The symmetry of the solution was monitored during the experiment but no significant deviations have been observed. In order to verify the grid-convergence of the EULAG solution, a set of experiments employing various spatial resolutions was performed. Four different spatial resolutions were used, with the grid distances of 200, 100, 50 and 25 m, the same in horizontal and vertical directions. The snapshots of the potential temperature field after 15 minutes of evolution, obtained with different grid resolutions are presented in Fig. 1.

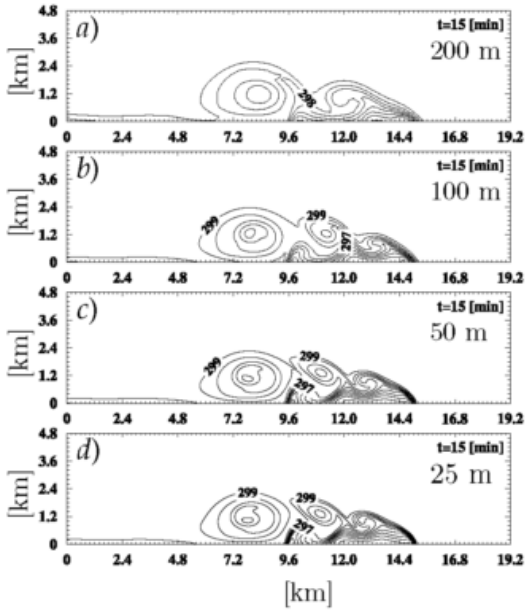

Figure 1: Plots of the potential temperature θ at 15 min for four different grid resolutions a) 200 m, b) 100 m, c) 50 m, d) 25 m computed using the EULAG model. Contour interval of the isentropes is 1 K.

It is seen, that there are no significant differences between potential temperature distribution obtained at resolutions between 25 m and 100 m. They all allow to identify the basic three-rotor structure of the flow, with a very small differences between the solutions obtained with 25 and 50 m resolutions. It shows that the EULAG simulation is grid-convergent and the simulation with the spatial resolution of 25 m can be regarded as the reference one, sufficiently resolving all scales of the flow, as is the case for the reference solution of Straka et al. (1993) employing also the grid size of 25 m.

Apparently, for the lowest grid resolution, applied (200 m), the flow is underresolved as after 15 minutes of the evolution only two well developed rotors are visible. This is similar to Straka et al. (1993) where 100 m spatial resolution was necessary to start capturing the three-rotor structure. On the other hand, solution provided by EULAG at 200 m has no numerical noise on the contrary to respective solution from Straka et al. (1993). Such robustness of the model is advantageous in NWP applications, where underresolved flow structures are unavoidable.

The quantitative comparison of the results of the EULAG simulation with the reference results from Straka et al. (1993) are presented in Table 1. They concern extreme values of

Table 1: Comparison of maxima and minima of p'-pressure perturbation, θ'-potential temperature perturbation, u-horizontal component of velocity and w-vertical component of velocity at 900 s for EULAG and Straka et al. (1993): REFC - the compressible model using unstaggered grid (resolution 25 m), REFS - the compressible model using a staggered grid (resolution 25 m), REFQ - the quasi-compressible model with unstaggered grid (resolution 25 m), for EULAG the grid size employed is shown. In the last row, location of the density current front (the $\theta' = -1^oC$ contour) from the EULAG simulations performed at four different grid resolution is given. REFC, REFS and REFQ values taken from Straka et al. (1993).

pressure perturbation, potential temperature perturbation and both components of velocity, after 15 minutes of the flow evolution. The names of the reference models presented in the current paper are consistent with the original notation used in Straka et al. (1993). The reference model simulations from Straka et al. (1993) are: compressible with unstaggered grid (REFC), compressible with staggered C-grid (REFS) and quasi-compressible with unstaggered grid (REFQ), each operating at 25 m resolution. EULAG results are presented for grid size ranging from 200 m to 25 m.

For most of the parameters, the EULAG simulation with 25 m resolution gives their values inside the interval defined by the values obtained with the reference compressible simulations employing staggered or unstaggered grid (it concerns minimum pressure perturbation (p), minimum and maximum wind (u), maximum vertical velocity (w); minimum (w) differs from the reference value from Straka by 0.01 m/s). The difference of the maximum potential temperature perturbation between EULAG and the reference compressible model from Straka et al. (1993) Straka is very small (in the range of 2%). The largest difference between compressible and EULAG solution concerns the maximum pressure perturbation being in the range of 1.2 hPa. To some degree it can result from the anelastic approximation of EULAG. On the other hand, the difference between the staggered and unstaggered compressible simulation reaches about 0.4 hPa.

Another quantitative analysis of model accuracy is based on comparison of the location of a cold front perturbation (after 15 minutes evolution of the current). A front location is defined as the place near the edge of the current where the perturbation potential temperature at the ground reaches 1 K. It is represented by the value of the x-coordinate at the location. In Fig. 2a, a front location from EULAG simulations are compared with the results of Straka et al. Straka et al. (1993). The reference data are taken from Table IV of Straka et al. (1993) and concern the simulations performed with the resolution of 200 m, except the results of fully compressible and quasi-compressible models REFC25, REFQ25,

computed with the grid size of 25 m. The EULAG results are presented for four different grid resolutions and are labeled as follows: 200 m – EULAG200, 100 m – EULAG100, 50 m – EULAG50 and 25 m – EULAG25. Additionally, the extreme values of potential temperature perturbation are plotted in Figs. 2b and 2c, for its minimum and maximum values, respectively. The differences between the solutions of different models, illustrated in Fig. 2,

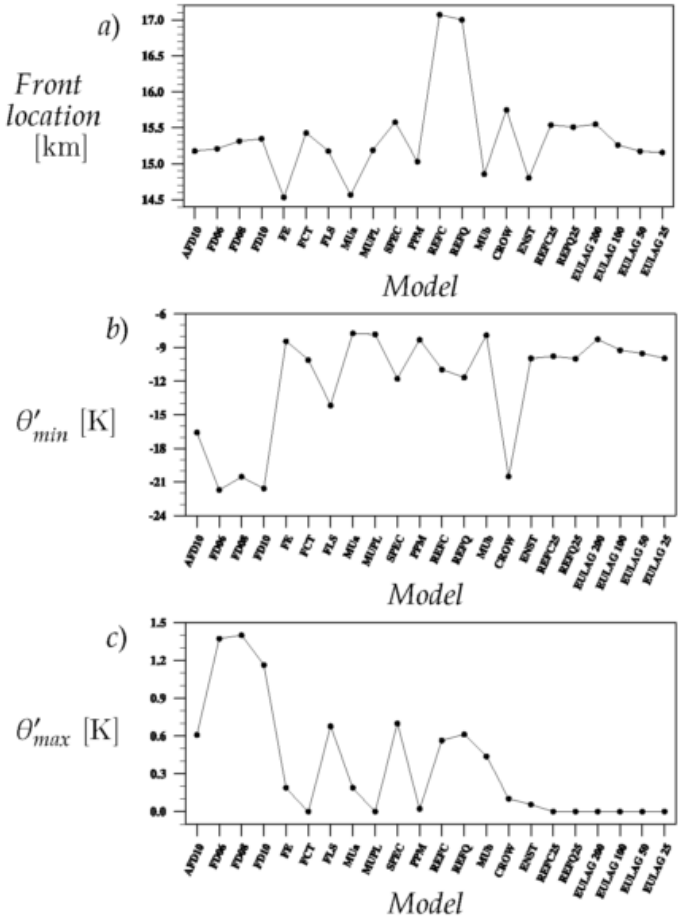

Figure 2: Quantitative comparison of front location and extreme values of potential temperature perturbation at t =15 min. Names of the models corresponds to acronyms used by Straka et al. (1993).

result both from differences in their analytical formulations and in their numerical design. However, analysis of Fig. 2a, showing the cold front location, leads to a general conclusion, that the differences resulting from analytical formulations of the models (compressible, anelastic, quasi-compressible) influence the solutions much less than the differences in the numerical schemes, employed. Note, that the majority of the models calculated with 200 m resolution (of all three analytical types, considered, including EULAG) give similar results in the range 14.5 km to 15.5 km, while the two outliers (giving very similar results of about 17.0 km) result from analytically differing compressible and quasi-compressible models. The detailed comparison of the simulations employing 200 m resolution with the reference, grid-convergent solution REFC25 (employing 25 m resolution and representing the 'true' value of about 15.5 km), confirms the above. Front positions similar to the reference one were achieved by both compressible (FCT) and anelastic models (both SPEC and EULAG). On the other hand, the results of the compressible model REFC and of the quasi-compressible model REFQ, calculated with 200 m resolution, differ significantly from the reference result. For both models, a relatively large error was a result of the under-resolving setup. This is not

the case for EULAG, as the difference between the solutions obtained with the 200 m and 25 m resolutions is relatively small. It shows reliable numerical properties of the model and confirms a grid-convergence of the solution that is very close to the reference compressible result.

The analysis of Fig. 2b, showing the minimum potential temperature perturbation after 15 minutes of evolution, leads to a similar conclusion. The majority of models using different analytical formulations give similar results being in the range of -14 K to -8 K (in a general agreement with the reference solution of -9.77 K). There are also outliers, resulting from quasi-compressible models, with much smaller values of the parameter. However, as not all quasi-compressible models are outliers, such a difference is a consequence of the numerics rather than of the analytical formulation. It is worth noting, also, that the outliers give reasonably good solutions for the front locations. This shows that the model comparison should not be limited to a single parameter only. Concerning EULAG simulations we observe both a good agreement with the reference solution from Straka et al. (1993) (-9.96 K for EULAG) and a grid-convergence to the EULAG reference solution employing 25 m grid size (see Tab. 1).

The analysis of Fig. 2c, showing the maximum potential temperature perturbation, allows for another quantitative comparison of the models. For this parameter the correct solution is known, as due to the adiabaticity of the process the actual value of the parameter is zero. Note, that the majority of the simulations performed with 200 m resolution gives incorrect results, including the compressible REFC model. However, as discussed above, these models give basically credible results for the front location and minimum θ'. The maximum potential temperature perturbation was correctly reproduced only by EULAG (anelastic), FCT (compressible), MUPL (quasi-compressible high-order accurate) and PPM (compressible high-order accurate).

The above analysis leads to the conclusion that for the problem at hand, the analytical formulation of the model equations does not have a significant impact on the simulation results, on the contrary to the numerics. The anelastic approximation allows for a correct representation of the dynamics of the system, provided the appropriate numerical design of the model, as is the case for EULAG. This result is in a general agreement with the analysis by Cullen et al. (2000) of the simulations of realistic mesoscale flow over the Scandinavian topography.

Optimal size of a time step for model integration is of great importance as it may significantly affect computational efficiency. The EULAG solutions presented above were obtained employing the same time step size as in Straka et al. (1993), i.e. 0.125 s. Additionally, several experiments with time steps increased by a factor of 2 up to 8 were performed. The tests were conducted at 100 m resolution and the results are presented in Rosa et al. (2011) Qualitative comparison of potential temperature field between solutions obtained for the original time step and the one being 8 times greater does not reveal any significant differences Rosa et al. (2011). A quantitative comparison in terms of a cold front location is presented in Table 2. The differences between the simulations for Courant numbers ranging from 0.045 to 0.36 are smaller than the grid spacing and the maximum relative difference between the solutions does not exceed 0.2 %. The presented results confirm that EULAG is not sensitive to such an increase of the Courant number.

Table 2: Front location at t=15 min and Courant number (CFL) for different time steps. Resolution is fixed at 100 m.

Time step size	CFL ($V_{max} = 36m/s$)	Front location [m]
$dt_{Straka} = 0.125\ s$	0.045	15279
$2dt_{Straka} = 0.25\ s$	0.09	15276
$4dt_{Straka} = 0.5\ s$	0.18	15269
$8dt_{Straka} = 1\ s$	0.36	15260

2.3 Bubble convection test

The goal of the second experiment is to test the feasibility of the anelastic approach for modeling a system of two interacting density currents (warm and cold). Configuration of the experiment follows the setup proposed originally by Robert (1993). The original experiment was performed employing fully compressible model, defining a suitable benchmark for the EULAG anelastic solution.

In the experiment the atmosphere is isentropic, thus the potential temperature of the reference state is $\theta = 300$ K. The reference profile of density for the EULAG simulations is the same as used for the cold density current (Straka test). Moist processes such as condensation, evaporation or rain formation are not considered. The initial conditions are set similarly to the Robert's experiment Robert (1993). The two bubbles are defined as perturbations of potential temperature with a Gaussian profile. The maximum values of temperature perturbation are 0.5 K for the warm bubble and -0.15 K for the cold one. Domain covers an area of 1 km $\times$ 1 km. Simulations are performed at three different resolutions 16×16, 8×8 and 4×4 m^2. Free-slip, rigid boundary condition are imposed on each side of the computational domain. The time step is set to $\Delta t = 1$ s. Pure Eulerian set of governing equations is used without any sub-grid scale model for viscosity. There is no external flow so that dynamics is governed only by density currents.

Figure 3 presents results of the EULAG simulation performed at the resolution 8×8 m^2, as results employing two other resolutions do not reveal substantial differences, during the 10 minutes of simulations. Robert (1993) performed the original experiment at the resolutions of 10×10 and 5×5 m^2. Comparing Fig. 3 with the benchmark results from Robert (1993) (Figs. 8 and 9 therein) we conclude that the differences between fully compressible and anelastic models are visually hardly to notice, which confirms the EULAG abilities to correctly represent the complicated and highly nonlinear processes.

2.4 Numerical modeling of inertia-gravity waves

In this section we demonstrate EULAG capabilities for simulating two-dimensional inertia-gravity waves. The waves are excited in air flowing through a long, periodic channel via an initial perturbation of potential temperature. The experiment was proposed by Skamarock and Klemp (1994) and is widely used for testing numerical schemes of the meteorological models.

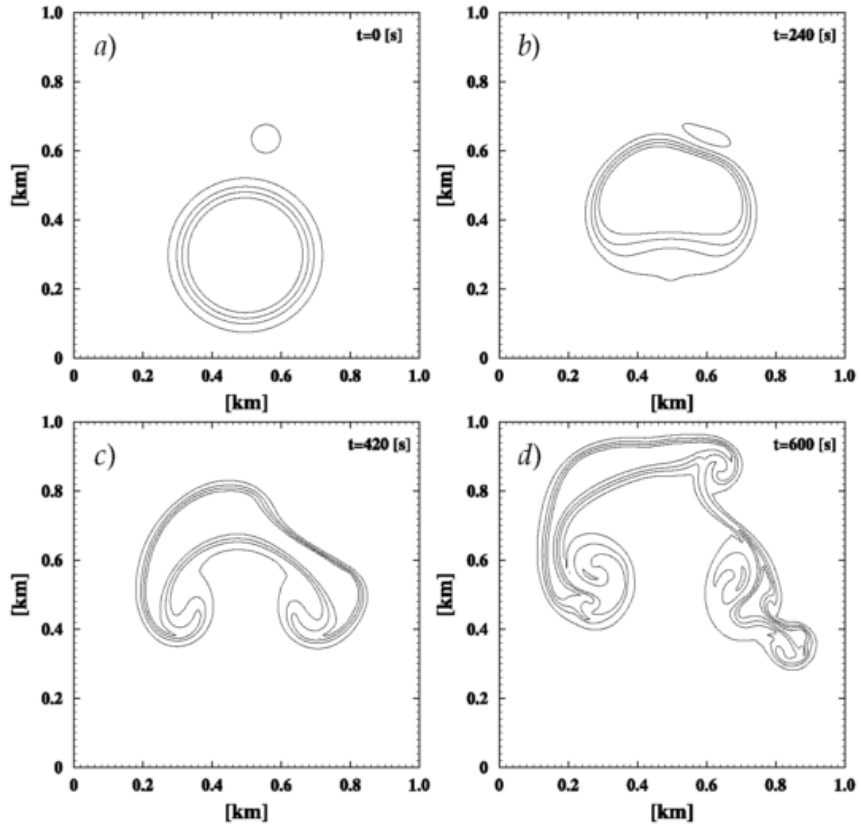

Figure 3: Time evolution of potential temperature perturbation θ' at $t = 0, 240, 420$ and 600 s. The initial distribution is depicted in panel *a*. The flow is induced by a rising large warm bubble and a descending small cold bubble. The asymmetry results from initial horizontal displacement between centers of the two bubbles.

2.4.1 Experiment setup

The computational domain is a periodic flat channel with solid, free-slip upper and lower boundaries. The simulations are performed for two different lengths of the channel, namely 300 km and 6000 km, and the same domain height of 10 km. The atmosphere inside the channel is uniformly stratified with a Brunt-Väisälä frequency equal to 0.01 s^{-1}. Constant horizontal ambient flow at an inlet is set to 20 m/s. The spatial distribution of the potential temperature perturbation, which leads to excitation of the gravity waves is defined as

$$\theta'(x, z, t = 0) = \Delta\theta_0 \frac{sin(\pi z/H)}{1 + (x - x_c)^2 / a^2}, \tag{1}$$

where $H = 10$ km is a domain height and $\Delta\theta_0 = 10^{-2}$ K is small amplitude of initial perturbation. The center of the initial perturbation x_c depends on the length of the channel and is 100 km for the short (300 km) and 2000 km for the long (6000 km) one.The half-width of the initial perturbation a also depends on the domain length and is $a = 5$ km and 100 km for the short and the long channel respectively. For the short channel, the resolution of computational grid in horizontal and vertical direction is the same. Simulation in a long channel is performed on a grid with an aspect ratio $\Delta x/\Delta z = 20$. Coriolis force is considered in both simulations, but its significant contribution to the flow dynamics is observed only for the long channel. Similarly to the previous experiments, there is no surface friction nor viscosity. More details about the experiment setup can be found in Skamarock and Klemp (1994).

2.4.2 Short channel

First, we analyze EULAG results for simulations performed for the short channel and the Boussinesq set of governing equations. In order to test the grid convergence of the solution, three different grid resolutions, namely $\Delta x = \Delta z = 1$ km, 0.5 km and 0.25 km are used. Figure 4 compares the perturbation of potential temperature at t = 50 min for the analytical solution (*a*) with numerical results ($b - d$), computed at the three grid resolutions. It is seen, that the numerical solutions converge to the analytical one with decreasing grid sizes.

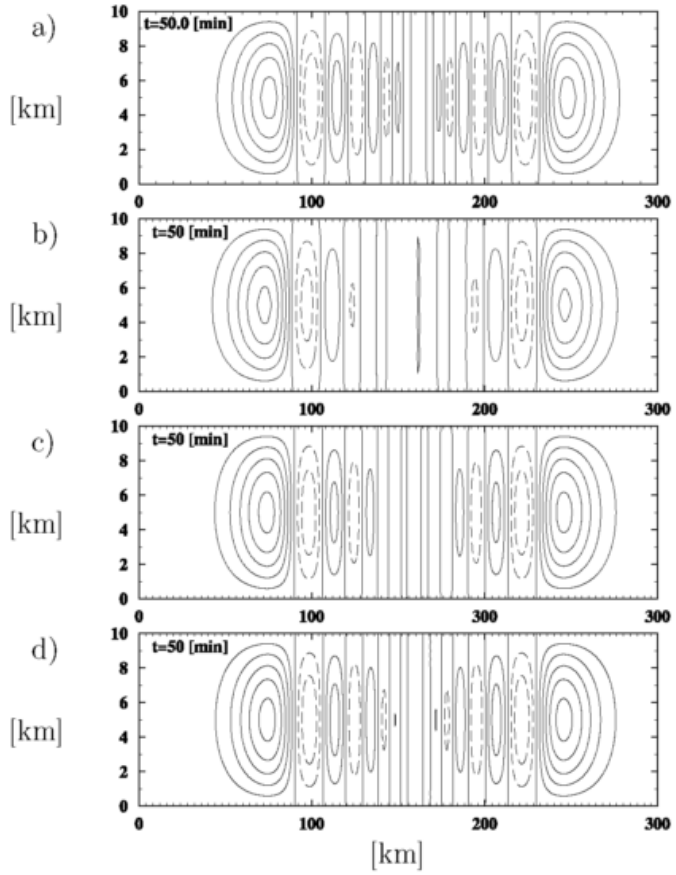

Figure 4: Spatial distribution of the potential temperature perturbation θ' after $t = 50$ min plotted (using contour values between −0.0015 K and 0.003 K) with a contour interval of 0.0005 K. Comparison of analytical solution *a*), with numerical solutions based on Boussinesq approximation computed using three different grid resolutions *b*) $\Delta x = \Delta z = 1$ km, *c*) $\Delta x = \Delta z = 0.5$ km, *d*) $\Delta x = \Delta z = 0.25$ km; negative values dashed.

In the original numerical experiment by Skamarock and Klemp (1994), the grid size was fixed to $\Delta x = \Delta z = 1$ km. Our result at this resolution (Fig. 4c) is very similar to that benchmark (see their Fig. 1c). Nevertheless, such grid size still does not allow to fully resolve the flow, which motivated us to apply higher resolutions, as described above.

Additionally, Fig. 5 compares the analytical solution for the potential temperature perturbation at constant height of 5 km above the surface (red line), with the EULAG results at three grid sizes, employed (black lines). Although small differences between numerical and analytical solutions are noticeable, the convergence to the analytical one is clearly visible. As the resolution of computational grid increases, the differences between numerical and analytical solutions diminish quickly, except the most central part of the wave-train, where 0.25 km grid size still underresolves the flow.

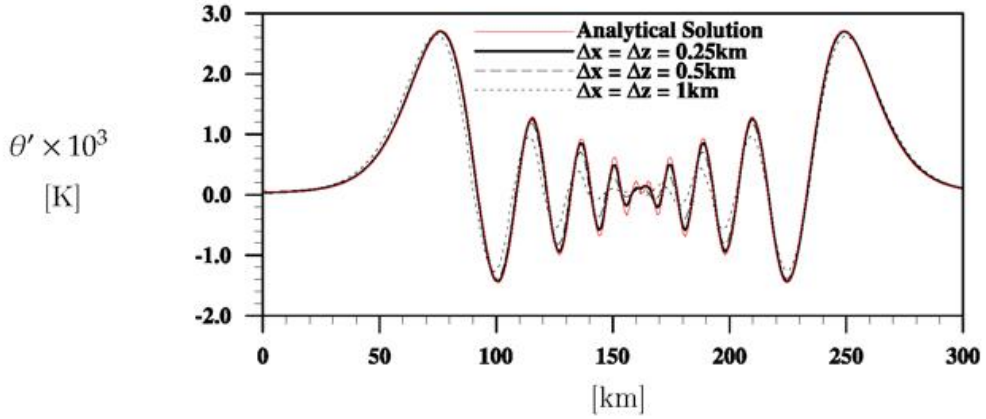

Figure 5: Profiles of potential temperature perturbation θ' along 5000 m height for the analytical solution and three different grid resolutions presented in Fig. 4.

2.4.3 Long channel

For the experiment involving 6000 km domain we used longer time step $t = 200$ s (previously 1 s), longer simulation time equal 1000 min, and different initial location of temperature perturbation ($x_c = 2000$ km). The computational grid has the same number of nodes in every direction, what implies a relatively large aspect ratio $\Delta x/\Delta z = 20$. As discussed in Skamarock and Klemp (1994), simulating atmospheric flows on grids with such high aspect ratio could be challenging for compressible models based on explicit numerical schemes. For such models, vertically propagating acoustic modes are disruptive for the slower modes of physical interest. Here, we intend to show that the numerics of EULAG provide a stable and accurate solution.

Figure 6 presents a comparison between the analytical and EULAG's numerical solutions for the potential temperature perturbation at 1000 min computed on grids with sizes of (20 km × 1 km, 10 km × 0.5 km and 5 km × 0.25 km), in horizontal and vertical directions, respectively. For different resolutions, the general pattern is similar but some differences in temperature gradients on the lateral sides of the perturbation are noticeable. With increasing resolution, the differences between the analytical and numerical solutions diminish significantly and we can conclude that the EULAG numerical solution is grid-convergent to the analytical formula. Similar to the short channel experiment, the highest resolution employed locally underresolves the potential temperature distribution, this time at the sides of the wave-train.

It is also interesting to analyze the grid convergence more quantitatively. Figure 7 presents the distribution of the potential temperature perturbation along the horizontal line at 5 km height. It confirms the grid-convergence of the numerical solutions, showing also that the largest differences between the analytic and numerical solutions can be found in the regions of high horizontal gradients of θ'.

Additional results from EULAG simulations performed using linearized version of the governing equations and pseudo-incompressible system of Durran (1989) one can find in Rosa et al. (2011).

2.5 Modeling of mountain gravity waves

The aim of that class of experiments is a comparison of the anelastic EULAG simulations of mountain flows with results of compressible models by Bonaventura (2000) and Pinty et al.

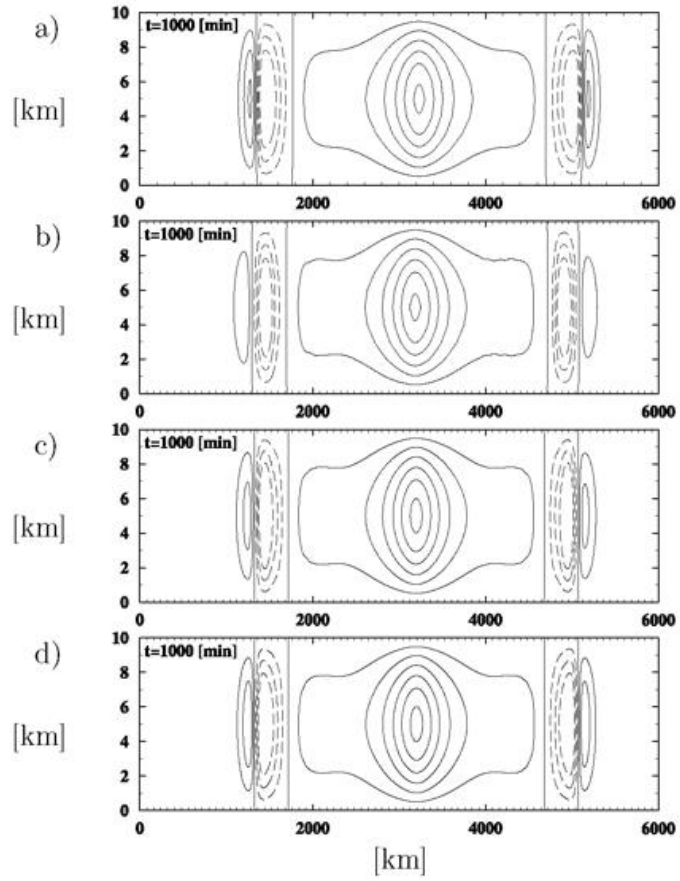

Figure 6: Spatial distribution of the perturbation of potential temperature θ' after t = 1000 min plotted with a contour interval of 0.0005 K. Comparison of analytical solution *a*) with the numerical solution based on Boussinesq approximation computed with three different grid resolutions *b*) Δx = 20 km, Δz = 1 km, *c*) Δx = 10 km Δz = 0.5 km, *d*) Δx = 5 km Δz = 0.25 km; negative values dashed.

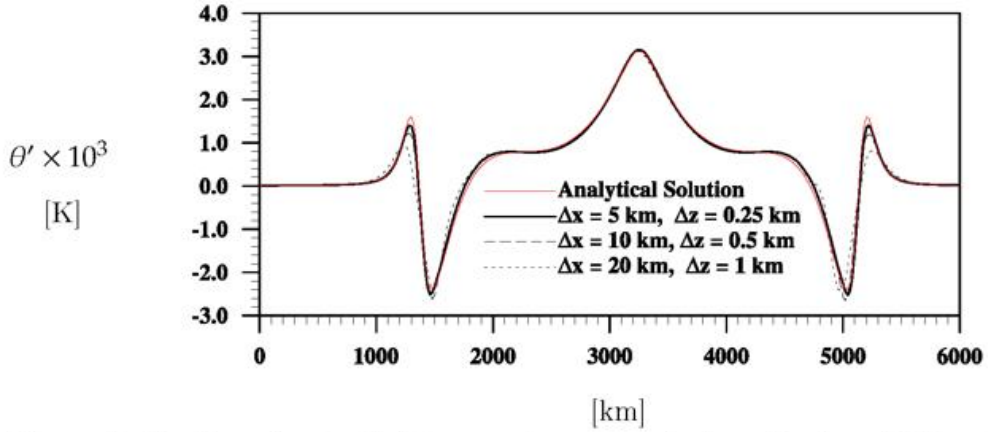

Figure 7: Profiles of potential temperature perturbation θ' along 5000 m height for the analytical solution and three different grid resolutions presented in Fig. 6.

(1995). The experiments are performed for different flow regimes, such as linear hydrostatic, linear nonhydrostatic, nonlinear hydrostatic and nonlinear nonhydrostatic.

2.5.1 Experiment setup

The flow configurations are based on Bonaventura (2000) and Pinty et al. (1995). The shape of the hill is defined by the Agnesi formula:

$$h(x) = \frac{h_0}{1 + [(x - x_0)/a]^2}, \qquad 0 \le x \le L, \tag{2}$$

where h_0, x_0 and a are height, center location and half width of the hill, correspondingly. The parameters defining shape of the hill define also a flow regime, so they differ between the simulations.

For all simulations, the reference potential temperature is given by the Clark-Farley formula. Height of the computational domain is 25 km, while its length depends on the particular flow regime. In order to avoid reflections of the gravity waves from the upper and lateral boundaries, absorbing layers are applied. Thickness and strength of the lateral damping layer depends on the flow regime. In vertical direction, the absorbing layer is the same for each experiment and covers the whole domain above 10 km height. There is no Coriolis force, nor explicit viscosity nor surface friction in the simulations.

2.5.2 Linear hydrostatic regime

The linear hydrostatic regime is characterized by the nondimensional parameter $aN/U \approx 10$ and a very small aspect ratio of h_0/a. An initial horizontal velocity U is 32 m/s. Height and half width of the hill are $h_0 = 1$ m and $a = 16$ km, correspondingly. Computational grid has significant anisotropy. Its size in the horizontal direction is $\Delta x = 3$ km while in the vertical direction it is $\Delta z = 250$ m. While the grid size in the vertical direction is much larger then the height of the hill, its presence is defined via terrain following coordinates. Brunt-Vaisala frequency is set to $N = 0.0187$ s^{-1} and the time step $\Delta t = 40$ s.

An analytical stationary solution for the wind perturbation for linear hydrostatic wave regime was developed by Klemp and Lilly (1978), for compressible atmosphere. Therefore, accuracy of the numerical solution can be directly verified against this result. Figure 8 shows a comparison of EULAG horizontal wind after 11.11 hours integration with that analytical solution. The general agreement between the solutions is apparent and is seen especially in the velocity pattern. The small differences concern mainly wave amplitudes, which are about 5% smaller for EULAG, in the areas outside the absorber. While Pinty and Bonaventura did not present a direct comparison of their simulation results with the analytical solution, we can conclude that the EULAG velocity distribution is in a close agreement with their compressible solutions.

2.5.3 Linear nonhydrostatic regime

For the linear nonhydrostatic flow regime we chose the nondimensional parameter aN/U to be of the order of 1, and the hill aspect ratio slightly smaller than 1. Thus, the hill shape parameters are $a = 500$ m and $h_0 = 100$ m for $N = 0.0187$ s^{-1} and $U = 14$ m/s. Resolution of computational grid is $\Delta x = 100$ m in horizontal and $\Delta z = 250$ m in vertical direction, to follow possibly closely a configuration applied by Bonaventura (2000). Time step used for the integration is $\Delta t = 4$ s. Distribution of the velocity and vertical momentum flux is analyzed after 1.2 h. In normalized time scale it corresponds to $t^* = Ut/a = 120$ and we can expect that they are close to the stationary solutions.

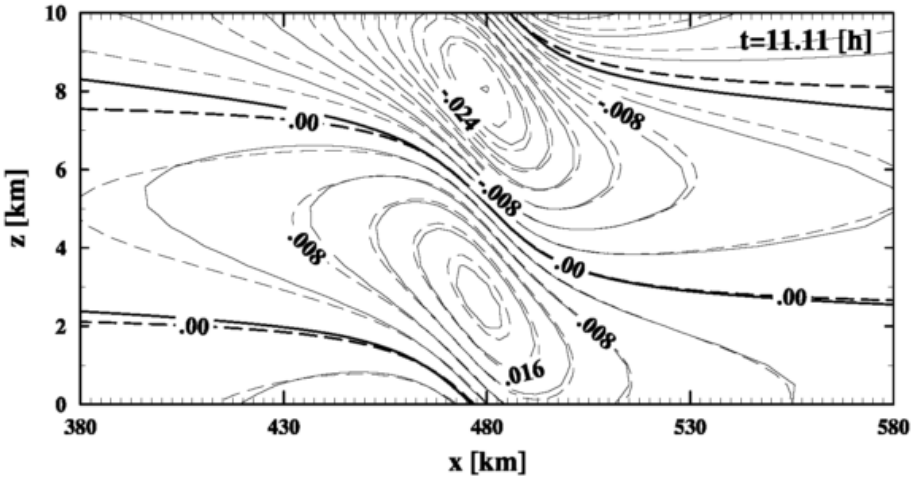

Figure 8: Perturbation of horizontal component of velocity after 11.11 hours. Comparison of numerical EULAG's solution (solid lines) with analytical solutions (dashed lines).

Vertical and horizontal components of velocity from EULAG are plotted in Figs. 9a and 9b. Their comparison with the compressible results from Bonaventura (2000) (Fig. 5 therein) shows that the characteristic features of the flow are properly reproduced and this concerns especially the pattern amplitude of the vertical velocity distribution. The small difference between the anelastic and compressible solution by Bonaventura is noticeable in the direction of the wave propagation, as in the EULAG solution, the waves propagate more steeply. Precise determination of this difference is somehow problematic due to limited resolution of Bonaventura's figure. Nevertheless, it can be said that the difference in the direction of the wave propagation does not exceed 5 degrees.

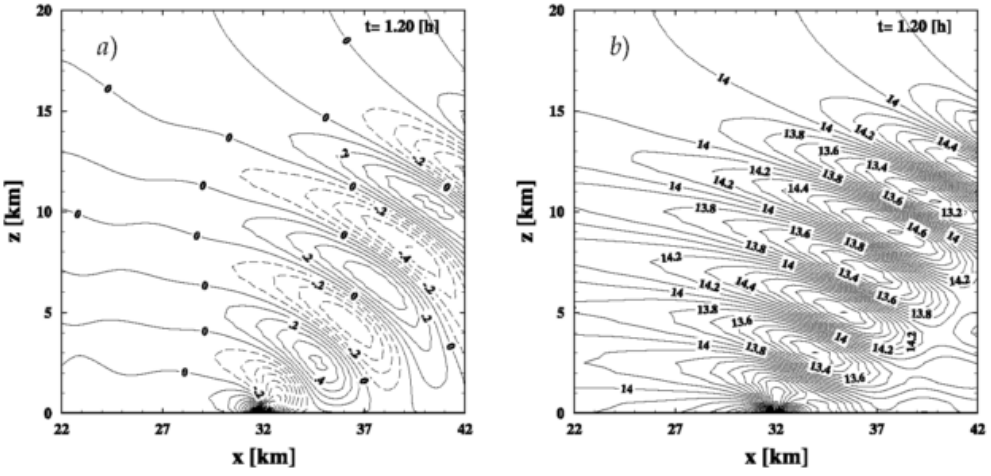

Figure 9: Velocity flow field in linear nonhydrostatic regime. Vertical *a*) and horizontal *b*) component of velocity (after 1.2 hour) computed using EULAG code, contours every 0.1 m/s.

2.5.4 Nonlinear hydrostatic regime

Nondimensional parameter aN/U for this test is equal 10. The mountain shape parameters are $a = 16$ km and $h_0 = 800$ m, while $U = 32$ m/s. Brunt-Vaisala frequency for this simulation is slightly increased $N = 0.02$ s^{-1}. Grid size is $\Delta x = 2.8$ km in the horizontal and $\Delta z = 200$ m

in the vertical direction. The whole domain covers the area of 1728 × 25 km. The equations are integrated over 23.9 h with the time step $\Delta t = 30$ s.

Figure 10 presents EULAG results for vertical and horizontal components of velocity perturbation. The comparison of the vertical velocity perturbation (Fig. 10b) with corresponding results from Pinty et al. (1995) (see their Fig. 8b) shows that both solutions are characterized by similar velocity pattern, as well as positions and magnitudes of the velocity extrema. This is also the case for the horizontal velocity perturbations, as both models place its first maximum at 8 km height with maximum value of about −3.5 m/s and the first minimum at ~ 9 km height with value −25 m/s for EULAG and ~ −26 m/s for Pinty et al. (1995). Also, the EULAG solution is more smooth in the upper part of the domain.

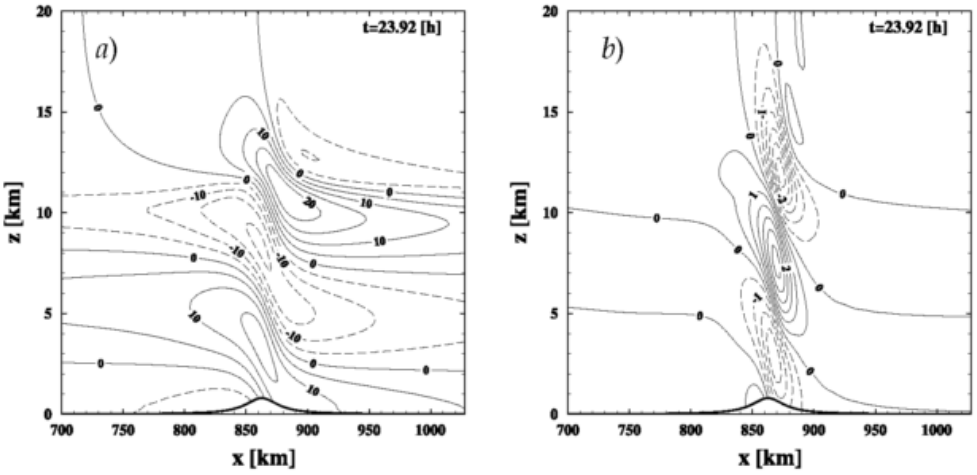

Figure 10: Spatial distribution of velocity perturbation in the hydrostatic nonlinear regime *a*) horizontal component with contour interval every 5 ms^{-1}, *b*) vertical component with contour intervals every 50 cms^{-1}. The dashed line indicate negative values.

2.5.5 Nonlinear nonhydrostatic regime

The nonlinear, nonhydrostatic flow regime is characterized by nondimensional parameter aN/U equal 1.5. Complexity of the flow results from the high steepness of the hill characterized by $a = 1000$ m and $h_0 = 900$ m giving a relatively high aspect ratio $h_0/a = 0.9$. Initial velocity at the inlet is set to $U = 13.28$ m/s. Brunt-Väisälä frequency is $N = 0.02$ s^{-1}. Resolution of the computational grid is $\Delta x = 200$ m in horizontal and $\Delta z = 100$ m in vertical direction. Size of the domain is 127.8 × 25 km. The experiment is run for 2400 s with the time step of 4 s. In EULAG simulations the hill is represented using the terrain following coordinates, while the Bonaventura's model uses Cartesian rectangular coordinates with step-like representation of the orography.

Figure 11 shows the EULAG solutions for vertical and horizontal components of velocity after 2400 s of calculations and, similarly to Bonaventura, focuses the analysis on the lee-side of the hill. The comparison with the compressible model of Bonaventura (2000) shows that even for this highly complicated flow regime and differing representations of orography, the main characteristic features of the flow are the same for both models. For horizontal velocity, they show similar spatial perturbation structure, with the area of positive perturbation elongated just above the lee-side slope. In EULAG solution, center-line of the area is closer to the ground comparing with the Bonaventura's solution and the difference may result from different representations of orography pattern. Maximum value of the horizontal wind inside the perturbation area and located close to the mountain peak is 25 m/s in EULAG and

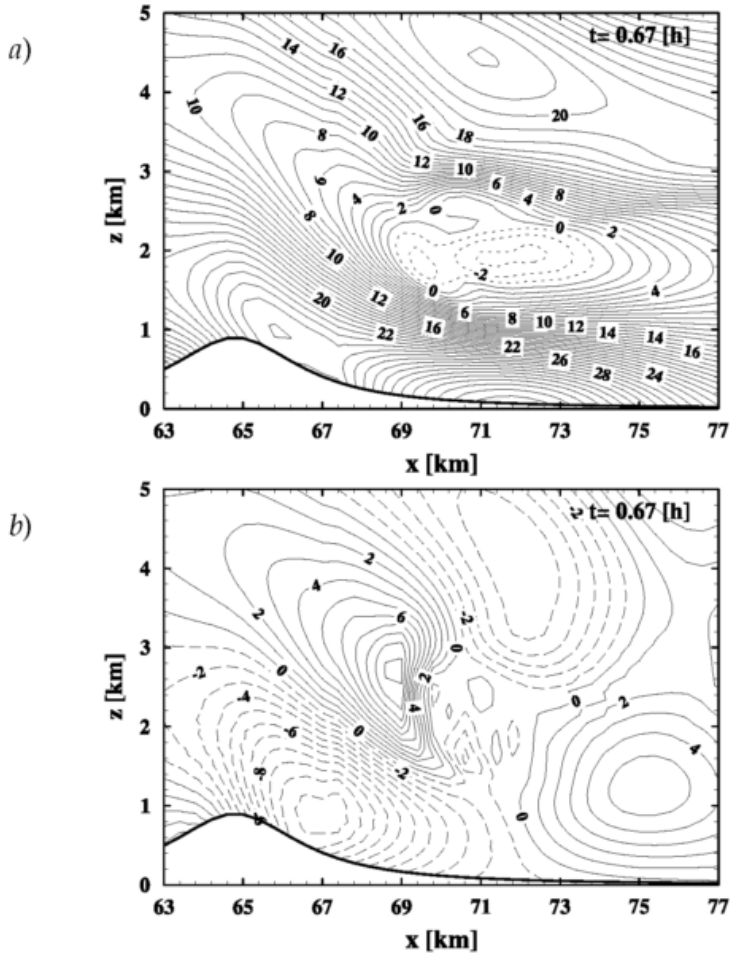

Figure 11: Velocity flow field in nonhydrostatic nonlinear regime *a*) EULAG - horizontal wind perturbation with contour interval 1 m/s, *b*) EULAG - vertical velocity with contour interval of 1 cm/s.

27.9 m/s in Bonaventura's solution. Region of negative horizontal velocity is also similar in location and shape with the corresponding region in the Bonaventura's solution Bonaventura (2000)(Fig. 15 therein). The minimum value of the horizontal velocity in EULAG is ~ -3 m/s while in the Bonaventura's solution is slightly smaller and equal ~ -5 m/s.

Vertical velocity field on the lee side of the hill (Fig. 11) is organized into a quadrupole structure. The flow pattern, as well as the position of minima and maxima are consistent with results obtained with compressible model (see Fig. 16 in Bonaventura (2000)).

In summary, the results show that anelastic approximation does not impose any significant limit for accurate modeling of the mountain gravity waves for tested flow regimes, including the nonlinear nonhydrostatic one, featuring also a strong wave-breaking process.

2.6 Summary and conclusions

The paper presents results of the study aimed at testing the anelastic dynamical core of the multiscale research flow model EULAG. The study is focused on the two-dimensional dry flows, free of phase transitions of water vapor. All the tests show that the results obtained using the anelastic EULAG core agree to a high degree with the benchmark compressible solutions, for all analyzed classes of the flow. This is also the case for comparisons with the

analytical solutions, where they are obtainable, that is for the inertia gravity waves, as well as for the orographic waves in the linear and hydrostatic flow regime. Additionally, the tests confirm the robustness of the EULAG numerical design.

The test of Straka et al. (1993) allows to thoroughly analyze the properties of EULAG via comparison of its solutions with results of an ensemble of fluid models of different analytic and numerical designs. The analysis confirms that the differences between the reference compressible benchmark solution and results of other simulations depend rather on their numerical designs and not significantly on their analytical formulations, with the anelastic EULAG solutions being very close to the benchmarks ones. In this sense, the experiment confirms findings by Cullen et al. (2000) concerning an influence of numerical model design on realistic representations of mesoscale flows over Scandinavian Peninsula. Our analysis shows also that EULAG solutions well represent the flow structure, even underresolved by the model. That virtue characterizes a small minority of the tested models, not even the benchmark one of Straka et al. (1993).

In summary, the analysis of EULAG results and its comparison with the benchmark solutions confirms that the model has a number of characteristics desirable from the view point of mesoscale NWP applications. They involve the high degree of conformity with the benchmark results, as well as consistent and smooth representation of subscale process, always present in NWP applications.

3.1 Introduction

In this section, the results of two moist benchmark tests (Klemp and Wilhelmson 1978, hereafter KW78; and Weisman and Klemp 1982, hereafter WK82) performed by the EULAG model for convection-permitting scales are documented. The both experiments consider development and evolution of a three-dimensional supercell over a flat terrain. Our strategy follows the idea of Skamarock et al. (2004), in which supercell experiments define one of the tests regarding standard verification of nonhydrostatic dynamical cores. Since the problem is strongly nonlinear and moist processes are coupled with three-dimensional dynamics, the supercell simulations are considered one of the most complex cases proposed in the test set. This is also because supercell formation involves a variety of coupled microphysical and dynamical aspects, including ice processes, gust fronts and cold pool dynamics, mesocyclone formation, forward and rear downdrafts, storm splitting, surface inflow, and multi-phase precipitation. However, a basic requirement of the test is to reduce relevant physics in order to facilitate evaluation of the results. In consequence, a set of simplifications was imposed on the experimental setup, e.g., moist physics is limited to bulk parameterization allowing only for warm rain formation. Nonetheless, the simplified setup is suitable for studying supercell development and to qualitatively reconstruct the most typical storm features, as shown in KW78 and WK82. The results of severe convection simulations presented in this report along with a set of additional sensitivity studies performed by EULAG were already published in the scientific literature (Kurowski et al. 2011).

3.2 General model setup

The two experiments presented in this report (i.e., KW78 and WK82) use a highly consistent numerical setup but different initial and boundary conditions. All simulations are carried out in a horizontally homogeneous environment and in the absence of orography. The reference profiles are based on observations and represent realistic conditions for severe storm development. The moist framework of EULAG is based on the Lipps and Hemler (1982) approach. The EULAG's reference (environmental) state is defined by the profiles of temperature and potential temperature (what allows for a derivation of reference pressure used in the moist thermodynamics), water vapor mixing ratio and both components of horizontal velocity. The initial perturbation of the potential temperature has a form of bubble with positive temperature excess in the center gradually decreasing to zero at its edge. It is placed near the ground in order to initiate convection. The Coriolis effect is not taken into account.

The bulk moist thermodynamics is represented in the model by three prognostic variables: water vapor (q_v), cloud (q_c) and rain (q_r) mixing ratios (cf. eqs. 1b, 1c and 1d from Grabowski and Smolarkiewicz, 2002). Condensation and evaporation processes are based on an instantaneous saturation adjustment (i.e., no supersaturation) while rain development is represented through a Kessler scheme. Respective mathematical formulas describing the processes of autoconversion, accretion, evaporation and rain subsidence along with a set of accompanying parameters follow KW78.

The subgrid-scale (SGS) mixing scheme (Margolin et al., 1999) is based on the prognostic equation of a volume averaged turbulent kinetic energy (TKE), which is subsequently used to prescribe the subgrid-scale turbulent mixing coefficient for momentum: $Km = c_m TKE^{1/2}(\Delta x \Delta y \Delta z)^{1/3}$, where c_m is a constant. As in KW78, the Prandtl number (i.e. $Pr = K_m/K_h$, where K_h is the subgrid-scale mixing coefficient for scalars) is 0.33. Because some of the SGS parameters of the KW78 scheme are not given explicitly, the subgrid-scale model used in KW78 may differ from the model employed in EULAG.

Rigid and free-slip boundary conditions are imposed at the top and bottom of the domain. The model's lateral boundaries are defined as follows: each explicit variable (i.e. the potential temperature, momentum, mixing ratio, etc.) has an inflow boundary value which is defined by a constant in time environmental profile; processes taking place within the domain do not affect the inflow conditions; the actual state of the flow is a superposition of the reference state and a perturbation; the perturbations are advected out of the domain at the outflow boundary by a prescribed environmental flow. We will further refer to this type of boundary condition as open. When absorber of the Davies type (Davies, 1976; Smolarkiewicz and Margolin, 1997; see discussion after eq. 9 and eqs. 17a-17d) is applied then the perturbations are attenuated to zero in this region. It helps to control an excess and propagation of gravity waves in a stably stratified atmosphere. If not otherwise stated, the sponge layer is not applied. This is because the effects of gravity wave propagation were found to be insignificant for the short-term integration time. We also tested periodic boundary conditions, and, as will be shown further, the choice between open and periodic b.c. is of negligible importance to the EULAG's solutions.

3.3 Klemp and Wilhelmson (1978) experiment

3.3.1 Setup details

The KW78 experiment represents a classic study on a supercell formation, however, it does not provide the details of initial soundings applied in the model. The approximate profiles subjectively reproduced from a skew-T diagram (cf. Fig. 1 in KW78) are given in Table 3. A well-mixed boundary layer extends in the lowest part of the atmosphere (up to 1600 m), with two layers of different stability aloft, having an interface at about 6 km. Convective available potential energy (CAPE) is about 1400 J with the lifted condensation level located at 870 mb. It should be stressed that skew-T representation is a source of insufficient information and a small modification of the initial conditions significantly affects CAPE. For instance, an ensemble of a few profiles within an envelope not exceeding 0.3 K, with respect to the values given in Table 3, changes CAPE by about 5%. The initial perturbation of the potential temperature is defined in the same way as in KW78 (cf. eq. 4.1 and 4.2 therein) and is placed near the ground in the center of the domain. Moist initial fields are not affected by this perturbation and water vapor mixing ratio changes only according to the sounding. Surface pressure is 965 hPa. The model timestep is 10 s and a total integration time is 24 min for a case with no external flow, 36 min for the simulation with a shear flow and 40 min for a case with a veering wind profile. Two sets of simulations are reported here. One does not include any explicit turbulent diffusion (NSG). The other uses the SGS scheme. Basic domain size is 24 km × 24 km × 10 km with a uniform grid spacing $\Delta x = \Delta y = 1$ km and $\Delta z = 500m$. Since the size of a developing supercell is relatively large compared to the domain, we also performed sensitivity study for domains of 36 km × 36 km × 10 km and 256 km × 256 km × 10 km with the same spatial resolution as for the basic simulations. This is to verify how convective development depends on the proximity of lateral boundaries and on the volume of the surrounding where subsiding air may differently respond to the strong

convective updraft.

Table 3: Initial profiles of height (z), pressure (p), potential temperature (θ), temperature (T), dew point temperature (Td) and water vapor mixing ratio (qv) used in KW78 experiment. Surface pressure is $965hPa$.

z [m]	p [Pa]	θ [K]	Td [K]	qv [g/kg]
0	965	300.19	290.15	$1.32 \cdot 10^{1}$

10285	250	351.73	142.15	$1.38 \cdot 10^{-7}$

3.3.2 Atmosphere-at-rest case

Comparison of EULAG's results for simulations with and without explicit subgrid-scale mixing is presented in Fig. 12 and should be compared with Fig. 2 from KW78. Note that zero isoline is not plotted for positive defined fields such as cloud and rain mixing ratios in contrast to the plots from KW78. The results of the simulations are in qualitative agreement with KW78, that is, the dynamic and thermodynamic fields have similar patterns. A general picture of the process compares well with the reference experiment, however, some differences can be found in details. SGS model reduces the strength of convection and leads to suppressed cloud and rain development. This effect is physical and shows an influence of enhanced subgrid-scale diffusion on water species. A better consistency with KW78 is obtained when no sugbrid-scale diffusion is applied, however, the results still suggest a possible deficiency in the initial sounding. The EULAG's dynamical fields such as vertical velocity are similar to KW78, except that maximum updraft velocity is 24 m/s in KW78, 21 m/s and 18 m/s in NSG and SGS simulation, respectively. As for the moist fields, the vertical extent of convection as seen by the cloud top level (defined by the height of $q_c = 0.5$ g/kg isoline) reaches 6.5 km (SGS) or 7.5 km (NSG). These are smaller than about 8 km in KW78. Similarly to KW78, a vortical structure of cloud water is visible around the cloud base for NSG. Such a pattern is also present in SGS simulation, but for a smaller isoline interval than used in Fig. 12. The most significant differences regard maximum values of the rain field, which are strongly reduced especially for SGS case. This is a straightforward consequence of

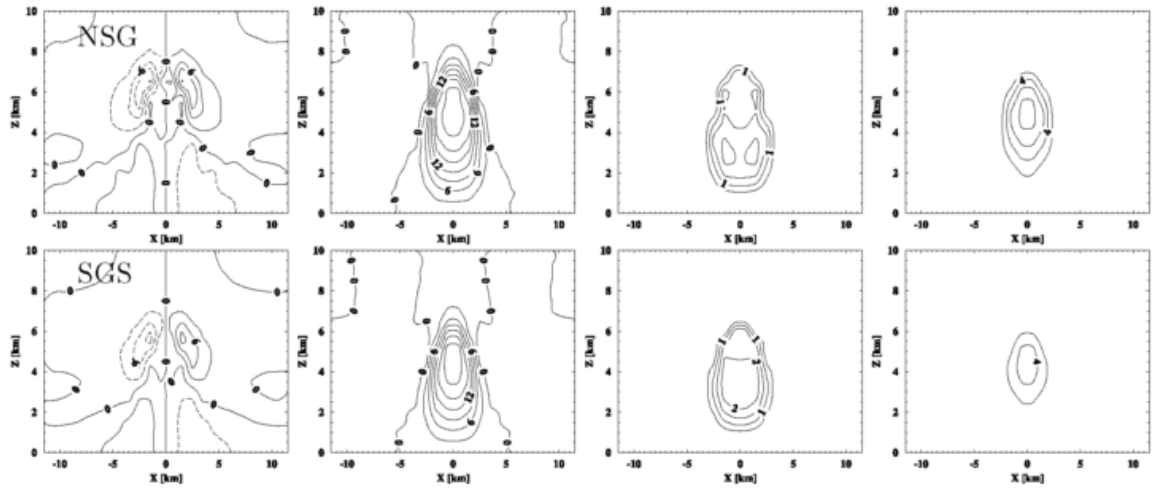

Figure 12: Starting from left column: vertical cross section of u (m/s), w (m/s), q_c (g/kg) and q_r (g/kg) at y = 0 for simulation in resting atmosphere. Results for NSG (upper row) and SGS (right column) are plotted at t = 24 min. Intervals between the isolines exactly correspond to those used in KW78. Negative values of velocity are dashed.

lower amount of cloud water converted into rain water, accordingly to the Kessler formula. Maximum isoline of q_r is 12 g/kg in KW78, 8 g/kg in NSG and 4 g/kg in SGS case.

A significant difference in the moist fields between SGS and NSG models illustrates an important role of diffusion in controlling the supercell formation. This is especially important for the large-gradient fields as narrow convective updraft that impinges upon the dry environment. The diffusion can reduce buoyancy of a rising thermal what in turn limits moisture supply. On the other hand, our sensitivity study shows that at 24 min the cell undergoes a vigorous development characterized by intensive growth of maximum updraft velocity and maximum values of water species. Therefore, even relatively small differences in model speed-up may lead to significant differences between models, at this moment. The comparison of the results at a more mature stage of the cloud development would be more illuminating, but KW78 does not offer such results for the atmosphere-at-rest case. Nonetheless, this example illustrates the complexity of a seemingly simple problem, where the coupling between dynamics and moist thermodynamics with precipitation may result in noticeable model-to-model differences in physically important fields such as cloud and rain water.

3.3.3 Shear flow case

A low-level shear is an essential component of a supercell formation as it is responsible for the storm splitting with subsequent separation of updraft and downdraft structures. This process is initiated when a vorticity tube associated with the low-level vertical shear flow is tilted up by a convective current and subsequently deformed into two separate horizontally counter-rotating branches of the air (e.g. Klemp, 1987). A low-level shear is a necessary prerequisite of the process but it also affects the vertical structure of the supercell, which may be torn apart when the shear is too strong (Weisman and Klemp, 1982). In the current simulations, a horizontal velocity in x-direction changes linearly from -5 m/s at z = 0 km to 5 m/s at 3.25 km and remains constant (5 m/s) above.

Horizontal cross sections of vertical and horizontal velocites, and cloud and rain water mixing ratios at 24 min and 36 min are presented in Fig. 13 and Fig. 14, respectively, and should be compared to Fig. 4 and 5 from KW78. Cloud water shown in Fig. 13 is replaced with the

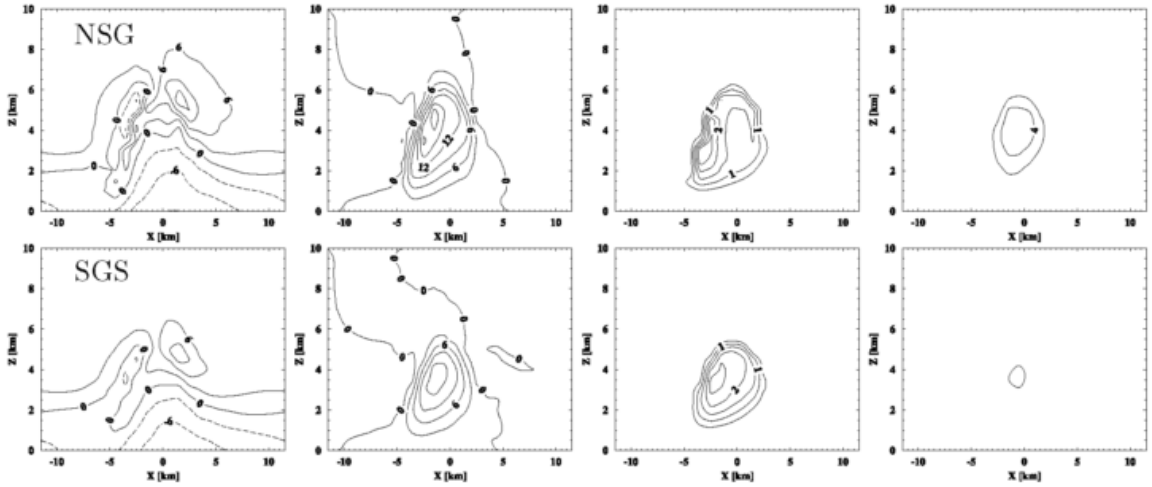

Figure 13: As in Fig. 12 but for sheared environment at 24 min.

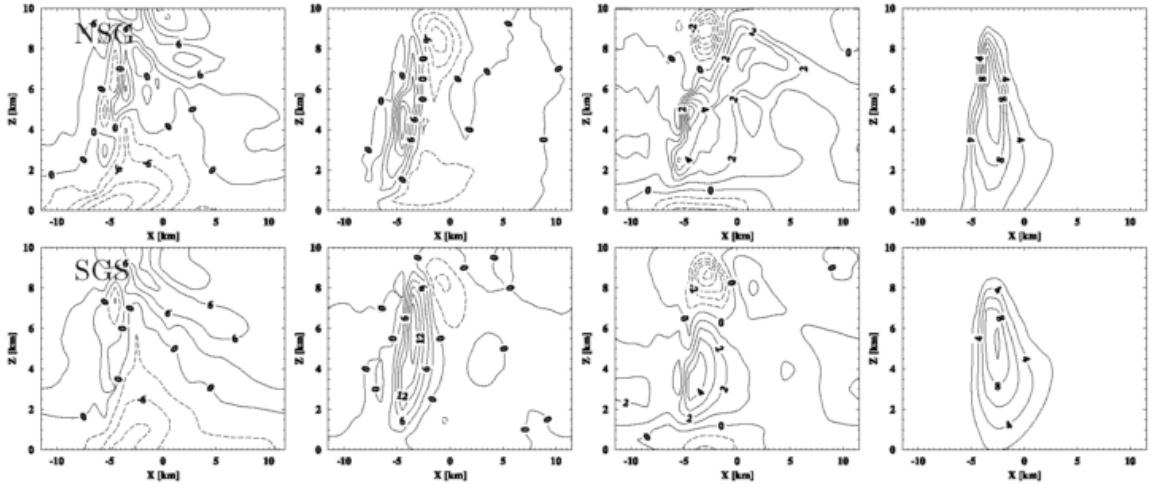

Figure 14: As in Fig. 13 except at 36 min and the third column is potential temperature perturbation (θ') in (K).

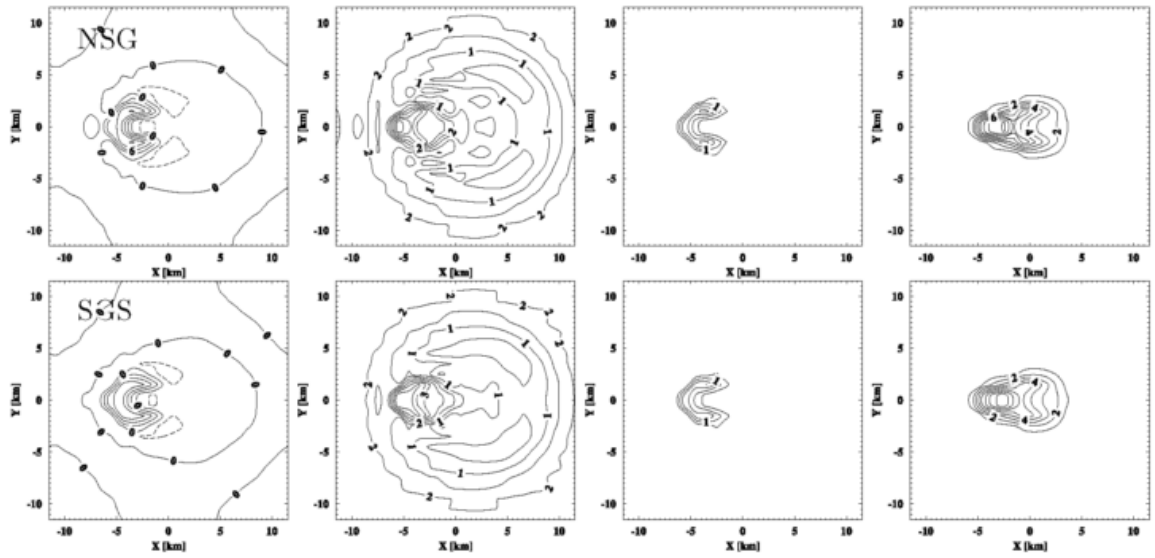

Figure 15: Horizontal cross sections at $z = 2.75$ km for one-directional shear simulations at 36 min. From left to right: vertical velocity, potential temperature perturbation, cloudy and rain water are presented for NSG (top row) and SGS (bottom row) model.

potential temperature fluctuation in Fig. 14, in agreement with Fig. 5 from KW78. Again, all the fields are in qualitative agreement with KW78 and a general picture of supercell formation in sheared environment is similar in both cases. The main differences regard the amount of rain water that is lower in the EULAG simulations. The rain water mixing ratio is especially reduced at 24 min for SGS case. This is associated with approximately 40% lower intensity of a convective updraft and thus lower moisture supply. At later times, the EULAG results compare better with KW78. For instance, after 36 min cloud and rain fields are very close to KW78. NSG model produces slightly more rain than is seen in the reference experiment as a small region of high rain water amount ($q_r > 12$ g/kg) is present in between 6 and 7 km. Rain water advected into upper parts of the supercell by a strong updraft overshoots the cloud top height (not shown) by about 2.5 km. Maximum potential temperature excess resulting from the latent heat release (4 K in EULAG simulations) compares well with KW78. As shown in Fig. 14, results of SGS model at 36 min are more consistent with KW78 than at 24 min, and only a slight delay of rain fallout is present (note that isoline of 4 g/kg have not yet reached the ground).

Horizontal cross sections of vertical velocity, potential temperature perturbation and cloud and rain mixing ratios at z = 2.75 km and at 36 min are depicted in Fig. 15 using the same intervals as in Fig. 6 from KW78. A characteristic horse-shoe-shaped deformation of an updraft region with the two nearly separate convective branches marks the beginning of the storm splitting. Rain water and potential temperature fields still have only one maximum, similarly to KW78. The rain water at 2.75 km, falling out between convective updrafts, covers larger horizontal area than the cloud water. As discussed above, the difference between EULAG and KW78 at 24 min can be due to different model spin-up. A longer integration time removes transient differences in moisture supply. In consequence, similar intensity of an updraft is achieved at later times and thus the cumulative total water amount is more consistent in both cases.

z [m]	u [m/s]	v [m/s]

Table 4: Numerical values of both components of horizontal velocity (u, v) as used in EULAG's simulation of the flow with a veering wind.

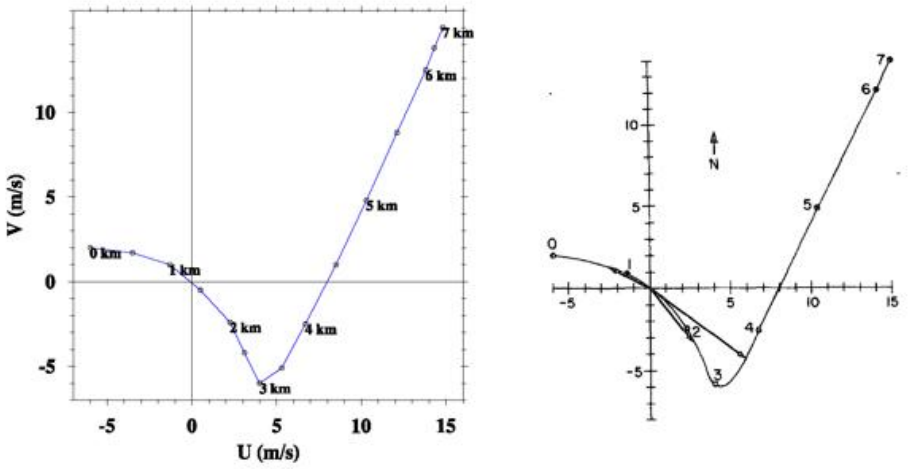

Figure 16: Hodograph of the horizontal velocity as used in EULAG's simulations (left panel) and that from the original KW78's setup (right panel). Empty circles on the left panel indicate the values exactly at model's vertical levels, i.e. the distance between adjacent points is $\Delta z = 0.5$ km.

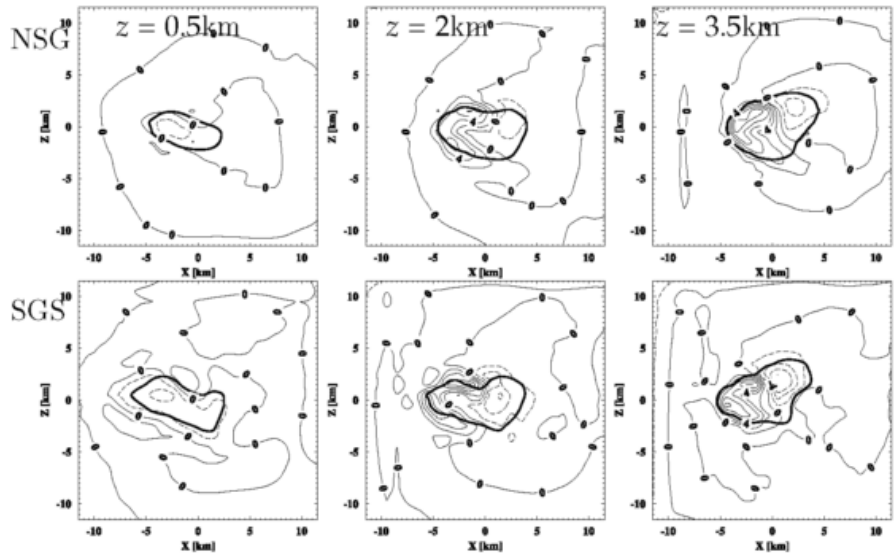

Figure 17: Horizontal cross sections of the vertical velocity w for veering wind simulation at three different levels: 0.5 km (left column), 2 km (middle) and 3.5 km (right) and after 40 min of simulation. Thick line denotes rain water contour of $q_r = 1$ g/kg.

3.3.4 Veering wind case

A case with a veering wind is the most complex out of the three presented in this study and most typical for severe storm formation (KW78). For a straight hodograph used in the previous case along with the Coriolis force omitted, supercell development is symmetric to the XZ plane at y = 0 and none of the branches is favored (cf. Fig. 15). Presence of veering wind, however, causes asymmetry in the supercell propagation and strongly affects evolution of its internal structure. This allows for a development of new characteristics that resemble supercell features observed in nature.

The environmental profile of horizontal velocity shown in Fig. 16 was reproduced from Fig. 12 in KW78 and appropriate numerical values used for the study are given in Table 3.3.4. Figure 17 presents horizontal cross sections of the vertical velocity and rain water fields after 40 minutes of simulation at three different levels: 0.5 km, 2 km and 3.5 km (using the same contour intervals as in KW78) for NSG and SGS simulations. The results were obtained for slightly larger horizontal domain size (i.e. 32 km × 32 km) in order to minimize boundary effects.

The structure at z = 0.5 km consists of two updrafts separated by rain-laden downdraft. The convective branches merge at upper levels where asymmetry of the structure is evident. The branch of stronger updraft borders upon the downdraft and the convection is more vigorous than at lower levels. The rain water contour of 1 g/kg at z = 0.5 km encloses only a region of the descending air. At upper levels, the region expands into an area where the updrafts are also present. Maximum value of the vertical velocity is similar to that from KW78, but about 25% lower for SGS model. YZ vertical cross sections of cloud and rain water as well as vertical velocity and potential temperature perturbation at x = -2 km are depicted in Fig. 18. The vertical velocity field has two updrafts in the lower part of the supercell which are merged together in the upper part. There is a region of negative velocity in between the convective branches, close to the ground, which is associated with a cold pool formation.

The potential temperature field is separated into three regions, as in KW78. The amplitude of its perturbation near the cloud top reaches -6 K in KW78 and -4 K in both EULAG

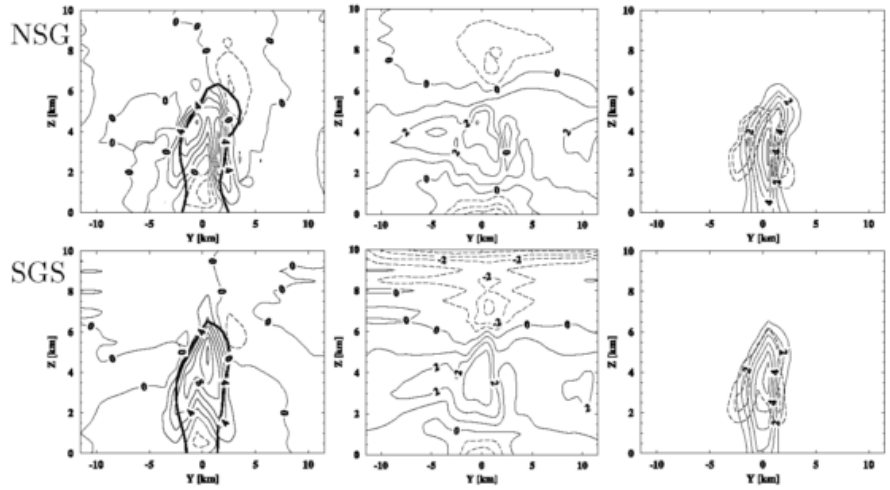

Figure 18: Vertical cross section along yz direction at $x = -2$ km after 40 min: w field (m/s) (left) with bold solid line enclosing the region of $q_r > 1$ g/kg, θ' (K) (middle), and water fields (g/kg) (right) where dashed line refers to q_c and the solid line to q_r.

simulations. The maximum positive temperature excess is 3 K in all cases. The cold pool at the bottom of supercell is characterized with temperature decrease to -4 K in KW78, -4 K for NSG and -3 K for the SGS model. The cloud and rain patterns have similar structure as in KW78 except that the maximum values of q_r are 8 g/kg in both EULAG simulations and 4 g/kg in KW78. The cloud top level reaches about 8.5 km in NSG, 8 km in SGS and 7 km in KW78 simulations.

3.3.5 Sensitivity tests

The influence of horizontal domain extent, the type of lateral boundary condition and spatial resolution were investigated in a series of sensitivity tests. As for the horizontal extend of the domain, the proximity of lateral boundaries noticeably suppresses vertical supercell development. This is evident for the maxima of rain water and updraft velocity, which are about 20% and 40% larger for 256 km × 256 km domain than for 24 km × 24 km one, at 24 and 36 minutes, respectively. The spread of the results for different domain sizes depends on the environmental flow and is generally the smallest for the veering wind where at 40 min of evolution the spread is about 20% for q_r and q_c and about 40% for maximum updraft velocity. The largest differences concern maximum updraft velocity for the atmosphere at rest, where w varies between 6 and 16 m/s at 40 min. The comparison suggests that in general terms the presence of external flow, allowing for convection organization, makes representation of convection less dependent on the model setup.

Changes in horizontal and vertical gridlength turned out to have a dominant impact on the supercell dynamics. According to the results, larger values of the extrema are generally obtained for a finer grid resolution. The strongest sensitivity is observed for maximum vertical velocity which increases from about 26 m/s for $\Delta x = 1$ km and $\Delta z = 500$ m to about 34 m/s for $\Delta x = 500m$ and $\Delta z = 170m$. Changes in resolution also affect the moist fields. Notice however, that doubling horizontal resolution (i.e. using $\Delta x = 500m$ instead of $\Delta x = 1$ km) leads to relatively small changes in the evolution of q_c and q_r extrema, whereas modification of the vertical grid has a significant impact on the fields. Another observed effect is earlier development of convection for finer grid resolution. This indicates that a simple comparison of instantaneous fields may lead to misleading conclusions, especially

when similarly evolving supercells are only shifted in time for different model setups.

The experiments with different types of boundary conditions show that the choice between open and periodic b.c. is of negligible importance to the EULAG results. The spread of results for the updraft velocity, cloud and rain mixing ratio for the most complex case (with a veering wind) is at least an order of magnitude smaller than that introduced by other modifications (i.e., resolution and domain size). For the atmosphere-at-rest case the differences between the two types of boundary conditions in terms of vertical velocity and water condensate did not exceed 0.1%.

3.4 Weisman and Klemp (1982) experiment

3.4.1 Setup details

Setup of the experiment is based on the analytic profiles of the potential temperature, relative humidity and uni-directional horizontal wind (cf. eq. 1, 2 and 4 from WK82) extending vertically up to 17.5 km. Horizontal and vertical gridlength is 2 km and 350 m, respectively. WK82 employs vertical stretching from 350 m near the ground to about 1 km at the top of the domain. This is the main difference from the EULAG's setup which employs a uniform grid. Based on the symmetry of the problem, WK82's horizontal domain was limited to one-half, in order to reduce computational cost. In contrary, we use a full domain with a horizontal size of 128 km $\times$ 128 km. This size was found to be optimal for representing propagation of supercell during the storm splitting without any noticeable interference with the lateral boundary effects. Initial perturbation of the potential temperature is similar to KW78 experiment, but the temperature excess is now 2 K. Open boundary conditions, a Kessler-type warm rain parametrization and a TKE-based subgrid-scale mixing scheme are employed in the experiment. EULAG's physics and numerics are the same as in the previous experiment. This is in contrast to WK82, where a modified version of KW78 model was used (cf. section 2 in WK82). Again, neither ice processes nor Coriolis effects are included. Total integration time is 120 min. It is worth mentioning that a SGS model is a necessary prerequisite for the simulations as the lack of subgrid-scale transport leads to disintegration of a well-organized internal supercell structure.

3.4.2 Shear flow case

The environmental horizontal shear flow employed in the simulations is defined as follows: $U(z) = U_s tanh(z/z_s)$, where z_s = 3 km, and U_s is a free parameter which changes in the range from 5 m/s to 45 m/s (see Fig. 2 in WK82 and its explanation in the text). We consider five cases, namely U_s = 5 m/s, 15 m/s, 25 m/s, 35 m/s and 45 m/s. A constant wind U of a different strength for different simulations is added as Galilean transformation to keep the supercell in the middle of the domain during the simulation. Its magnitude is chosen experimentally and depends on U_s. Using a constant U does not affect the solution since free-slip bottom boundary condition is imposed and no surface fluxes are applied.

Results of the simulations for this setup are presented in Figs. 19, 20 and 21 in a similar manner to WK82. Each figure shows the time evolution of the following fields: horizontal flow at 175 m height (black vectors), vertical velocity at 4900 m (black lines, dashed for negative values), surface precipitation (light blue lines) and a cold front defined as the edge of a cold pool ($\Delta\theta$ = -1K) at the surface (bold blue line). Dotted area marks region of q_r >2 g/kg at the ground. In addition, results from WK82 are plotted in the figures. Such representation of the storm development gives an insight into the supercell dynamics, however, WK82 does not

show any vertical cross sections of the storm structure, what precludes more comprehensive comparison of the results. Note that a mean horizontal flow ($\bar{U}$) of different magnitude was subtracted from EULAG and WK82 solutions, what affects representation of storm-relative low level flow (e.g. to keep the solution for U_s =15 m/s in the domain center, $\bar{U}$=9.15 and 12m/s were used in EULAG and WK82, respectively).

The storm system evolves in a similar way for three different values of U_s (Figs. 19, 20 and 21). After 40 min of simulations the storm splitting is already underway, but only one maximum of the surface precipitation is being formed. Apparently, horizontal extent of convective perturbations depends on the shear strength. For larger U_s the fields become more asymmetric in x and y directions. This reduces the maximum updraft velocity due to lower moisture supply. This in turn suppresses precipitation-laden downdraft and delays formation of a cold pool, as compared to the other cases. After 80 min, each supercell consists of two clearly separated convective cores with a precipitation area between them. Again, intensity and horizontal extent of the vertical velocity and rain water fields decreases with increasing U_s. After 120 min, the splitting of the surface precipitation is completed for U_s = 25 m/s and U_s = 35 m/s as the rain pattern no longer extends over a single area. A local circulation within each core induces a downdraft in its rear part which diverges near the ground away from the supercell center. The largest velocity of diverging flow is for U_s = 15 m/s. These velocity perturbations are superimposed on the external flow that results in larger western component of horizontal velocity for greater U_s. A cold pool develops on the rear side of the supercell with a cold front located near the leading edge of the convective structure during the whole simulation. One of the most characteristic features is that the distance between the two convective branches almost does not depend on the shear-strength. It differs less than a few percent for U_s ranging from 15 to 35 m/s. The shear mostly affects the supercell evolution through the intensity of convection.

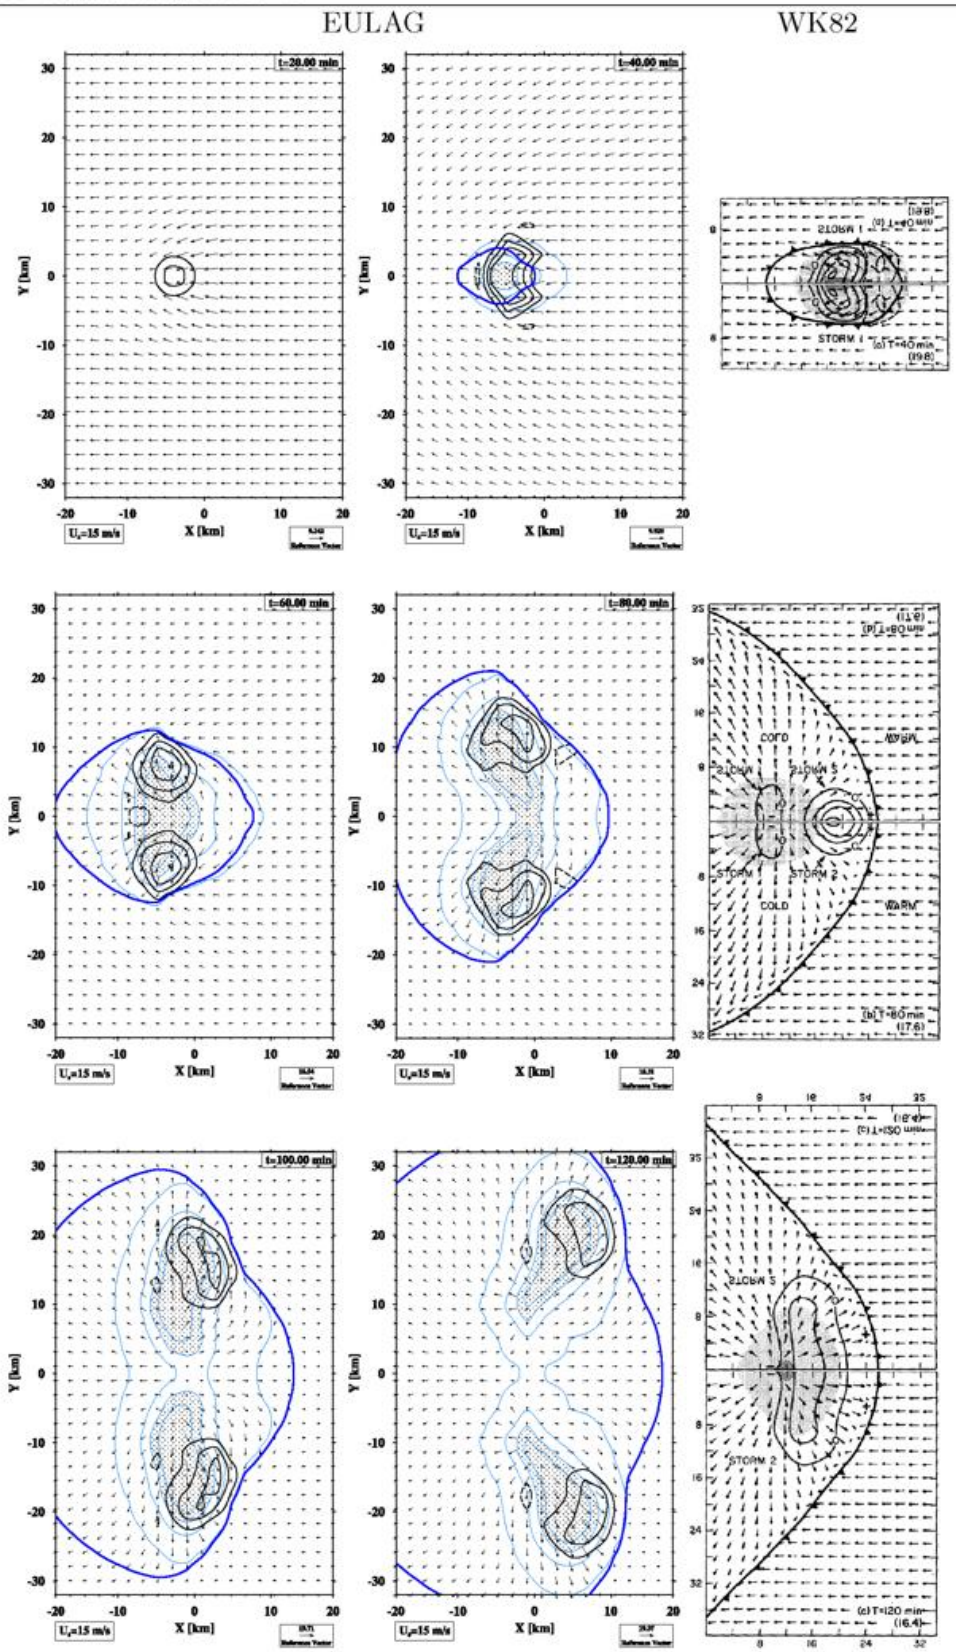

Figure 19: Time evolution of horizontal flow at 175 m (black vectors), vertical velocity at 4900 m (black lines, dashed for negative values), surface precipitation (light blue lines) and a cold front defined as the edge of a cold pool ($\Delta\theta$ = -1K) at the surface (bold blue line). Dotted area marks region of q_r ¿ 2 g/kg at the ground. Vertical velocity is contoured every 5 m/s for positive values and 2 m/s for negative values. Surface precipitation is contoured every 1 g/kg. The results are plotted for U_s = 15 m/s. Right column represents the results from WK82 experiment).

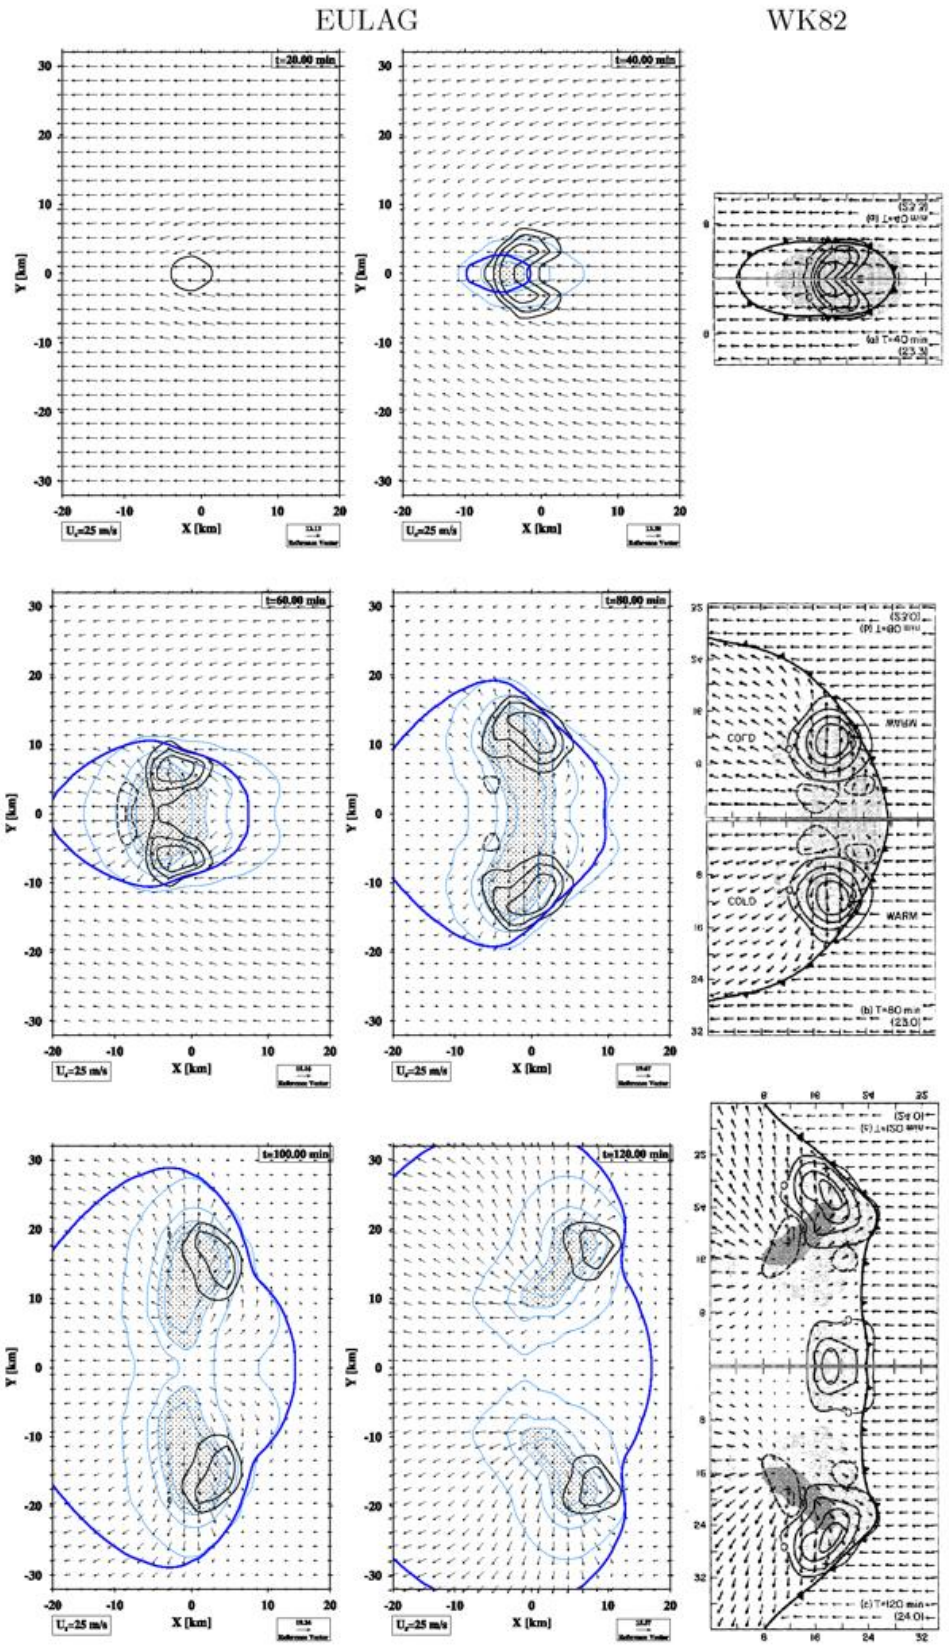

Figure 20: Same as in Fig.19 but for $U_s = 25$ m/s

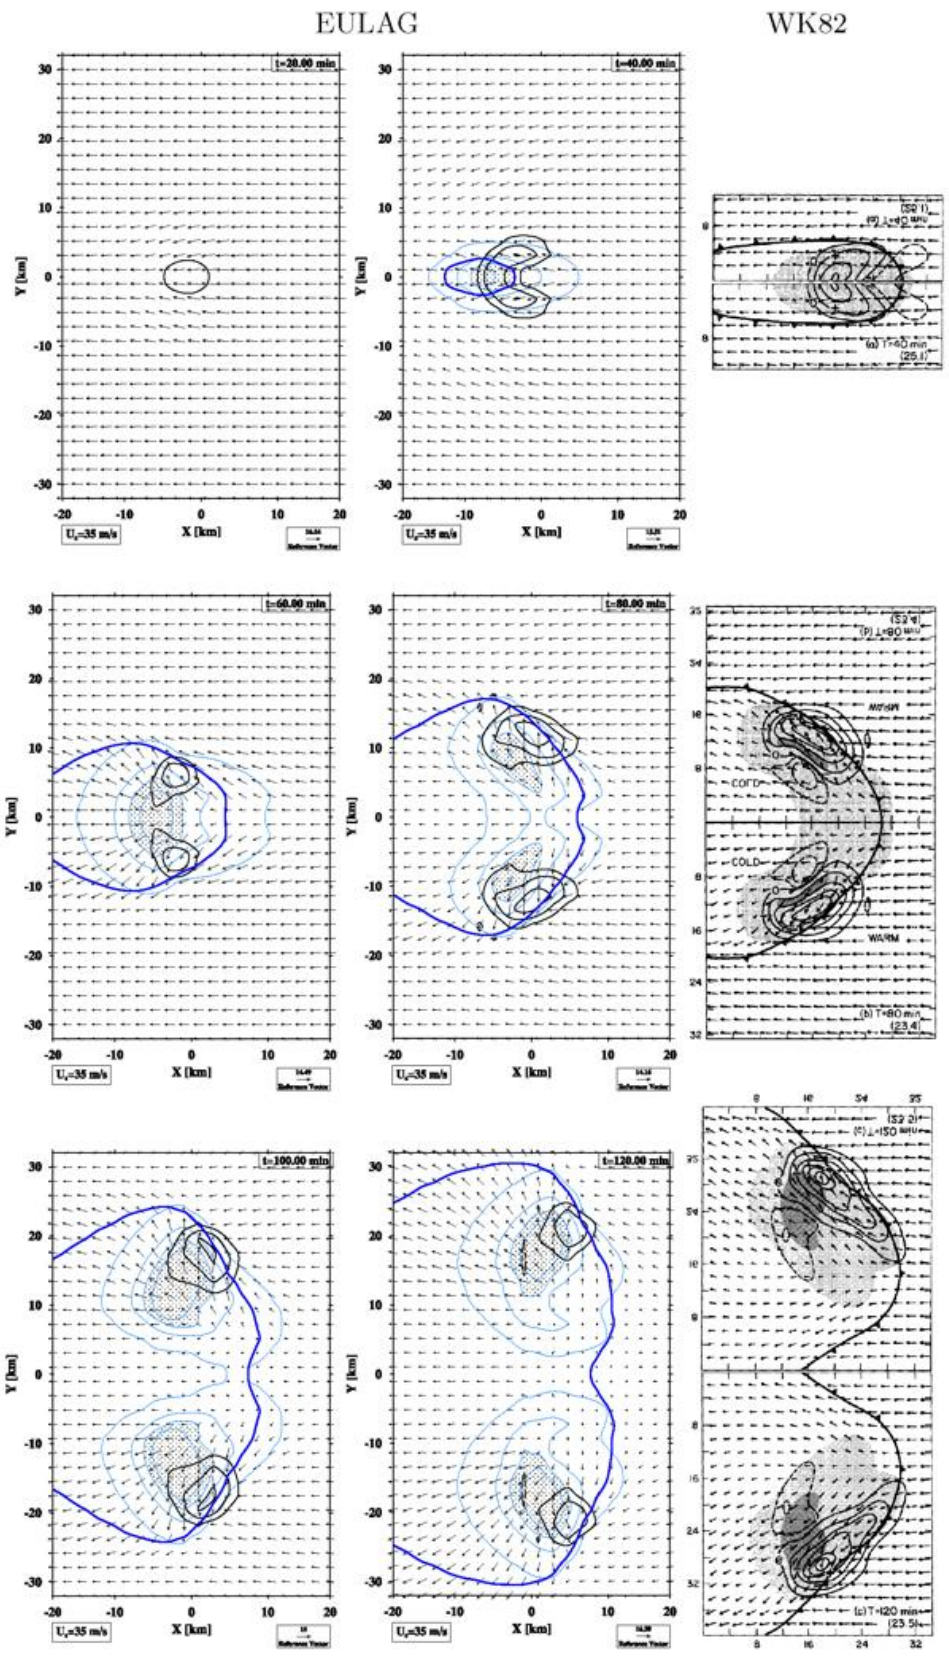

Figure 21: Same as in Fig.19 but for $U_s = 35$ m/s

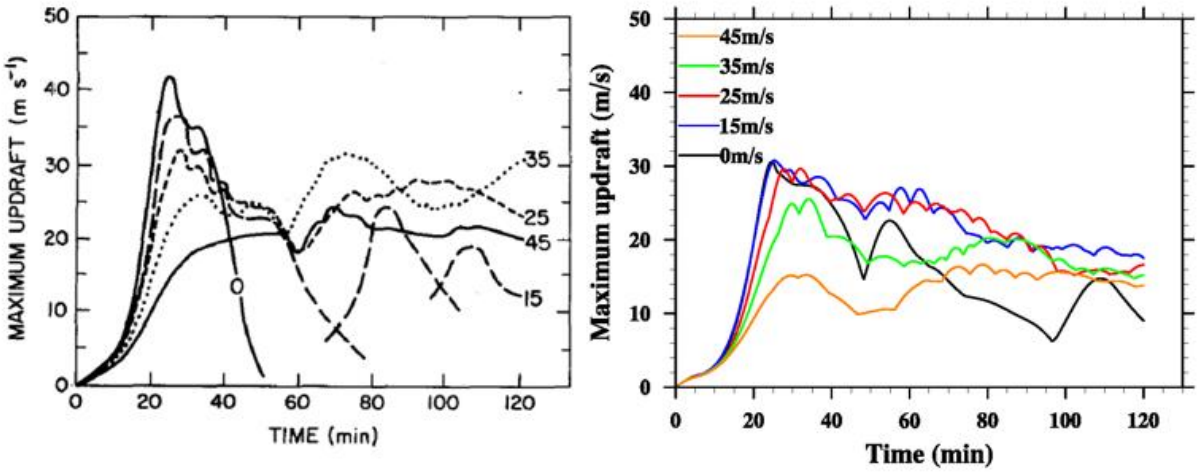

Figure 22: Comparison of the time series of maximum vertical velocity for simulations with different U_s. The results from WK82 (left) and EULAG (right) are shown.

Comparison of the results with WK82 shows that EULAG correctly reconstructs the convective process leading to formation of storm splitting and a cold pool. The main difference concerns buoyancy production that is lower in EULAG simulations. With lower strength of maximum updraft the EULAG simulations yield lower amount of surface precipitation. Additional sensitivity study indicates, however, relatively high sensitivity of convection characteristics to horizontal and vertical resolution. Reducing model's grid box size by a factor of 2 leads to about 40% increase in updraft intensity and about 50% and 10% enhancement for maximum amount of cloud and rain water, respectively. It should be underlined that, for this particular case, the improvement is stronger when horizontal resolution is refined rather than vertical one. The spread of the results is larger than for KW78 experiment, especially for water species. This suggests that we are in a flow regime where the problem is strongly underresolved. Thus a comparison between the models is somewhat burdened with possible susceptibility of the results to the details of numerics (see e.g. discussion in Rosa et al., 2011, on cold density current experiment according to Straka et al., 1998).

Detailed comparison of the storm splitting shows that the EULAG's representation of the process is similar to WK82 in terms of horizontal extent of the cells and the relative distance between them during the storm development. In both cases, formation of rear precipitation is observed in similar regions. The area of the cold pool depends directly on the distance between the cores and is larger for more mature supercells. The main difference between the models is that the storm splitting starts at lower shear strength for EULAG simulation and is already observed for $U_s = 15$ m/s, in contrary to $U_s = 25$ m/s for WK82.

Time evolution of maximum updraft velocity for different values of U_s is shown in Fig. 22. A supercell developing in a resting atmosphere ($U_s = 0$) decays quickly in WK82 but it is able to restore secondary circulations in EULAG simulation. Convection is also less vigorous in EULAG simulations since w_{max} reaches about 30 m/s in contrary to about 40 m/s in WK82. This parameter, however, is especially sensitive to the simulation details, as shown through sensitivity experiment for KW78 and WK82. Generally, the spin-up time is shorter in WK82 than in EULAG. The EULAG's spin-up time depends on the resolution in such a way that for smaller grid box sizes the convection starts earlier. The differences are relatively large as the model reaches first maximum of rain water mixing ratio after 38 min for basic resolution and at about 30 min for a doubled one. Such a time shift is also observed for maxima of cloud and rain water mixing ratios.

3.5 Summary and further development

This section documents the results of two moist benchmark experiments (KW78 and WK82) carried out by the EULAG model in order to verify its performance as a potential candidate for the future dynamical core of weather forecasting model. Both experiments concern formation of supercell in a deep atmosphere, which is unstable to moist convective motions. The results of EULAG simulations show that the model is capable to reconstruct main features of the supercell development, such as storm splitting and a cold pool formation. The EULAG solutions are realistic and compare well qualitatively with the reference solutions from KW78 and WK82 for a wide set of initial conditions (i.e., atmosphere at rest, unidirectional shear flow of different strength, veering wind). In general, the EULAG model yields less intense storm development, however, it is difficult to find the factors controling the results. Sensitivity studies indicate that convection-permitting NWP models operating at resolution of $O(1km)$ are in a strongly underresolved regime where relatively small modifications in resolution can significantly change the result (e.g., about 40% enhancement of the updraft strength for doubled vertical resolution). Moreover, the comparison between different numerical models does not allow for credible estimation/separation of the numerical and mathematical effects in the solution.

More recently, a compressible version of the EULAG model has been developed (see e.g., Kurowski et al., 2013). This created a new opportunity to compare the anelastic and compressible solutions using a highly unified numerical framework, and thus to limit the effects associated with different numerical design of the models. Currently, the model has been verified in a set of moist experiments regarding various scales of the atmosphere. First results of these experiments were already published (Kurowski et al., 2013). As for moist deep convection, the results obtained for Weisman and Klemp (1982) experiment have confirmed high consistency of anelastic and compressible solutions. It was also found that non-hydrostatic pressure perturbations are of negligible importance to the storm development. Concomitantly, sensitivity of the solutions to the numerical details (e.g., resolution) and/or physical parameterizations (e.g., subgrid-scale mixing) turned out to be at least one order of magnitude larger than for mathematical differences. Detailed results of these experiments are expected to be published soon.

Institute of Meteorology and Water Management - National Research Institute, Poland, and MeteoSwiss, Switzerland

4.1 The experiment setup

The aim of the experiment was to test the EULAG dynamical core over realistic high-mountain orography for its robustness and for general physical viability of the solutions and their consistency for varying but very high horizontal resolutions (grid sizes of 2.2, 1.1 and 0.55 km). For such resolutions, the approximation of quasi-horizontal flows is no longer valid, as the models begin to resolve explicitly convective processes. Also, the model-represented inclinations of high-mountain slopes begin to resemble their actual steep values. In consequence, the dynamical cores for very-high-resolution NWP require reliable and robust solvers, which do not compromise the advantages of very high horizontal resolutions via, e.g., the introduction of a strong artificial smoothing of the orography or the simulated flow. The experiment allows also to investigate how increasing horizontal resolutions influence model-represented flow over high and diversified orographies, for horizontal grid sizes that allow a realistic representation of mountain slopes and heights. The detailed description of the experiment and its results can be found in Ziemiaski et al (2011).

The experiment employs the frictionless and adiabatic flow, which allows direct focus on the dynamical aspects of the flow, influenced only by the model-represented orography, independent of the impacts of the parameterized boundary layer physics or moist processes. An additional argument is that knowledge of mountain boundary layer physics is limited, which also concerns its parameterizations (see e.g., Rotach et al., 2008 and references therein). It was important also to employ relatively simple and easy-to-reproduce initial and boundary conditions. The idea of the experiment follows previous studies, where the numerical simulations of mountain flows were used to study varying spatial resolutions on mountain drag, e.g., Clark and Miller (1991), Hoinka and Clark (1991), Salvador et al., (1999), Rontu (2006) and Smith et al., (2006), or to study the influence of varying numerical schemes on the properties of the simulated flows, as in Cullen et al., (2000).

a. Domain

The experimental setup is based on the operational NWP COSMO model employing horizontal grid length of 2.2 km, used by MeteoSwiss (the COSMO-2 model, see description in Leuenberger et al., 2010). It concerns the experimental domain (see Fig. 23) which for 2.2 km horizontal grid spacing involves 520 by 350 grid points, so that the horizontal size of the domain is 1144 by 770 km, respectively. The locations (geographical coordinates) of the grid points for the experiment are the same as for the grid points of operational COSMO-2. For the experiment involving 1.1 km horizontal grid spacing, the locations of the grid points collocate with the grid points of COSMO-2, where possible, while the locations of the additional points are defined via halving the distances between the COSMO-2 grid points. Similarly, the additional grid points for the simulations with 0.55 km grid spacing are calculated by halving the distances between the grid points used for simulations employing the 1.1 km grid. As a consequence, the simulations at 1.1 km grid size employ a 1040 by 700 grid point

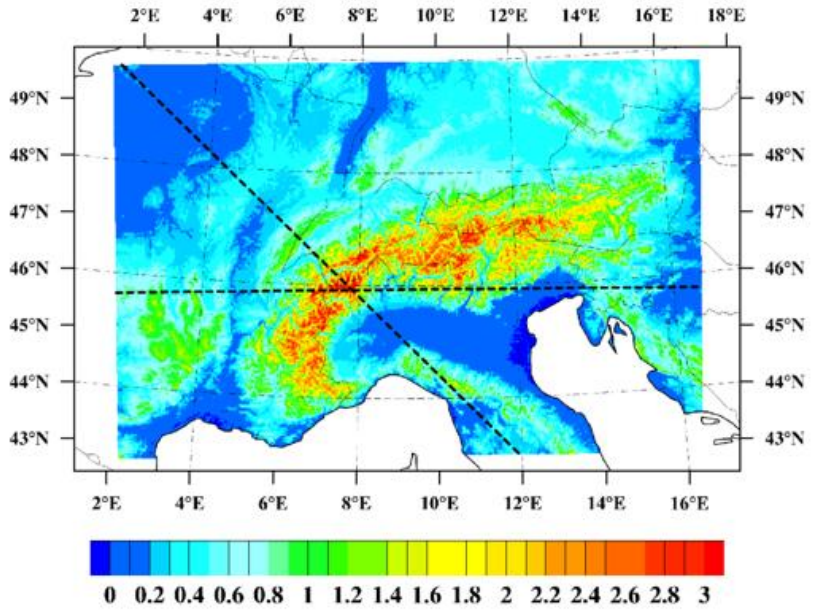

Figure 23: Model orography for 1.1 km grid size (in km, colors), illustrating the orientation of the model domain relative to the main geographic features of the area and political boundaries (thin lines). The thick dashed lines show positions of the cross sections discussed in the paper.

domain, and simulations at 0.55 km grid size employ a 2080 by 1400 grid point domain. The time steps used are 20, 12 and 6 s, for horizontal resolutions of 2.2, 1.1 and 0.55 km, respectively.

The orography for the 2.2 km grid length experiment is the same as the orography employed by COSMO-2. The orography for higher horizontal resolutions was calculated using the satellite SRTM data (Rabus et al., 2003) of approximately 90 m grid size, separate for experiments employing 1.1 and 0.55 km grid length. The satellite data were averaged over the target model grid cells, resulting in a model orography with increasing detail for decreasing grid spacing. No additional smoothing was applied for the data.

In the vertical, the model domain spans from the surface to a height of 23.5 km and employs terrain-following Gal-Chen coordinates (Gal-Chen and Somerville 1975) for the whole vertical extent of the domain using 61 grid levels. The definitions of the grid levels, except the lowest one, are as in the COSMO-2 model, with the vertical grid spacing ranging from about 10 m near the surface to about 500 m in the stratosphere, as is typical for NWP models having relatively high vertical resolution in the near-surface area of the boundary layer. The number and configuration of the vertical grid levels is the same for all the resolutions, employed.

b. The flow configuration

The model employs a free-slip boundary condition on its bottom and top levels, and there are no parameterizations of physical, subgrid-scale processes. The Coriolis force is incorporated into the simulation setup. To avoid the effects of gravity wave reflections from the top of the domain, an absorber was applied above 16 km altitude.

The ambient flow configuration of potential temperature and wind is possibly simple and defined as horizontally uniform. It is imposed by appropriate initial and constant in time boundary conditions. Such a flow configuration is commonly used for idealized simulations

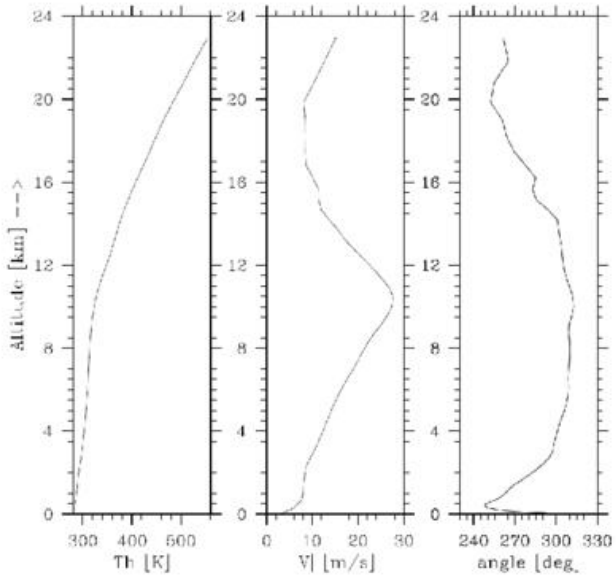

Figure 24: Profiles of the parameters of the ambient flow: potential temperature (left), wind velocity (middle), and wind direction (right).

of deep convective flows (e.g., Klemp and Wilhelmson 1978, Weisman and Klemp 1982, Rotunno and Klemp 1985, Bryan and Fritsch 2002) even though it does not formally preserve the thermal wind balance. It allows for a simple definition of the initial conditions for resolution-dependent configurations of orography.

To ensure that the wind and potential temperature profiles take typical atmospheric values, they are based on an actual meteorological situation in Central Europe on 12 November 2009 at 00.00 UTC. The profiles were calculated as horizontally-averaged wind and potential temperature coming from the operational COSMO-2 analysis of MeteoSwiss. The profiles (Fig. 24) indicate typical moderate north-westerly atmospheric flow of moderate stratification (the Brunt-Väisälä frequency for the lower half of the troposphere equals 0.013 s^{-1}), with a presence of a moderate jet stream characterized by maximum wind reaching 27.6 ms^{-1} at 10450 m above the sea level.

4.2 Results

The aim of the experiment is to analyze and compare the EULAG results for different horizontal resolutions when a quasi-stationary state of the flow is established. The analysis of time-dependent flow diagnostics (not shown) indicates that the flow fields of all simulations have reached a quasi steady-state after 24h of integration time.

a. Surface wind

Figure 25 compares the distribution of the horizontal wind on the second computational level (counting from the Earths surface) of EULAG (located about 10 m above the ground) for the tests using horizontal grids of 2.2, 1.1 and 0.55 km.

For all resolutions used, results have a very high level of consistency and realism. The large-scale flow pattern is practically the same for all resolutions, showing a westerly inflow on the Alpine ridge that divides the flow into two branches around the Alps from north and

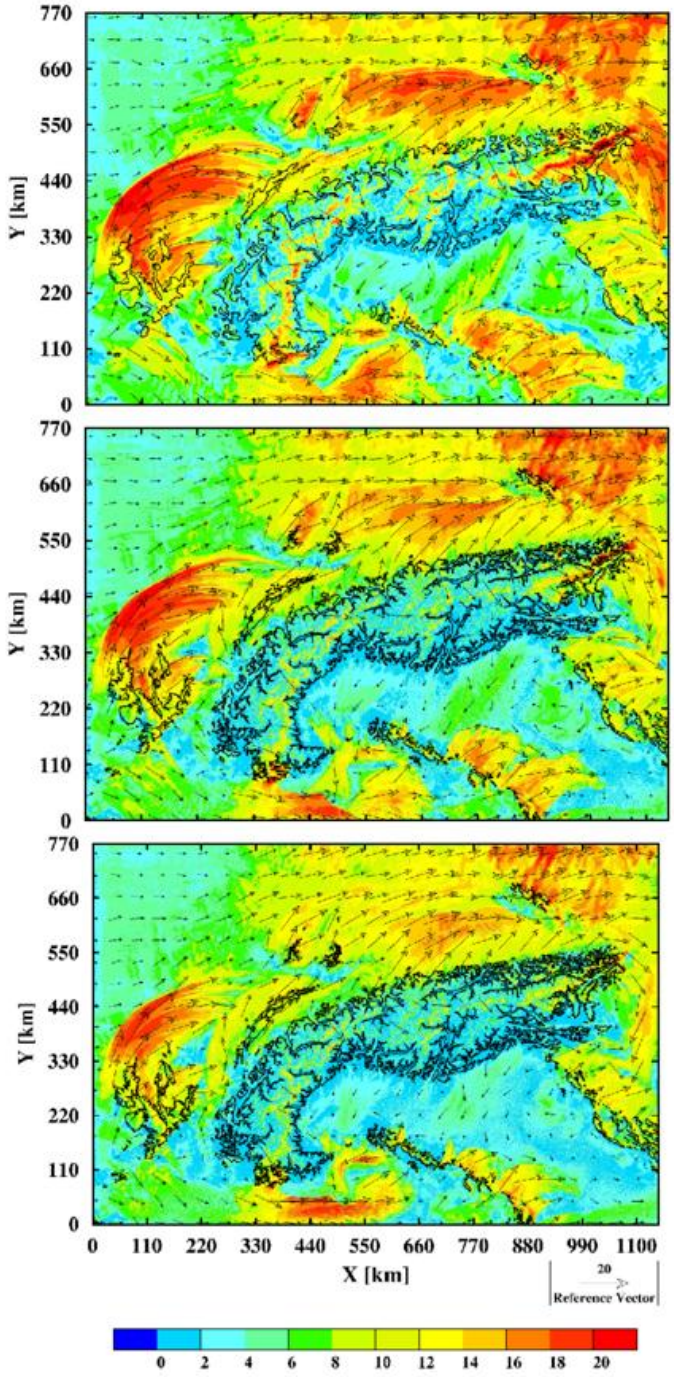

Figure 25: Distribution of the surface (10 m above the ground) wind (arrows) and its speed in m/s (colors) after 24-hours for grid sizes of 2.2 km (upper panel), 1.1 km (middle panel), and 0.55 km (lower panel).

south. The scenario agrees with a blocking condition, characterized by low Froude number (see e.g., Brighton (1978) for laboratory or Smolarkiewicz and Rotunno (1990) for numerical experiments). The Froude number is defined as $F = U/(NH)$, where U is the characteristic horizontal wind velocity, N is the Brunt-Väisälä frequency, and H is the characteristic mountain height. For the characteristic wind speed and stability defined by the ambient temperature profile, it is about 0.2. There is also a signature of an easterly circulation, opposite to the ambient wind, that turns into a southerly flow west of the windward slopes of the western Alps, consistent with the blocking condition. On the lee, southeastern side of the Alps (Po Valley), a weak-to-moderate easterly and northeasterly flow is also present. The Rossby number, assuming a half-width of the Alpine ridge ranging between 100 to 400 km and the wind speed in the lower troposphere in the range of 5 to 10 ms^{-1}, is less than 1 (for average values of the above parameters, its value is 0.3), indicating that Coriolis effects limit the spatial extent and strength of the return upstream circulation (Pierrehumbert and Wyman, 1985), in agreement with the simulation results.

All the experiments show the presence of many mesoscale (size of about 100 km) features of the wind distribution. They show the flow response to the topography and especially to its mesoscale features of sizes and elevations smaller than that of the Alps. Areas of enhanced flow are mainly located over and north-northwest of major terrain obstacles. This effect is particularly evident in the Massif Central, the western Alps and Jura, Vosges, and Schwarzwald. South of the Alps, such areas are located over the Ligurean Sea, south of the Gulf of Genoa, on the lee side of the Appenines, and on the lee side of the Dinaric Alps on the Balkan Peninsula. Areas of pronounced deceleration of the flow are the upper parts of the Saône and Rhine Valleys, and the area west of the Sumava Mountains. South of the Alps, two pronounced areas of relative deceleration are parts of the Gulf of Genoa and of the Adriatic Sea south of the Gulf of Venice.

The prominent difference between the simulations at different horizontal resolutions involves the flow magnitude. While the domain-averaged wind velocity on that level equals 9.09 ms^{-1} for 2.2 km grid size, it is 8.16 and 7.25 ms^{-1} for grid sizes of 1.1 and 0.55 km, respectively. As the simulations do not employ an explicit drag, the results show the influence of terrain-induced form drag of the explicitly represented orography (see e.g., Welch et al., 2001), which increases significantly at higher resolutions. This extends the findings of Clark and Miller (1991) and Smith et al., (2006) to higher resolutions.

Figure 26 shows that the patterns of wind speed differences between the simulations employing different resolutions span a range of scales from the smallest to hundreds of kilometers. The amplitudes of the differences are relatively high and reach -19 to 17 m/s for the difference between 1.1 and 2.2 km grid lengths, -20 to 19 m/s for the difference between 0.55 and 1.1 km grid lengths, and -24 to 17 m/s for the difference between 0.55 and 2.2 km grid lengths. Horizontally, the most extended difference patterns are located over the outskirts of the Alps and form elongated areas aligned with the wind direction (see Figure 3). The narrow streaks of extremum wind speed differences in such structures can be identified with differences in spatial extent of main mesoscale features of wind distribution, discussed above. There are also many features on a scale of about 100 kilometers, where the amplitudes of wind speed differences exceed 10 ms^{-1} and have both signs. They primarily occur in areas between or on the lee sides of main orographic features. Frequently, these flow features are systematic enough to be recognized on all the figures by their similar location and size, and they frequently have the same sign. Therefore, increasing the resolution to grid sizes of 1.1 and 0.55 km tends to have a similar effect on the mesoscale differences of the simulated flow. On the other hand, the differences between simulations with 0.55 and 1.1 km grid lengths tend to be smaller in terms of horizontal sizes and magnitudes. There is also an abundance of very small-scale differences in the wind speed pattern - of an amplitude of a few m/s -

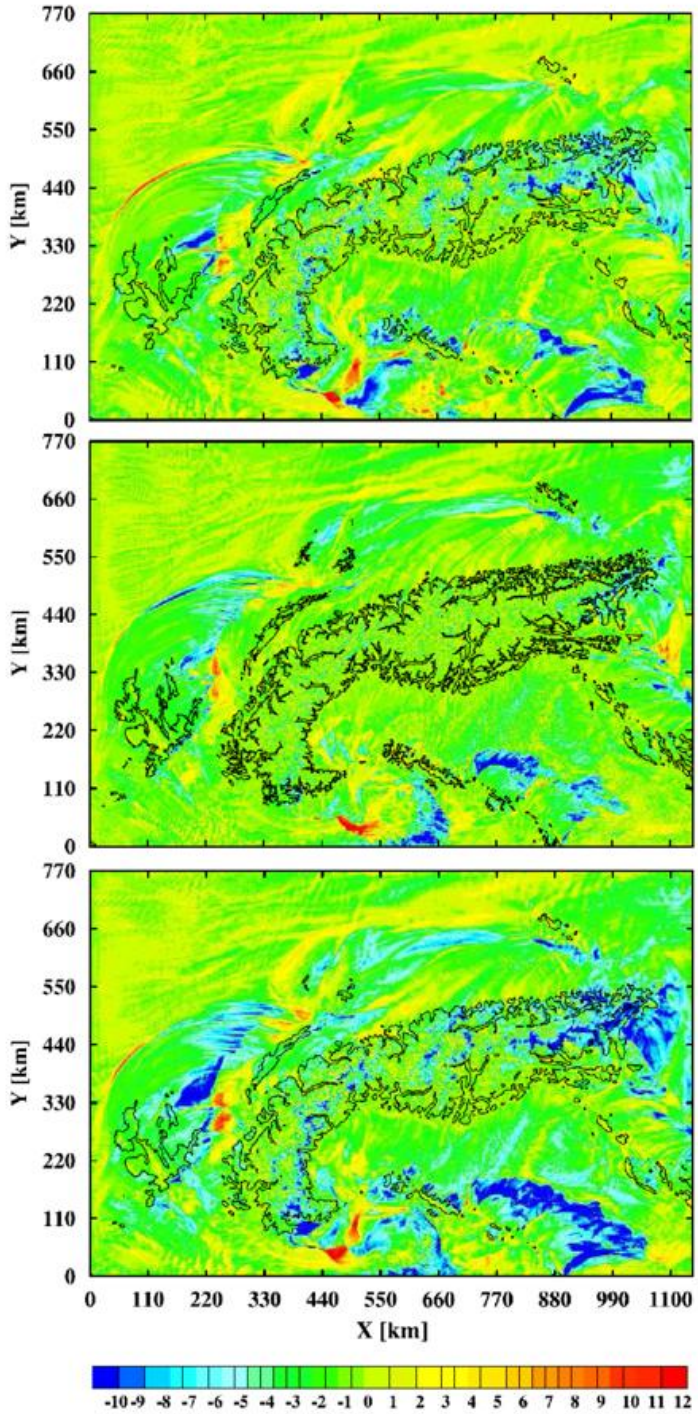

Figure 26: Distribution of the differences for surface (10 m above the ground) wind speeds in m/s (colors) after 24 hours. These difference plots compare the experiment using 1.1 km grid size (averaged to 2.2 km grid box) with the one using 2.2 km grid size (upper panel), the experiment using 0.55 km grid size (averaged to 1.1 km grid box) with the one using 1.1 km grid size (middle panel), and the experiment using 0.55 km grid size (averaged to 2.2 km grid box) with the one using 2.2 km grid size (lower panel).

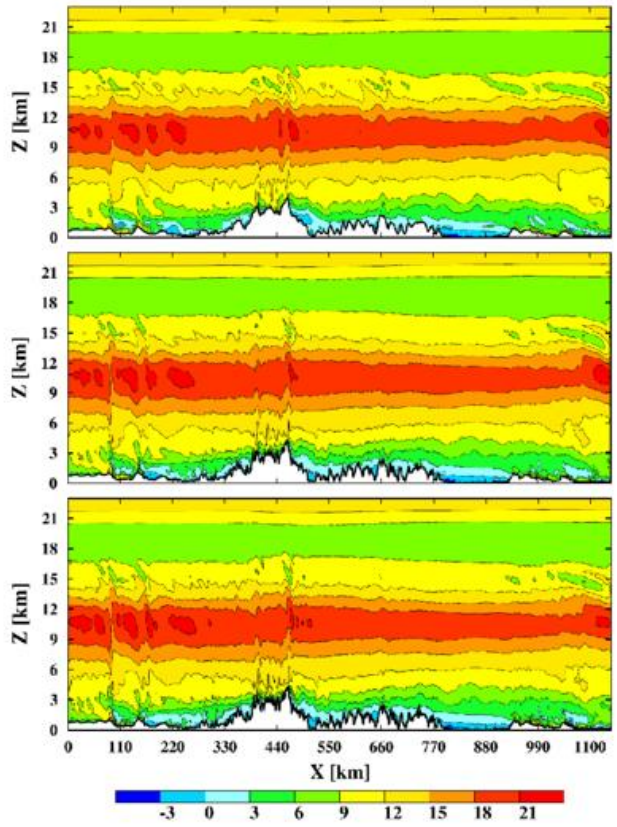

Figure 27: Vertical cross section through the u-component of wind (in ms^{-1}) after 24-hour simulations, for grid sizes of 2.2 km (upper panel), 1.1 km (middle panel), and 0.55 km (lower panel).

both over the relatively flat terrain (including sea surface) and over orographic features.

b. Vertical wind structure

Figure 27 shows west-east vertical cross sections of the u-component of wind velocity, along a line crossing the highest surface elevation represented by the model (Mt. Rosa). The general pattern of the flow is very similar for all the horizontal resolutions in the study. Its main feature is a moderate jet stream, and there are a number of mesoscale flow features over the whole domain. In the jet stream area, the locations and overall shapes of the mesoscale features are similar for all the simulations, which include e.g., pronounced acceleration areas above and in the lee of the Massif Central (left), over the Mt. Rosa area, and in the lee of the Dinaric Alps (right). Small-scale details differ between the simulations: very sharp horizontal wind gradients above the Massif Central and the Cevennes are especially pronounced, and they are reproduced with more detail and sharper gradients as the resolution increases.

The flow variability is closely related to mountain wave activity, which is abundant in the whole model domain and occurs on scales of about 50 km and smaller. All the simulations show similar flow features on the horizontal scales between 20 and 50 km (e.g., the structures over the Massif Central and the Cevennes, or over the Dinaric Alps). But there are also many smaller-scale features that differ significantly between the simulations.

Figures 28 shows the u-components of wind for a magnified part of the domain shown in Figure 27 located in the vicinity of the highest Alpine peaks (the x-coordinate is the same for

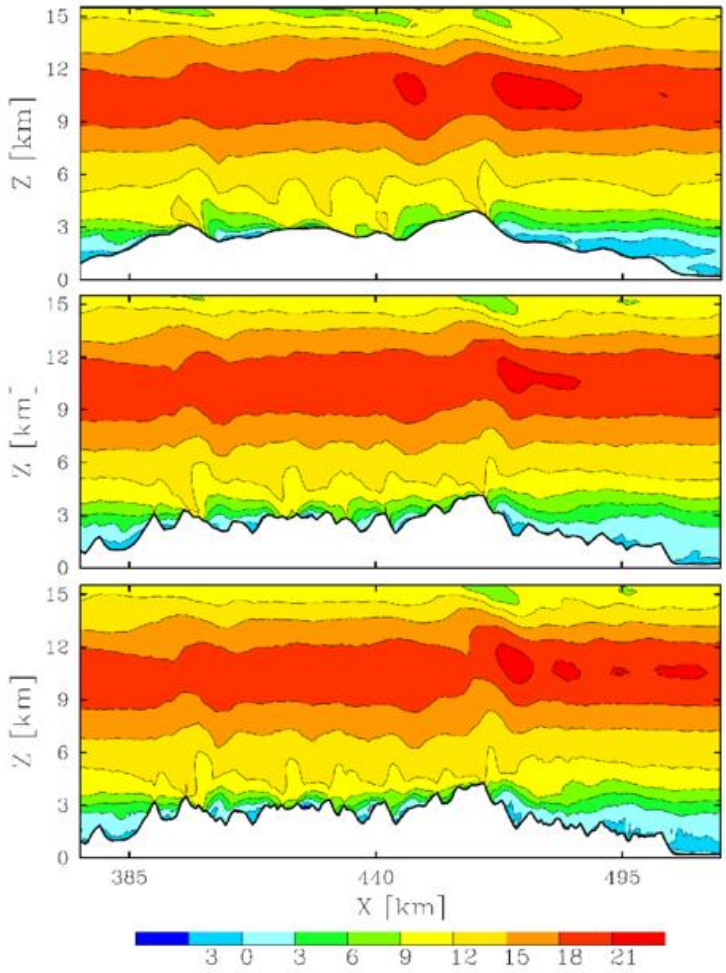

Figure 28: Closer view of the wind u-component (in m/s) over the highest Alpine peaks shown in Fig. 27 for a more detailed comparison as model resolution increases. Upper panel shows model output at 2.2 km grid size, middle shows 1.1 km grid size, and lower shows 0.55 km grid size.

all three figures). It confirms that the overall flow pattern is similar for all three resolutions. The differences are especially evident in many small-scale details of about 1 to 20 km in horizontal size for the u-component of the wind. They are seen in the jet stream area, particularly in the spatial structure of the maximum wind pattern. The largest differences appear, as expected, in the near-surface flows. Some of the differences represent circulations related to valleys, peaks, or ridges, represented only with very-high-resolution orography.

Qualitatively similar results are found for the v-component of the horizontal velocity (not shown).

Table 5 compares the RMS wind speed differences between simulations of different horizontal resolutions. It uses the 0.55 km simulation as the reference and compares data interpolated to a fixed height above ground (or above mean sea level). The comparison is done using grid point values and only grid points present in coarser resolution are used. To focus on the mountain regions, the comparison concerns areas of surface elevations exceeding 800 m above the mean sea level, for orography employing 0.55 km horizontal grid length. The table shows the wind differences on a few near-surface levels (at 20, 100, 500 and 2000 m above the ground) and on a few levels representing middle and upper troposphere (5, 6, 7 and 10 km

Altitude (m) above surface	RMS wind speed difference (m/s) between models of grid sizes (km):	
	0.55-2.2	0.55-1.1
20	3.92	1.83
100	3.80	1.64
500	2.87	1.10
2000	1.65	0.72
Altitude (m) above mean sea level	RMS wind speed difference (m/s) between models of grid sizes (km):	
	0.55-2.2	0.55-1.1
5 000	1.12	0.39
6 000	0.73	0.28
7 000	0.57	0.28
10 000	0.91	0.32

Table 5: RMS wind speed difference between simulations with 0.55 and 2.2 km grid sizes and between simulations with 0.55 and 1.1 km grid sizes, at selected altitudes above the surface and above mean sea levels. The differences are calculated only over the areas of surface elevation exceeding 800 m above mean sea level.

above the mean sea level). The table demonstrates larger differences between experiments with 0.55 km and 2.2 km grid sizes as compared to the differences between the experiments with 0.55 km and 1.1 km grid sizes. The largest differences between the experiments are located just above the surface, with values reaching almost 4 m/s for comparison between experiments with 0.55 and 2.2 km grid sizes. The differences diminish rapidly above 100 m height. The differences still decrease with height in the middle troposphere, but tend to increase near the tropopause.

c. Potential temperature

The general pattern of the potential temperature field is very similar for all three resolutions, and only small-scale details differ between the simulations (not shown). The differences are largest in the near-surface layer. They are due to both the ambient relation between the temperature and height, and the differences in the orographically induced flows. Also, the undulations of the isentropes in the near-surface layer of about 2 km depth above the Alpine ridge tend to have larger amplitudes for higher-resolution simulations. The differences between the simulations are hardly noticeable in the middle and upper troposphere.

Table 6, calculated analogously to Table 5, shows the RMS differences in the potential temperature between the simulations using interpolated values at the selected height levels. The table shows that the differences between simulations with 0.55 km and 2.2 km grid lengths are larger than the differences between experiments with 0.55 km and 1.1 km grid lengths. The largest differences are located in the near surface layer, and are in the range of 1 and 0.6 K for comparison with 2.2 km and 1.1 km grid simulations, respectively. In the middle troposphere the differences reach about one third of the surface values and increase in the tropopause area.

Altitude (m) above surface	RMS potential temperature difference (K) between models of grid sizes (km):	
	0.55-2.2	0.55-1.1
20	0.97	0.56
100	0.83	0.47
500	0.71	0.36
2000	0.52	0.25
Altitude (m) above mean sea level	RMS potential temperature difference (K) between models of grid sizes (km):	
	0.55-2.2	0.55-1.1
5 000	0.37	0.18
6 000	0.37	0.17
7 000	0.22	0.09
10 000	0.33	0.15

Table 6: RMS potential temperature difference between simulations with 0.55 and 2.2 km grid sizes and between simulations with 0.55 and 1.1 km grid sizes at selected altitudes above the surface and above mean sea levels. The differences are calculated only over the areas of surface elevation exceeding 800 m above mean sea level.

d. Vertical velocity

Figure 29 shows the horizontal distribution of the vertical velocity at level 40, located in the free atmosphere at a height of about 10400 m for all simulations. While the general pattern of the main features of the vertical velocity distribution is basically similar for all three resolutions, and while the regions of gravity wave activity do not change, significant small-scale differences are also present. In all simulations, it is common for the main patterns of the vertical velocity to be located in the vicinity of orographic features with the wave crests typically oriented perpendicular to the mean flow direction. This description generally applies to the Massif Central and the Cevennes, the Vosges Mountains and Schwarzwald, and the Sumava Mountains and the Alps. The amplitudes of the vertical velocity are in the range of 0.5 m/s, which is a realistic value.

For the area above the Alps, the pattern of the vertical velocity structure is generally similar for all the simulations in the sense that the main activity is located over the eastern slopes of the southwestern Alps and over the central crests of the eastern Alps. There are, however, clear differences. As the horizontal grid size of the model diminishes, the wave activity over the main Alpine body seems less pronounced as its spatial extent is also smaller and the wave amplitudes tend to be smaller in the area. In contrast, the wave activity over the areas south of the southwestern (Maritime) Alps and southeast of the eastern Alps seems to be at least as vigorous as for the coarser resolution simulation, but with a more complicated wave structure and many additional small-scale details.

Figure 30 presents vertical cross sections of vertical velocity, crossing the highest surface elevation of the model (Mt. Rosa), along the wind direction in the middle and upper troposphere and spanning the full model domain (see Figure 23 for the exact location of the cross-section). It shows similarity of the high-amplitude component of the wave distribution

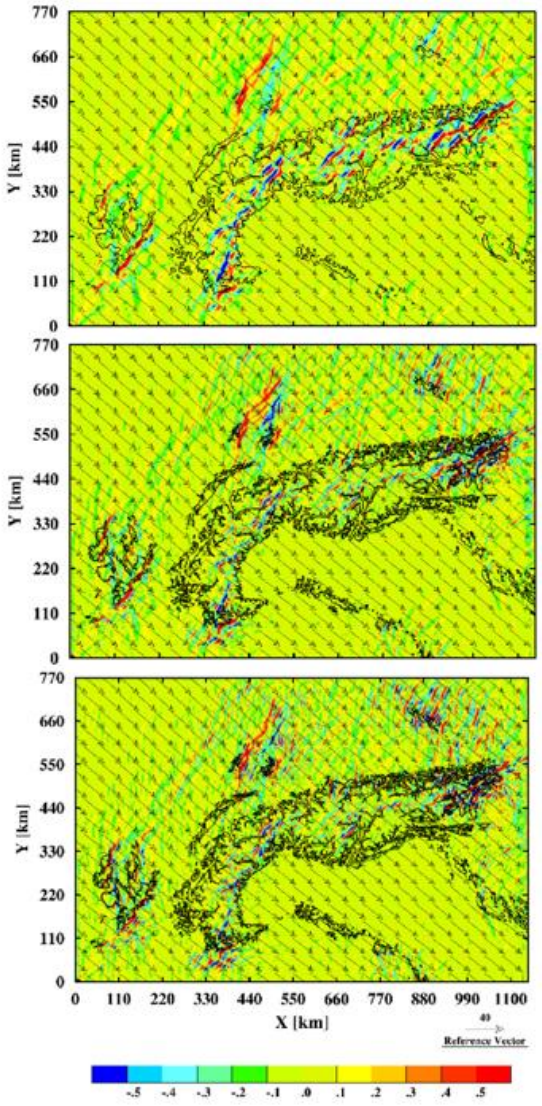

Figure 29: Horizontal distribution of wind (arrows) and the vertical velocity in ms^{-1} (colors) at 10400 m height after 24-hour simulations for grid sizes of 2.2 km (upper panel), 1.1 km (middle panel), and 0.55 km (lower panel).

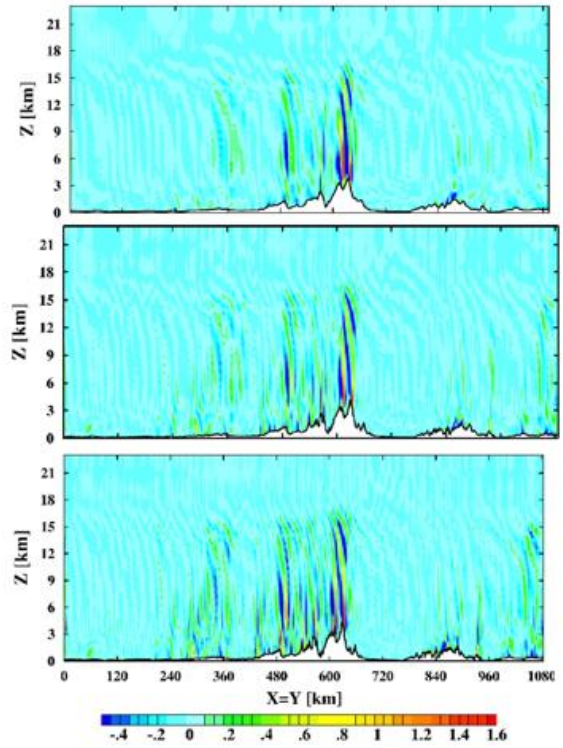

Figure 30: Vertical velocity distribution (colors in m/s) after 24 hours for simulations with grid sizes of 2.2 km (upper panel), 1.1 km (middle panel), and 0.55 km (lower panel). The cross section is oriented along the prevailing wind in the middle and upper atmosphere.

for different resolutions, but it confirms also the significant influence of horizontal model resolution on the simulated structure of vertical velocity. The differences appear in both the relatively low highlands, like the Plateau de Langres, where the 2.2 km grid shows the presence of only a single wave pattern in the middle and upper troposphere. In contrast, the higher resolution simulations show rich wave structures of slightly larger amplitudes in the middle troposphere and significantly higher amplitudes near the surface. The differences are also clearly seen above the higher mountains, especially in the area between the Jura and Mt. Rosa, where the higher-resolution simulations have significantly richer wave structures characterized by larger amplitudes.

Figure 30 shows a detail of Figure 29 over the Alps. The significant influence of the horizontal model resolution on the vertical velocity distribution is seen by the presence of the complicated wave pattern in the area west of the Rhone Valley (left), obtained with the highest-resolution simulation. For the common features, the 0.55 km grid size gives significantly higher amplitudes and more realistic wave structures for the wave triggered by the Jura (the western part of the figure) and the eastern parts of the Bernese Alps. The wave pattern and magnitudes of extremes triggered by the Pennine Alps, including Mt. Rosa, are similar at all three resolutions. However, the higher-resolution simulations show many small-scale details of the structure, especially in the near-surface layer, where small-scale terrain features play an important role in forming the shape of the wave pattern. For the area roughly 2 km above the surface, the influence of the larger scales prevails and the differences between the simulations become smaller.

The realism of the simulations can be further confirmed by noticing that the wave crests tend to change to a horizontal orientation in the upper part of the domain. This is a typical

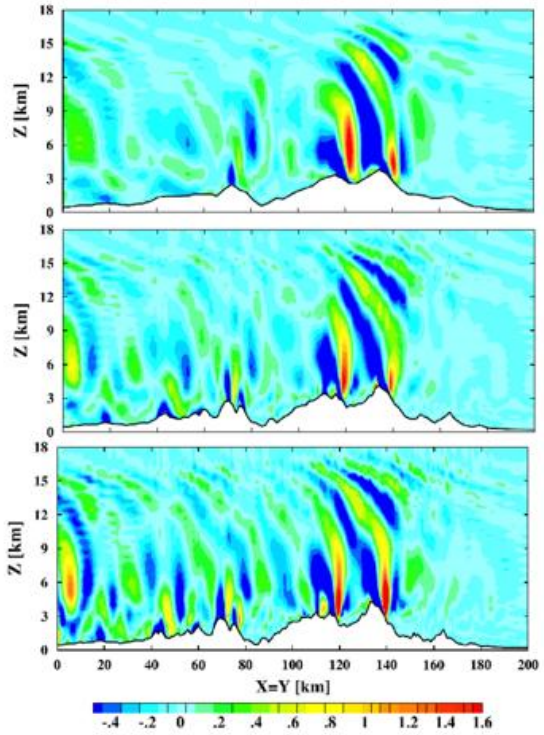

Figure 31: Enlarged picture of the flow over the Alps.

behavior for a gravity wave in the presence of the critical layer, where the phase velocity of the wave equals the flow velocity. For the Brunt-Väisälä frequency on the order of 0.013 s^{-1}, and the wavelength in the horizontal and vertical directions on the order of 10 km, estimates place the critical velocity in the range of 20 m/s which corresponds well to the typical wind speeds found in the upper troposphere. This suggests the presence of the critical layer in our simulations and confirms the physical consistency of the simulated gravity waves.

Table 7 shows the RMS differences of the vertical velocity between the simulations at selected levels, for the areas with surface elevations above 800 m and not averaged to the coarser grid. It shows that the differences between experiments with 0.55 km and 2.2 km grid lengths are larger than the differences between simulations with 0.55 km and 1.1 km grid lengths. While the differences between analyses of velocities and potential temperature presented in Figure 30 and Tables 5 and 6 are relatively small, they are larger for the vertical wind. Table 7 shows that the vertical velocity differences between the solutions over higher elevations are almost three times larger than average. This is confirmed by a qualitative analysis of Figures 29 to 30, suggesting that vertical velocity perturbations are spatially related to the areas of highest elevations, and that the horizontal resolutions significantly affect the vertical velocity pattern. Over the mountains, the RMS differences are highest in the near-surface layer, reaching almost 0.9 m/s for the comparison between the experiments with 0.55 and 2.2 km grid lengths. They decrease with height by about one third at 2000 m altitude. In the middle and upper troposphere the difference still diminishes with height, consistent with Figure 30a.

4.3 Summary and conclusions

The tests show the numerical robustness of the EULAG dynamical core, as no numerical problems were encountered during the simulations and no artificial measures, like flow or

Altitude (m) above surface	RMS vertical velocity difference (m/s) between models of grid sizes (km):	
	0.55-2.2	0.55-1.1
20	0.87	0.54
100	0.80	0.47

orography smoothing, were applied to achieve the results. The scales of the values of the flows physical parameters are represented correctly. This concerns especially vertical velocity, magnitude of which is sensitive to possible problems in the model setups. This suggests that an anelastic dynamical core like EULAG has numerical robustness appropriate for NWP purposes at horizontal grid sizes of at least $O(1km)$.

The analysis of the results, especially of the spatial distribution of different parameters characterizing the flow and their comparison for varying horizontal resolutions, shows that the results are realistic and highly consistent. Results indicate a realistic low-level flow pattern characteristic of mountain blocking, and the presence of characteristic mesoscale features related to the flow over specific terrain features like large valleys, highlands, and mountains. The vertical flow structure shows that the orography significantly influences regional and local circulations, including low-level circulations like valley flows, but especially mountain waves, and the whole troposphere including the structure of the jet stream.

The flow structures are consistent between the three model resolutions, especially for flow features having characteristic sizes of 20 km and more. However, the differences between simulations involve a wide range of scales and are not limited solely to the barely resolved scales. The differences are seen especially clearly and abundantly in the near-surface tropospheric layer at a depth of about 1.5 to 3 km. For surface wind, differences between the three solutions have characteristic structures of horizontal sizes varying from hundreds of kilometers to the smallest resolved by the model, the amplitudes of the differences reach up to 20 m/s, and the RMS difference reaches 4 m/s. From the viewpoint of NWP, the near-surface area is highly important for a majority of the forecast users, including aviation.

5 Semi-realistic flow over the Alps with the COSMO-EULAG model

Michał Ziemiański, Marcin J. Kurowski, Zbigniew P. Piotrowski, Bogdan Rosa, Damian Wójcik

Institute of Meteorology and Water Management - National Research Institute, Poland

5.1 Introduction

This section reports on semi-realistic simulations of weather for the Alpine region using a prototype COSMO model equipped with the anelastic dynamical core. The prototype couples the dynamical core of the EULAG model with a limited set of standard COSMO parameterizations. The report begins with a brief description of the implementation of the EULAG dynamic core into the operational software environment of the COSMO model. Next, it shows the results of testing the COSMO-EULAG prototype (CE) for a simulation of mesoscale weather for 24 hours forecast at three different horizontal resolutions i.e. with 2.2, 1.1 and 0.55 km horizontal grid size. The CE results for 2.2 km grid are compared with analogous results obtained using the COSMO model employing standard Runge-Kutta dynamical core and the same limited set of physical parameterizations (RK) to evaluate the viability, consistency and correctness of the CE results. The goal of the comparison is to assess whether the anelasticity of the CE dynamical core has noticeable detrimental effect on the simulation results. Also, the CE results for various resolutions are inter-compared and analyzed to assess whether they are consistent, realistic and robust.

Both model setups involve physical parameterizations of boundary layer effects with surface fluxes, radiation and moist processes. The experiment employs also realistic initial and changing in time boundary conditions for a selected actual weather situation, provided by MeteoSwiss and taken from its operational data. The experiment has, therefore, a higher degree of realism comparing with the one described in the previous section, but the model prototype is still not in a full and consistent NWP setup.

5.2 The COSMO-EULAG prototype

The implementation of the EULAG dynamical core into the COSMO operational environment required addressing a number of technical issues. First, the EULAG dynamical core has been translated from Fortran 77 to Fortran 90/95 which allowed the implementation of alternative programming structures required by the COSMO programming standards. Common blocks were replaced by modules, and the data structure in the translated code is based on explicit dynamic memory allocation. The MPI communication of the CE model was organized in a consistent way with COSMO framework. The key steps of the implementation and the relevant technical details regarding translation have been reported by Wojcik et al. (2012).

The coupling of the two codes (COSMO and EULAG) required a development of specially designed interface. Its main purpose was to allow a data communication between dynamical core and physical parameterizations applying different types of computational grids. The nodal points of the EULAG grids are non-staggered (A-grid) whereas algorithms of COSMO parameterizations have been developed for the staggered C-grid.

The interface is designed according to the rule that the COSMO mass levels and mass

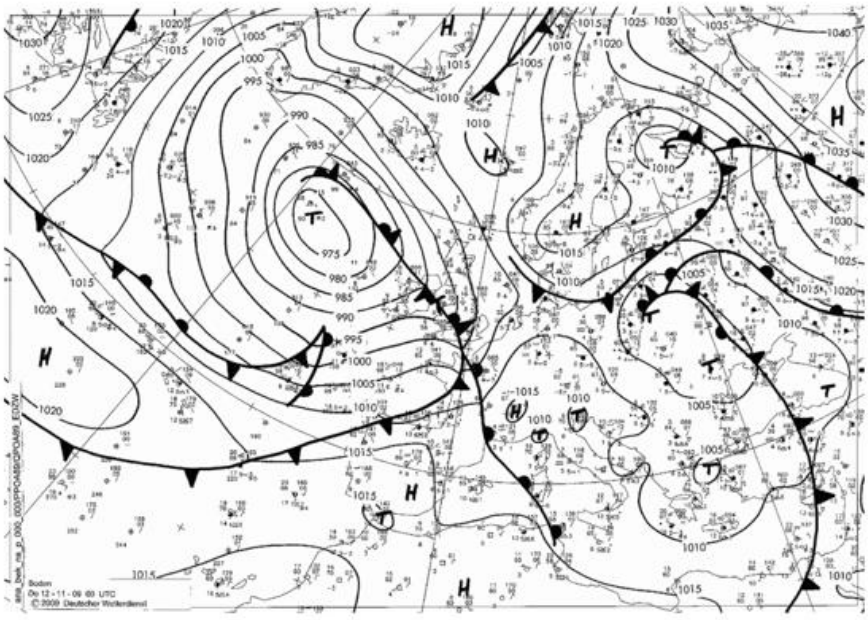

Figure 32: Surface synoptic chart of Europe for 12 November 2009, 00:00 UTC.

points collocate with the EULAG computational points and levels in order to avoid spatial interpolation of the mass-related flow parameters. In order to provide the bottom boundary conditions for the vertical component of velocity (w), an additional EULAG level is provided just at the ground. Its physical flow parameters are the same as the parameters on the next EULAG level collocated with the first COSMO mass level (counting from the surface) in order to ensure consistent values of the flow parameters from the finite-volume-wise view point (alteration of the physical parameters within the surface level would result in alteration of volume averaged values in the COSMO finite volumes around its lowest-lying mass points).

With such an approach, the interface requires interpolation of velocity values between grid A and C while providing information from the dynamical core to the parameterizations, and interpolation of their forcings, diagnosed by COSMO parameterizations, between grid C and A. It transforms also potential temperature of EULAG to temperature of COSMO, as well as temperature forcing from COSMO parameterizations to potential temperature forcing to be used by the dynamical core.

5.3 The experiment setup

The tests are based on 24-hour simulation of an Alpine flow using the COSMO model with the RK and CE setups, both using the same limited set of physical parameterizations. The employed parameterizations are:

- Vertical Turbulent Diffusion
- Surface Fluxes Louis (1979)
- Radiative Transfer Scheme Ritter, Geleyn (1992)
- Multilayer Soil Model
- Moist Microphysics with prognostic variables including rain, snow, ice and graupel.

Figure 33: Wind velocity (color scale and wind arrow length) and direction (wind arrow direction) on the 10 m model level for 12 hour (left panels) and 24 hour (right panel) forecast for the CE (upper panels) and RK (lower panels) model versions.

There was no special tuning of the physical parameterizations for the CE setup and their parameters took values tuned for the operational COSMO model using the RK dynamical core.

a. Domain

Similarly to the semi-realistic tests described in the previous section, the experiment setup is based on the COSMO-2 model of MeteoSwiss. Its domain (see Fig. 23 of the previous section), orography, vertical Gal-Chen coordinates and computational layers are configured as for the experiment described in the previous section. Only the size of the computational domain for the experiment employing 0.55 km resolution was limited and covers only a part of the full COSMO-2 domain (see Fig. 41) due to computational reasons.

b. The flow configuration

The experiment follows the actual operational COSMO forecast for 12 November 2009 and involves a 24-hour simulation starting at 00:00 UTC. The initial conditions are the same for RK and CE runs and are taken from operational data of MeteoSwiss. It concerns also the boundary conditions, which are interpolated linearly in time from the hourly data sets.

The synoptic situation, chosen, involves a moderately stratified westerly flow with a moderate

Figure 34: As in Figure 33 but for the 10th model level (approximately 500 m above the ground level).

jest stream. It features a relatively shallow low-pressure system with atmospheric fronts traversing the simulation domain (Fig. 32).

5.4 Results

An analysis of the simulation results is presented below. It compares the wind velocity distribution, cloud water and cumulative surface precipitation for the RK and CE models. Both models use 2.2 km grid size and their results are compared for 12 and 24 hour forecast. Also, the CE results after 12 and 24-hour forecasts are inter-compared for varying resolutions of 2.2, 1.1 and 0.55 km and analyzed.

RK and CE comparison

Figure 33 presents the wind velocity at 10 m above the ground (the first COSMO computational level) for 12 and 24 hour forecast for the CE (upper panels) and RK (lower panels) versions of the model. For both realizations, the general pattern of the flow is practically the same and follows the synoptic situation with weak to moderate south-westerly flow in the western part of the domain and relatively weak variable flow in the rest of the domain which is influenced by the anticyclonic pressure system. Moreover, both simulations very similarly represent the mesoscale structure of the flow with the same patterns of flow acceleration and deceleration(see for instance the pronounced flow patters over the Genoa Bay and Adriatic

Figure 35: As in Figure 33 but for the 26th model level (approximately 4600 m above the ground level).

Sea). Also the wind velocities are very similar for both model versions, with a tendency of the CE solution for slightly higher wind speeds. The effect is especially seen over the Alps. That may result from the lack of tuning of the parameterizations for the CE setup (note the diminishing surface wind velocities of the CE simulations for increasing resolutions, described below). The pattern of the flow areas with nearly zero wind velocities suggests also more patchy (spatially variable) structure of the CE velocity field within the smallest resolvable scales.

Figures 34, 35 and 36 present, respectively, the wind velocity on different computational model levels ranging from level 10 (approximately 500m above the ground), to 26 (approximately 4600 m above the ground) and 40 (approximately 10 km above the ground). Note that the levels are counted from the ground level up (that is opposite to standard COSMO level counting) and the approximate heights of the computational levels concern areas where the ground surface is located at the mean sea level. The results are for 12 (left panels) and 24 hour (right panels) forecast for the CE (upper panels) and RK (lower panels) versions of the model.

The figures show that both the synoptic and mesoscale patterns of the flow as well as wind velocities are to very high degree the same for both simulations and the similarity is even greater, comparing with the surface wind field, for the flow less or not affected by the friction. Only some differences are noticeable for wind velocities. For 10 and 26 model levels (lower and middle troposphere) CE gives slightly higher wind velocities in constrained, localized

Figure 36: As in Figure 33 but for the 40th model level (approximately 10 km above the ground level).

areas, especially immediately north of the Alpine ridge (see the 12 hour forecast at 10 level and 24 hour forecast at 26 level). For level 40 (near the tropopause) the situation is different: the CE solution brings slightly lower wind velocity at areas just over the Alpine ridge (for 12 and 24 hour forecast) and on the lee side of the Alps (for 24 hour forecast). That suggests generally stronger effects of the explicitly resolved orographically induced gravity wave drag in the CE representation of the flow.

Figure 37 presents the vertical cross section through the fragment of wind velocity field in the vicinity of Mt. Rosa. The orientation of the section line is from north-west to south-east (similar to Figure 27 of the previous section), for 12 hour (left panels) and 24 hour (right panel) forecast for the CE (upper panels) and RK (lower panels) model versions. The figure shows clear similarity of the general pattern of the flow but also some differences. The differences are located in the near surface layer where numerous differing very-small-scale details are superimposed within the same large-scale flow pattern. The localized differences are also present in the middle troposphere and have generally a signature of gravity wave structures. For the jet stream area larger-scale differences are seen especially over the mountains (12 hour forecast) and over their lee side (24 hour forecast) where CE wind velocities are smaller suggesting stronger gravity wave drag, in agreement with analysis of Fig. 36.

Figure 38 presents the vertical cross section through vertical velocity distribution in the vicinity of Mt. Rosa, in the area shown by Fig. 37. Also for the vertical velocity distribution the general pattern of the flow is similar for both realizations and for both instances.

Figure 37: Vertical cross section through wind velocity in the vicinity of Mt. Rosa, the north-west to south-east orientation of the section line for 12 hour (left panels) and 24 hour (right panel) forecast for the CE (upper panels) and RK (lower panels) model versions

It concerns especially the magnitudes of the amplitudes and general pattern of the most pronounced features. There are also noticeable differences between CE and RE simulations, which concern details of shape and extension as well as magnitudes of weaker flow features, but they are generally common for both representations.

Figure 38: Like in Figure 37 but for vertical cross section through vertical velocity field

The experiment involved also a simulation of moist processes. The results for CE and RK realizations are very similar. It is seen e.g. analyzing a 3-dimensional distribution of iso-surfaces of constant cloud condensate mixing ratio for which there are no significant differences between the realizations (not shown). A comparison of distribution of cloud water

mixing ratio is shown in Figure 39 presenting a vertical cross section through the field along the north to south oriented cutting line crossing the Western Alps for 6, 12 and 24 hour forecast. The figure demonstrates very similar cloud pattern for CE and RK simulations, especially for relatively dense cloud structures, with some differences concerning smaller scale details and the parameter's amplitudes. For less dense clouds the differences are more significant and in places concern also more general cloud patter. Nevertheless, the similarity of the solutions is significant.

Figure 39: Vertical cross section through the cloud water mixing ratio along the north to south oriented cutting line crossing the Western Alps for 6 (upper panel), 12 (middle panel) and 24 hour forecast; RK results on the left panel, CE on the right.

A good general indication of the consistency of simulations involving representation of moist processes comes from analysis of the resulting precipitation distribution. Figure 40 shows the precipitation accumulated within 12 (left panel) and 24 hours (right panel) periods. The figure confirms a very high degree of similarity of the precipitation pattern for the RK and CE realizations, for both instants. Also the precipitation amounts are similar, especially during the first 12 hours of forecast. Later, for the 24 hour accumulation of precipitation, the locations of maxima are still very similar for both model versions but CE tends to generally produce higher precipitation maxima.

Overall, the consistency of the RK and CE results involving the parameterizations tuned for the RK operational setup and simply implemented to the CE setup can be regarded as significant

CE inter-comparison for increasing horizontal resolution

Figure 40: Accumulated precipitation (color scale) and direction on the surface for 12 hour (left panels) and 24 hour (right panel) forecast for the CE (upper panels) and RK (lower panels) model versions.

Figure 41 presents an inter-comparison of surface wind (on the computational level 10m above the surface) obtained with the CE model for 2.2, 1.1 and 0.55 km horizontal grid size. The figures show consistently the same synoptic and mesoscale velocity pattern, discussed above, for all the resolutions. The differences concern mainly small scale details of the flow field and a general tendency for lower wind velocities for increasing horizontal resolution of the simulation, especially over the Alps, suggesting an influence of explicitly resolved orography drag, increasing with increasing model and orography resolutions.

Similarly, Figure 42 compares the wind on 10-th computational level (about 500 m above the surface) for the CE forecast with 2.2, 1.1 and 0.55 km horizontal grid size. The figures show very high consistency of the flow pattern, for all the resolutions. The differences concern mainly small-scale details of the flow field, especially in the immediate vicinity of high mountains. A general tendency for lower wind velocities for higher horizontal resolution is also seen over the Alps, especially while comparing the results for 2.2 and 0.55 km grid size.

Figure 43 (left panels) compares the vertical cross sections through a fragment of the wind velocity field obtained with horizontal grid sizes of 2.2, 1.1 and 0.55 km for the Mt. Rosa vicinity in location close to the one in Fig. 37. The figure allows analyzing in more details the differences in the forecasted velocity field as well as in the orography pattern for different resolutions. It shows that while the results keep consistency of the general flow pattern,

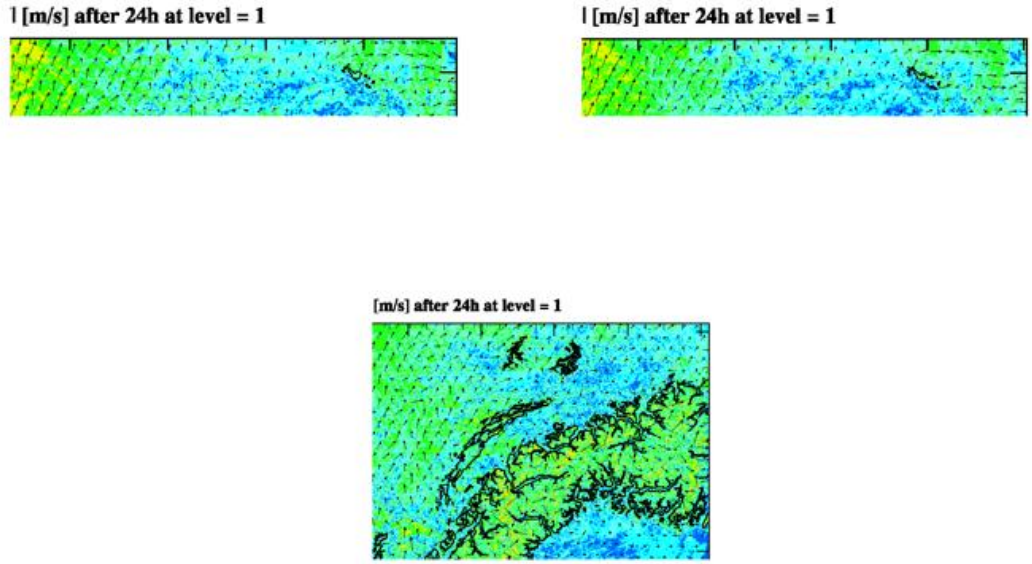

Figure 41: Wind velocity (color scale and wind arrow length) and direction (wind arrow direction) on the 10m model level for 24 hour forecast with the CE model version using horizontal grid size of 2.2 km (left, upper panel), 1.1 km (right panel) and 0.55 km (left lower panel).

the differences concern whole depth of the troposphere and are pronounced especially in the near-surface and the jet stream area. For increasing resolution, in the near-surface area there is more variability in the flow for the smallest scales, which results both from the increased variability of the resolved orographic forcing and of the model resolved scales. In the jet stream area, the differences concern mainly mesoscale patterns of the sizes of tens of kilometers. The general tendency is diminishing strength of the jet stream with increasing resolution, suggesting an increasing drag of explicitly resolved mountain waves. There is no grid-convergence of the simulated flow due to the resolution dependent orography pattern.

Figure 43 (right panels) compares also the vertical cross sections through the CE vertical velocity field obtained with grid sizes of 2.2, 1.1 and 0.55 km for the Mt. Rosa vicinity in the location shown in Figure 42. The wave features forecasted with the 2.2 km resolution and especially the most pronounced wave patterns are also clearly present in simulations with higher resolutions. The features have also similar amplitudes. On the other hand, the simulations with higher resolutions show a presence of increasingly complicated wave patterns with additional or significantly amplified features comparing with 2.2 km grid simulations. Such features are present not only in the vicinity of the surface but also in the middle and upper troposphere and in places reach magnitudes of the main wave features obtained with

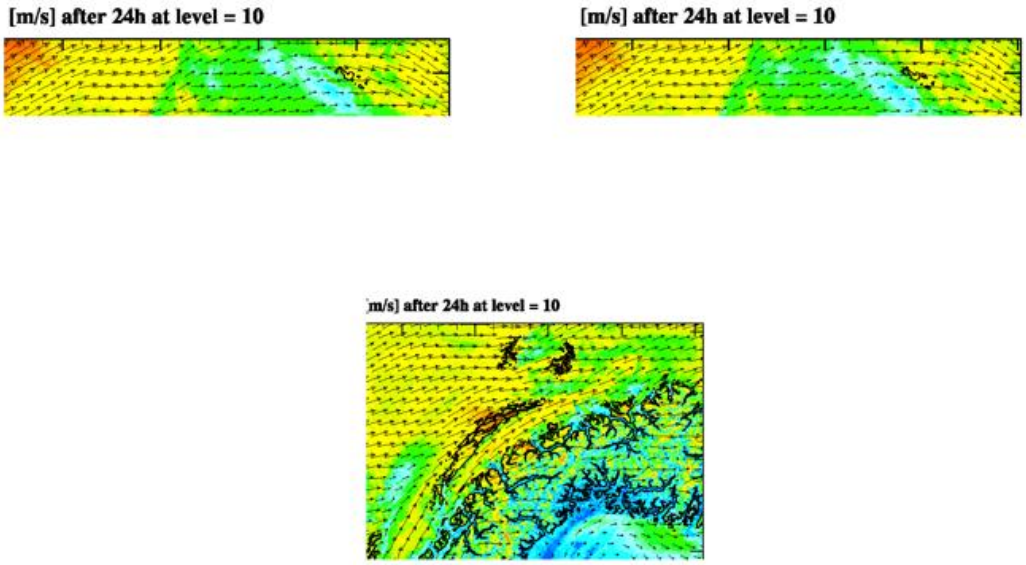

Figure 42: As in Figure 41 but for 10th model level above the ground.

2.2 km grid.

Finally, Fig. 44 compares vertically integrated cloud water for the CE forecast for 12 hours for 2.2 km (left panel) and 0.55 km (right panel) grid sizes. It presents high similarity of the obtained cloud fields, concerning both the cloud pattern and the amount of the condensate. The high-resolution simulation shows, however, a general presence of many very small-scale details absent in the lower-resolution simulations.

5.5 Summary and conclusions

The COSMO-EULAG prototype with EULAG dynamical core implemented into the software structure of the COSMO model and linked with basic physical parameterizations was successfully developed. The prototype was tested comparing its results with analogous COSMO model based on the compressible Runge-Kutta dynamical core for high-resolution 2.2 km horizontal grid sizes, for semi-realistic 24 hour forecast of the flow over Alps and its vicinity.

The tests have shown that the realistic CE results are similar to and consistent with the results of COSMO with RK dynamical core. It concerns not only basic parameters of the flow like wind and potential temperature distribution (the latter not shown) but also moist parameters like cloud condensate distribution and cumulative surface precipitation. Interesting differences between the models concern mountain gravity waves. While their distribution

Figure 43: Vertical cross section through wind velocity (left panels) and vertical velocity (right panels) for 24 hour forecast in the vicinity of Mt. Rosa with the CE model using horizontal grid size of 2.2 km (left, upper panel), 1.1 km (right panel) and 0.55 km (left lower panel).

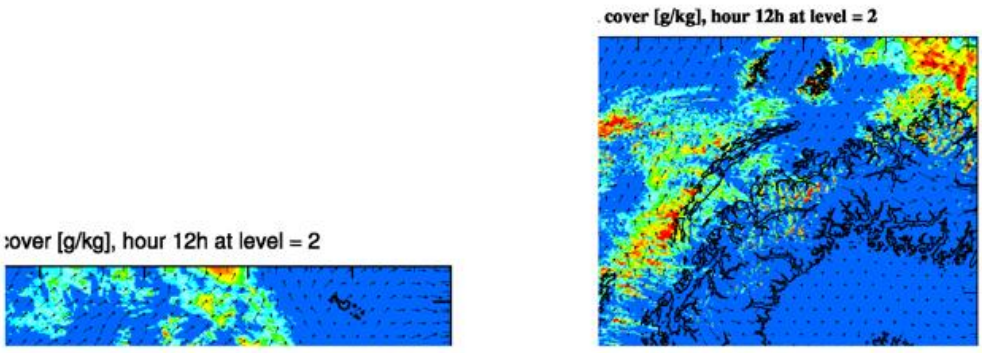

Figure 44: Vertically integrated cloud water (g/kg) for the CE forecast for 12 hours using 2.2 km (left panel) and 0.55 km (right panel) grid size.

is generally similar for both models, they differently influence the upper flow pattern leading to noticeable differences of the wind velocity in the jet stream area, while preserving similar general flow pattern. In general, no discrepancies of the CE simulations were found which would prove unsuitability of the EULAG dynamical core as well as of the anelastic approach for the very-high resolution regional NWP applications.

Finally, the CE prototype was tested for the varying horizontal resolutions with grid sizes of 2.2, 1.1 and 0.55 km. The simulations show a high degree of consistency of the results as well as the desirable robustness of the CE prototype. It was shown that with the increasing grid resolution the small scale variability of the flow increases with appearance of many small scale details especially in the near surface layer and gravity wave pattern. There are also resolution dependent differences in the jet stream velocity distribution suggesting effects of explicitly resolved gravity wave drag. There is no grid convergence of the solution for the orography significantly varying between the simulations.

6 MPDATA as an alternative tracer advection scheme

Guy de Morsier and Marie Müllner

MeteoSwiss, Krähbühlstrasse 58, 8044 Zürich, Switzerland

6.1 Introduction

The results shown here were achieved during a 6 month diploma work done by Marie Müllner at MeteoSwiss in 2010 and for the full details see the original work by Muellner (2010) (in German).
In the current COSMO model the advection of the prognostic variables is done with an upwind scheme[1]. This scheme is efficient and therefore well adapted for a fast operational model but it is not monotone and not conservative. For the advection of positive definite variables such as scalar tracer fields, i.e. all water constituents, possible aerosol particles and gaseous substances or turbulent kinetic energy, finite volume schemes are more appropriate. For the tracer transport the model provides already different formulations but all of them have some drawbacks.
The aim of this work is to implement, evaluate and test a fully three dimensional advection scheme for the COSMO model. The proposed advection scheme is MPDATA (multidimensional positive definite advection transport algorithm, see Smolarkiewicz and Margolin (1998)) which is used in the EULAG (Eulerian/Semi-Lagrangian fluid solver, see Prusa et al. (2008)) numerical model. The code used for the implementation is from Piotr K. Smolarkiewicz and it can be found in the appendix of Muellner (2010).

6.2 Advection of prognostic fields

In COSMO the advection of the wind components, the temperature and the pressure is operated with an upwind scheme of the 5th order. The upwind scheme is a numerical discretization for hyperbolic partial differential equations.
We take the following advection equation

$$\frac{\partial u}{\partial t} + a\frac{\partial u}{\partial x} = 0 \tag{3}$$

A solution of this equation is a wave that travels along the x-direction with the speed a. For a numerical approximation of $\partial u/\partial t$ we use

$$\frac{\partial u}{\partial t} = \frac{u_i^{n+1} - u_i^n}{\Delta t}$$

and for the approximation of $\partial u/\partial x$ we use the backward difference if $a > 0$

$$\frac{\partial u}{\partial x} = \frac{u_i^n - u_{i-1}^n}{\Delta x} \tag{4}$$

and the forward difference if $a < 0$

$$\frac{\partial u}{\partial x} = \frac{u_{i+1}^n - u_i^n}{\Delta x} \tag{5}$$

[1] upwind scheme of 5th order is used (Wicker and Skamarock, 2002); more general operators are described in (Doms et al., 2011, section 8.1.2) .

After replacement in (3) and depending on a we obtain

$$\frac{u_i^{n+1} - u_i^n}{\Delta t} + a\frac{u_i^n - u_{i-1}^n}{\Delta x} = 0$$

or

$$\frac{u_i^{n+1} - u_i^n}{\Delta t} + a\frac{u_{i+1}^n - u_i^n}{\Delta x} = 0$$

By defining $a^+ = \max(a,0)$, $a^- = \min(a,0)$, $u_x^- = \frac{u_i^n - u_{i-1}^n}{\Delta x}$ and $u_x^+ = \frac{u_{i+1}^n - u_i^n}{\Delta x}$ we can put the 2 cases together to

$$u_i^{n+1} = u_i^n - \Delta t(a^+ u_x^- + a^- u_x^+)$$

or

$$u_i^{n+1} = u_i^n - C(u_i^n - u_{i-1}^n)$$

where C is the Courant-Friedrichs-Lewy number (CFL) which is defined by

$$C = \left|\frac{a\Delta t}{\Delta x}\right|$$

This upstream scheme is of the first order and is only stable if $C \leq 1$.

6.3 Positive definite advection

For the advection of tracers the model provides a semi-Lagrangian scheme (SL) and direction splitted finite volume schemes. For the latter, several flux formulations exist under which the flux calculation by Bott (1989) is the standard one and the others are the vanLeer-scheme and a piecewise parabolic method (PPM). The different methods should satisfy the following conditions so that the physical properties are fulfilled:

- conservation of mass
- computation of the fluxes in upstream direction
- no production of new maxima or minima
- conservation of tracer relationships during the advection
- efficient computation in spherical coordinates

The Bott-scheme is a one-dimensional scheme which is used in split mode for the different directions. The advection is done in 2 steps. After weighting the advective fluxes, corrections are applied to make the scheme positive definite. These corrections gives the scheme a precision of the second or forth order. The second order is usually used for operational applications and is hereafter referred to as Bott_2. The SL-scheme is a fully 3-dimensional but it does not conserve the mass. More details about these schemes can be found in the chapter 8.3 of Doms et al. (2011).

6.4 MPDATA in 3-dimensions

MPDATA is a finite difference scheme which is positive definite, mass conserving and efficient. Moreover through a flux correction it can be made monotonous. It is an iterative scheme. In a first step a donor cell approximation (also called upstream method, positive definite but

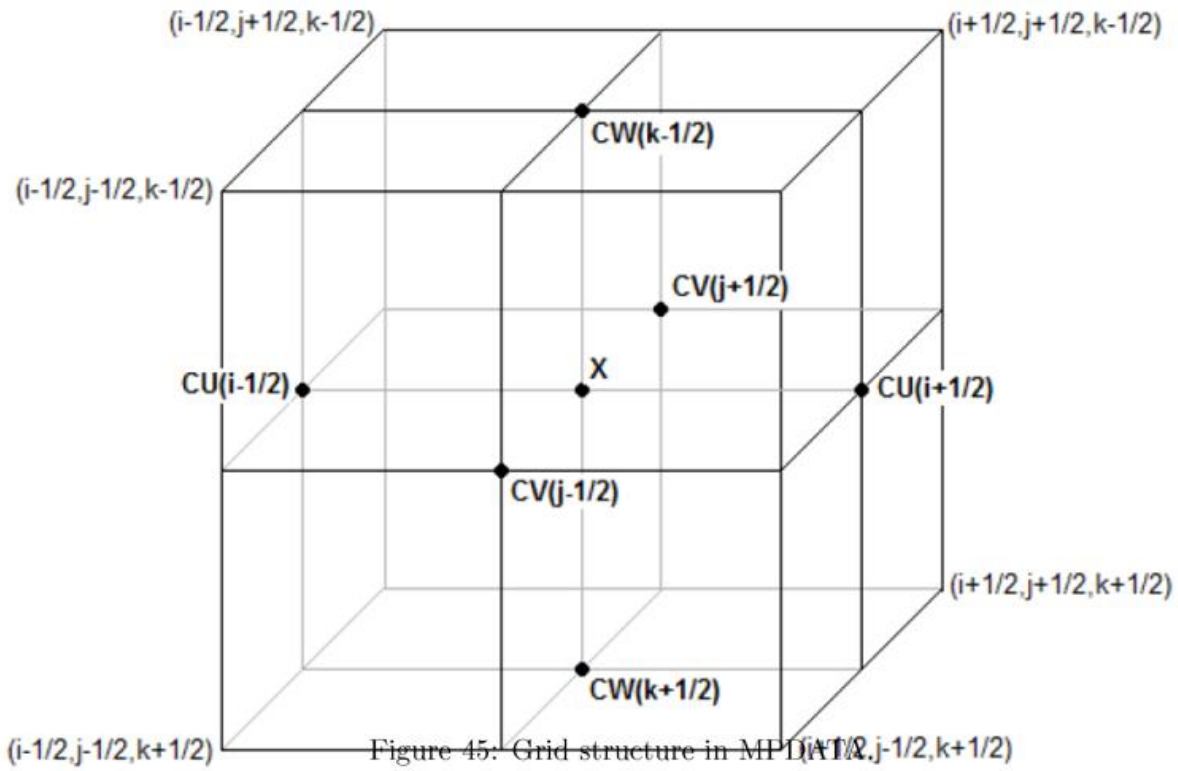

Figure 45: Grid structure in MPDATA

only of first order accuracy) is made. In the second step which can be repeated, corrections are applied to make the scheme more accurate (second order in time and space). In the first step, the physical velocities are used but in the iterations, the velocities are computed from the advection fields and we call them diffusive velocities.
The grid used in MPDATA is basically composed of two set of grids which are shifted by half a grid length in all directions so that the center of the cells are whole numbers i (i.e. the contribution of the first grid) and the grid summits (contribution of the second grid) with half valued indexes $i \pm 1/2$, see Figure 45. The **X** sign marks in the figure the position of the quantity to be advected, $\mathbf{CU(i-1/2)}$ and $\mathbf{CU(i+1/2)}$ are the Courant numbers in the x direction, $\mathbf{CV(j-1/2)}$ and $\mathbf{CV(j+1/2)}$ are the Courant numbers in the y direction and $\mathbf{CW(k-1/2)}$ and $\mathbf{CW(k+1/2)}$ are the Courant numbers in the z direction.
The equation of advection in 3-dimensions is

$$\frac{\partial \Psi}{\partial t} = -\frac{\partial}{\partial x}(u\Psi) - \frac{\partial}{\partial y}(v\Psi) - \frac{\partial}{\partial z}(w\Psi) \tag{6}$$

The equation for the donor cell approximation of (6) is then

$$\begin{aligned}\Psi^{n+1}_{i,j,k} = \Psi^{n}_{i,j,k} &- [F(\Psi^{n}_{i,j,k}, \Psi^{n}_{i+1,j,k}, U_{i+\frac{1}{2},j,k}) - F(\Psi^{n}_{i-1,j,k}, \Psi^{n}_{i,j,k}, U_{i-\frac{1}{2},j,k})] \\ &-[F(\Psi^{n}_{i,j,k}, \Psi^{n}_{i,j+1,k}, V_{i,j+\frac{1}{2},k}) - F(\Psi^{n}_{i,j-1,k}, \Psi^{n}_{i,j,k}, V_{i,j-\frac{1}{2},k})] \\ &-[F(\Psi^{n}_{i,j,k}, \Psi^{n}_{i,j,k+1}, W_{i,j,k+\frac{1}{2}}) - F(\Psi^{n}_{i,j,k-1}, \Psi^{n}_{i,j,k}, W_{i,j,k-\frac{1}{2}})]\end{aligned} \tag{7}$$

where the whole indexes correspond to the center and the half indexes are on the boundaries of the grid cells.
The Courant numbers U, V and W are $U \equiv u\delta t/\delta x, V \equiv v\delta t/\delta y$ and $W \equiv w\delta t/\delta z$ where the time step is δt and the grid space in x, y and z direction are $\delta x, \delta y$ and δz. The flux functions

are defined as

$$\begin{aligned} F(\Psi_L, \Psi_R, U) &\equiv [U]^+ \Psi_L + [U]^- \Psi_R \\ F(\Psi_L, \Psi_R, V) &\equiv [V]^+ \Psi_L + [V]^- \Psi_R \\ F(\Psi_L, \Psi_R, W) &\equiv [W]^+ \Psi_L + [W]^- \Psi_R \end{aligned} \tag{8}$$

with the Courant numbers

$$[U]^+ \equiv max(0, U),\ [U]^- \equiv min(0, U) \quad [V]^+ \equiv max(0, V),\ [V]^- \equiv min(0, V)$$

$$[W]^+ \equiv \mathrm{max}(0, W),\ [W]^- \equiv \mathrm{min}(0, W)$$

The $[U]^+$, $[V]^+$ and $[W]^+$ are the nonnegative, and $[U]^-$, $[V]^-$ and $[W]^-$ are the nonpositive parts of the Courant numbers. With a Taylor expansion and under the assumption that u, v and w are constant, we can again compute the donor cell approximation as:

$$\begin{aligned} \Psi^{n+1}_{i,j,k} &= \Psi^n_{i,j,k} + \delta t \frac{\partial \Psi}{\partial t} + \frac{(\delta t)^2}{2} \frac{\partial^2 \Psi}{\partial t^2} + \qquad O(\delta t^3) \\ &= \Psi^n_{i,j,k} + \delta t \frac{\partial \Psi}{\partial t} + \frac{(\delta t)^2}{2} u^2 \frac{\partial^2 \Psi}{\delta x^2} + \frac{(\delta t)^2}{2} v^2 \frac{\partial^2 \Psi}{\delta y^2} + \frac{(\delta t)^2}{2} w^2 \frac{\partial^2 \Psi}{\delta z^2} + \\ &\quad \frac{(\delta t)^2}{2} 2uv \frac{\partial^2 \Psi}{\partial x \partial y} + \frac{(\delta t)^2}{2} 2uw \frac{\partial^2 \Psi}{\partial x \partial z} + \frac{(\delta t)^2}{2} 2vw \frac{\partial^2 \Psi}{\partial y \partial z} + O(\delta t^3) \end{aligned}$$

$$\begin{aligned} \Psi^n_{i+1,j,k} &= \Psi^n_{i,j,k} + \delta x \frac{\partial \Psi}{\partial x} + \frac{(\delta x)^2}{2} \frac{\partial^2 \Psi}{\partial x^2} + O(\delta x^3) \\ \Psi^n_{i-1,j,k} &= \Psi^n_{i,j,k} - \delta x \frac{\partial \Psi}{\partial x} + \frac{(\delta x)^2}{2} \frac{\partial^2 \Psi}{\partial x^2} + O(\delta x^3) \\ \Psi^n_{i,j+1,k} &= \Psi^n_{i,j,k} + \delta y \frac{\partial \Psi}{\partial y} + \frac{(\delta y)^2}{2} \frac{\partial^2 \Psi}{\partial y^2} + O(\delta y^3) \\ \Psi^n_{i,j-1,k} &= \Psi^n_{i,j,k} - \delta y \frac{\partial \Psi}{\partial y} + \frac{(\delta y)^2}{2} \frac{\partial^2 \Psi}{\partial y^2} + O(\delta y^3) \\ \Psi^n_{i,j,k+1} &= \Psi^n_{i,j,k} + \delta z \frac{\partial \Psi}{\partial z} + \frac{(\delta z)^2}{2} \frac{\partial^2 \Psi}{\partial z^2} + O(\delta z^3) \\ \Psi^n_{i,j,k-1} &= \Psi^n_{i,j,k} - \delta z \frac{\partial \Psi}{\partial z} + \frac{(\delta z)^2}{2} \frac{\partial^2 \Psi}{\partial z^2} + O(\delta z^3) \end{aligned}$$

After putting this in (7) we get the following advection diffusion equation

$$\begin{aligned} \frac{\partial \Psi}{\partial t} &= -u \frac{\partial \Psi}{\partial x} - v \frac{\partial \Psi}{\partial y} - w \frac{\partial \Psi}{\partial z} + \\ &\quad (|U| - U^2) \frac{(\delta x)^2}{2 \delta t} \frac{\partial^2 \Psi}{\partial x^2} + (|V| - V^2) \frac{(\delta y)^2}{2 \delta t} \frac{\partial^2 \Psi}{\partial y^2} + (|W| - W^2) \frac{(\delta z)^2}{2 \delta t} \frac{\partial^2 \Psi}{\partial z^2} - \\ &\quad \frac{UV \delta x \delta v}{\delta t} \frac{\partial^2 \Psi}{\partial x \partial y} - \frac{UW \delta x \delta z}{\delta t} \frac{\partial^2 \Psi}{\partial x \partial z} - \frac{VW \delta y \delta z}{\delta t} \frac{\partial^2 \Psi}{\partial y \partial z} \end{aligned} \tag{9}$$

The error which arises from the diffusion term in (9) is estimated with a donor cell approximation and then subtracted from (7) to obtain a higher precision. The equation (9) is written with the diffusive velocities u_d, v_d and w_d as

$$\frac{\partial \Psi}{\partial t} = -\frac{\partial}{\partial x}(u\Psi) - \frac{\partial}{\partial y}(v\Psi) - \frac{\partial}{\partial z}(w\Psi) + \frac{\partial}{\partial x}(u^{(1)}_d \Psi) + \frac{\partial}{\partial y}(v^{(1)}_d \Psi) + \frac{\partial}{\partial z}(w^{(1)}_d \Psi) \tag{10}$$

with the following definitions:

$$
\begin{aligned}
u_d^{(1)} &\equiv (|U| - U^2)\frac{(\delta x)^2}{2\delta t}\frac{1}{\Psi}\frac{\partial \Psi}{\partial x} - r\frac{UV\delta x\delta y}{\delta t}\frac{1}{\Psi}\frac{\partial \Psi}{\partial y} - s\frac{UW\delta x\delta z}{\delta t}\frac{1}{\Psi}\frac{\partial \Psi}{\partial z} \\
v_d^{(1)} &\equiv (|V| - V^2)\frac{(\delta y)^2}{2\delta t}\frac{1}{\Psi}\frac{\partial \Psi}{\partial y} - (1-r)\frac{UV\delta x\delta y}{\delta t}\frac{1}{\Psi}\frac{\partial \Psi}{\partial x} - t\frac{VW\delta y\delta z}{\delta t}\frac{1}{\Psi}\frac{\partial \Psi}{\partial z} \\
w_d^{(1)} &\equiv (|W| - W^2)\frac{(\delta z)^2}{2\delta t}\frac{1}{\Psi}\frac{\partial \Psi}{\partial z} - (1-s)\frac{UW\delta x\delta z}{\delta t}\frac{1}{\Psi}\frac{\partial \Psi}{\partial x} - (1-t)\frac{VW\delta y\delta z}{\delta t}\frac{1}{\Psi}\frac{\partial \Psi}{\partial y}
\end{aligned}
\tag{11}
$$

with $r, s, t \in \mathbb{R}$ can be chosen arbitrarily. The implementation is independent of the choice for $r, s, t \in [0,1]$ and as default values we choose $r, s, t = 0.5$ The diffusive velocities must be built at the grid cell boundaries. The explicit form depends if the boundary is horizontal or vertical but they can be written in the following dimensionless form

$$
\begin{aligned}
U^{(1)} &\equiv \frac{u^{(1)}\delta t}{\delta x} = (|U| - U^2)A^{(1)} - 2rUVB^{(1)} - 2sUWC^{(1)} \\
V^{(1)} &\equiv \frac{v^{(1)}\delta t}{\delta y} = (|V| - V^2)B^{(1)} - 2(1-r)UVA^{(1)} - 2tVWC^{(1)} \\
W^{(1)} &\equiv \frac{w^{(1)}\delta t}{\delta z} = (|W| - W^2)C^{(1)} - 2(1-s)UWA^{(1)} - 2(1-t)VWB^{(1)}
\end{aligned}
\tag{12}
$$

with

$$
\begin{aligned}
A^{(1)} &\equiv \left[\frac{\delta x}{2\Psi}\frac{\partial \Psi}{\partial x}\right]_{i+1/2,j,k}^{n+1} = \frac{\Psi^{(1)}_{1+1,j,k} - \Psi^{(1)}_{i,j,k}}{\Psi^{(1)}_{1+1,j,k} + \Psi^{(1)}_{i,j,k}} \\
B^{(1)} &\equiv \left[\frac{\delta y}{2\Psi}\frac{\partial \Psi}{\partial y}\right]_{i+1/2,j,k}^{n+1} = \frac{1}{2}\frac{\Psi^{(1)}_{i+1,j+1,k} + \Psi^{(1)}_{i,j+1,k} - \Psi^{(1)}_{i+1,j-1,k} - \Psi^{(1)}_{i,j-1,k}}{\Psi^{(1)}_{i+1,j+1,k} + \Psi^{(1)}_{i,j+1,k} + \Psi^{(1)}_{i+1,j-1,k} + \Psi^{(1)}_{i,j-1,k}} \\
C^{(1)} &\equiv \left[\frac{\delta z}{2\Psi}\frac{\partial \Psi}{\partial z}\right]_{i+1/2,j,k}^{n+1} = \frac{1}{2}\frac{\Psi^{(1)}_{i,j,k+1} + \Psi^{(1)}_{i+1,j,k+1} - \Psi^{(1)}_{i,j,k-1} - \Psi^{(1)}_{i+1,j,k-1}}{\Psi^{(1)}_{i,j,k+1} + \Psi^{(1)}_{i+1,j,k+1} + \Psi^{(1)}_{i,j,k-1} + \Psi^{(1)}_{i+1,j,k-1}}
\end{aligned}
$$

6.5 Non-oscillating option

The algorithm described in the previous paragraph is positive definite but not monotone. The solution can show wrong extrema. The reasons for the oscillations in the numerical solution are that on one side some fluxes are overestimated and on the other an underestimation can arise from the first order accuracy of the fluxes. The flux-corrected transport (FCT) methodology enforces appropriate limits to the fluxes and removes these oscillations. The adopted method merges the FCT with the iterative formalism of MPDATA (Smolarkiewicz and Grabowski, 1990). The numerical diffusion of the advection is reduced by limiting the anti-diffusive fluxes so that no unphysical extrema occur in the solutions.

General form of the FCT methodology Starting with the conservation of a time dependent fluid variable (e.g. mass, momentum) Ψ can be written as

$$
\frac{\partial \Psi}{\partial t} + \nabla \cdot (\Psi \mathbf{u}) = S
$$

where $\mathbf{u}$ is the fluid velocity and S is a source term. First Ψ is advected. In the second FCT step Ψ is numerically diffused so that the solution is positive everywhere if the starting

profile Ψ^0 was positive. The source term S is added to obtain the low order value Ψ^l. In the next step the anti-diffusive fluxes are computed and we obtain a higher order approximation Ψ^h. The anti-diffusive fluxes are limited to not generate any new extrema and not to reduce any extrema of the start profile. Applying these fluxes to Ψ^l gives the new solution Ψ^n which is positive and monotone.

Limiters in MPDATA First the extrema Ψ^{min} and Ψ^{max} are computed

$$\Psi^{l,min}_{i,j,k} = \min(\Psi^l_{i,j,k}, \Psi^l_{i-1,j,k}, \Psi^l_{i+1,j,k}, \Psi^l_{i,j-1,k}, \Psi^l_{i,j+1,k}, \Psi^l_{i,j,k-1}, \Psi^l_{i,j,k+1})$$
$$\Psi^{l,max}_{i,j,k} = \max(\Psi^l_{i,j,k}, \Psi^l_{i-1,j,k}, \Psi^l_{i+1,j,k}, \Psi^l_{i,j-1,k}, \Psi^l_{i,j+1,k}, \Psi^l_{i,j,k-1}, \Psi^l_{i,j,k+1})$$

Then Ψ^h is computed using (7) and the new extrema Ψ^{min} and Ψ^{max} are found

$$\Psi^{h,min}_{i,j,k} = \min(\Psi^h_{i,j,k}, \Psi^h_{i-1,j,k}, \Psi^h_{i+1,j,k}, \Psi^h_{i,j-1,k}, \Psi^h_{i,j+1,k}, \Psi^h_{i,j,k-1}, \Psi^h_{i,j,k+1}, \Psi^{l,min}_{i,j,k})$$
$$\Psi^{h,max}_{i,j,k} = \max(\Psi^h_{i,j,k}, \Psi^h_{i-1,j,k}, \Psi^h_{i+1,j,k}, \Psi^h_{i,j-1,k}, \Psi^h_{i,j+1,k}, \Psi^h_{i,j,k-1}, \Psi^h_{i,j,k+1}, \Psi^{l,max}_{i,j,k})$$

The flux terms in (8) are computed and in the next step the total in- and outgoing anti-diffusive fluxes F^{in} and F^{out} of each cell can be computed as

$$F^{in}_i = \max(F_{i-1/2},0) - \min(F_{i+1/2},0)\ ,\ F^{out}_i = \max(F_{i+1/2},0) - \min(F_{i-1/2},0)$$
$$F^{in}_j = \max(F_{j-1/2},0) - \min(F_{j+1/2},0)\ ,\ F^{out}_j = \max(F_{j+1/2},0) - \min(F_{j-1/2},0)$$
$$F^{in}_k = \max(F_{k-1/2},0) - \min(F_{k+1/2},0)\ ,\ F^{out}_k = \max(F_{k+1/2},0) - \min(F_{k-1/2},0)$$

The partial in- and outgoing fluxes f^{in} and f^{out} which have to be applied to each grid cell are then

$$f^{in}_i = \frac{\Psi^{h,max}_{i,j,k} - \Psi^l_{i,j,k}}{F^{in}_i}\ ,\ f^{out}_i = \frac{\Psi^l_{i,j,k} - \Psi^{h,min}_{i,j,k}}{F^{out}_i}$$
$$f^{in}_j = \frac{\Psi^{h,max}_{i,j,k} - \Psi^l_{i,j,k}}{F^{in}_j}\ ,\ f^{out}_j = \frac{\Psi^l_{i,j,k} - \Psi^{h,min}_{i,j,k}}{F^{out}_j}$$
$$f^{in}_k = \frac{\Psi^{h,max}_{i,j,k} - \Psi^l_{i,j,k}}{F^{in}_k}\ ,\ f^{out}_k = \frac{\Psi^l_{i,j,k} - \Psi^{h,min}_{i,j,k}}{F^{out}_k}$$

Finally in the last step each of these partial anti-diffusive fluxes are limited so that no undershooting is produced at the exit and no overshooting at the entry of the grid cell. For the pseudo velocities u, v and w we use

$$u_{i+1/2,j,k} = \min(1, f^{out}_i, f^{in}_{i+1}) \max(0, u_{i+1/2,j,k}) + \min(1, f^{in}_i, f^{out}_{i+1}) \min(0, u_{i+1/2,j,k})$$
$$v_{i,j+1/2,k} = \min(1, f^{out}_j, f^{in}_{j+1}) \max(0, v_{i,j+1/2,k}) + \min(1, f^{in}_j, f^{out}_{j+1}) \min(0, v_{i,j+1/2,k})$$
$$w_{i,j,k+1/2} = \min(1, f^{out}_k, f^{in}_{k+1}) \max(0, w_{i,j,k+1/2}) + \min(1, f^{in}_k, f^{out}_{k+1}) \min(0, w_{i,j,k+1/2})$$

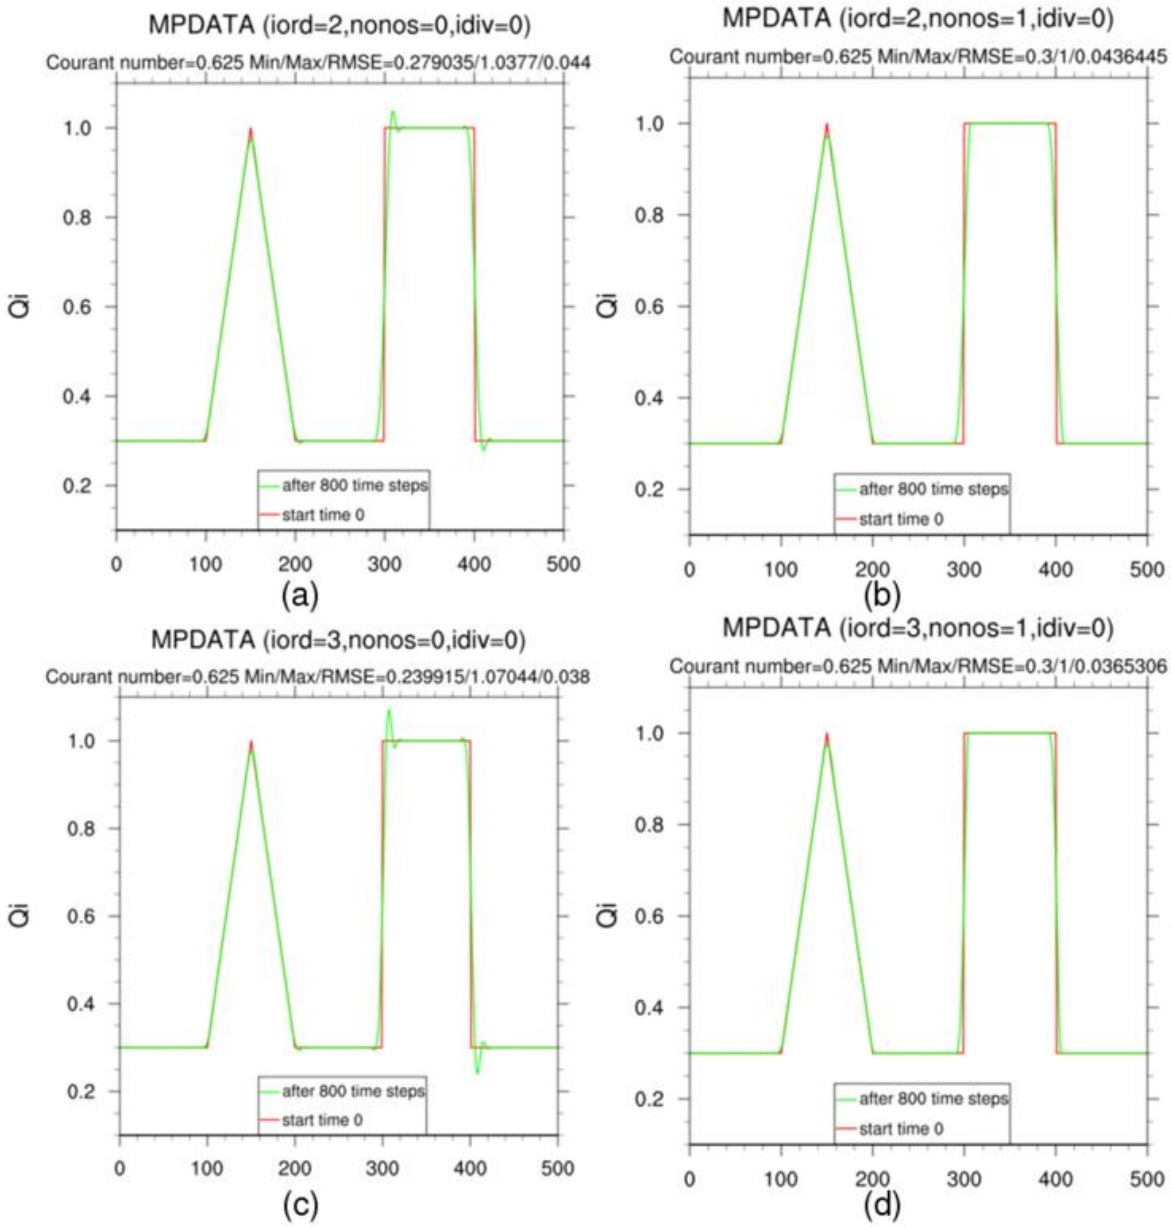

Figure 46: First example of MPDATA in one dimension, details see text.

6.6 Illustration in a one dimensional case

To show how MPDATA works a simple advection in one dimension is used here. The initial distributions of the tracer (Qi) are a triangle and a rectangular function with maximum value 1 and minimum value 0.3 over 100 grid points. These are shown in red in the Figure 46. A constant positive velocity (to the right) is applied to the tracer with a Courant number of 0.625 and periodic boundary conditions are used. After 800 time steps the distribution has passed over all the 500 grid points and is back at the initial position (in green in Figure 46) and the impact of the different advection options is visible. These options are the number of iterations (*iord*) used in the MPDATA algorithm, the non-oscillating option described in the previous section if *nonos* = 1 and a switch for non-divergent fields (*idiv* = 1 if the divergence of the velocity field is different than zero). For *iord* = 1 only the donor cell advection is operated and the scheme is very diffusive (not shown). With *iord* = 2 we have the basic

MPDATA scheme with only one anti-diffusive flux computed. This step can be repeated although for *iord* higher than 3 no significant improvement is obtained (not shown). On the top left of Figure 46 *iord* is equal 2 and on the left of the rectangular tracer there is a 4% overshooting and on the right an undershooting of 7%. This effect is totally absent in the part (b) of the figure where *nonos* = 1. With an extra iteration (*iord* = 3, lower left part c) the over- and undershooting are worse (respectively 7 and 20%) but the root mean square error (RMSE) of the overall distribution is reduced. The best results are obtained in the lower right corner in part (d) of the figure and one can also state that the triangular distribution does not seem to change much for any of the shown options. In a more stringent

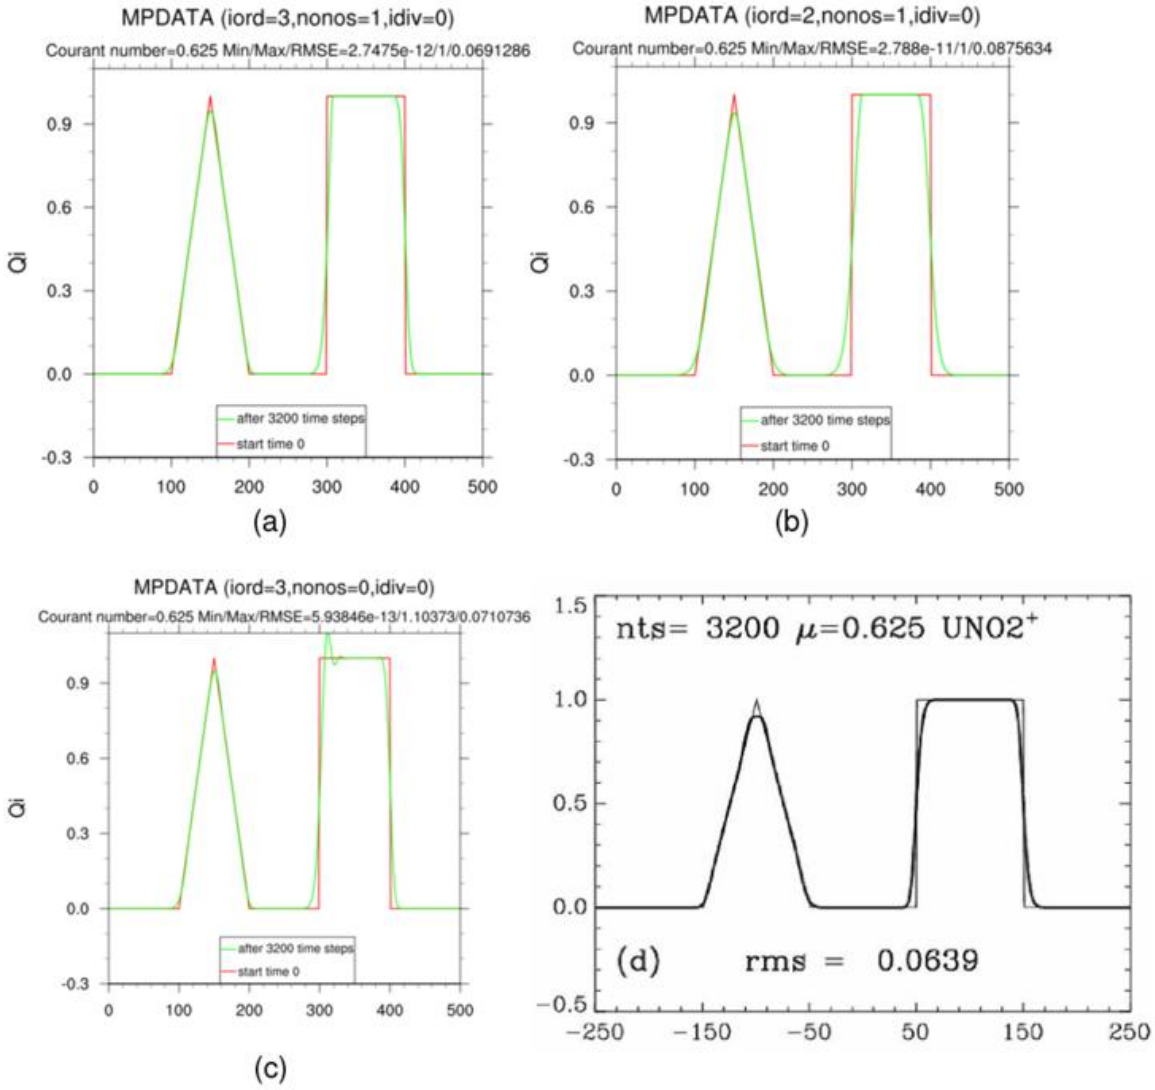

Figure 47: Second example of MPDATA in one dimension, details see text.

test the 2 previous distributions are compared after 3200 time steps which correspond to 4 complete rotations. In contrast to Figure 46 the starting distributions have a minimum of 0 and only three options are shown in Figure 47. In the lower right part an upstream non-oscillatory (UNO2+) solution from Li (2008) is displayed for comparison. The RMSE with the best MPDATA options (iord=3, nonos=1) is shown in the upper left part (a) and is similar to the UNO2+ method.

6.7 Advection tests

In a first configuration MPDATA was tested by conducting synthetic experiments with the module src_artifdata. This module permits to construct artificial initial and boundary data and all the usual settings of the model and then to do component testing while still using the whole COSMO model in its version 4.12 for the dynamics of the flow. MPDATA could therefore be easily compared to results obtained with Bott_2 or the semi-Lagrangian scheme (SL).
These so-called solid body rotation tests were computed on a domain of 80x80 grid points with an horizontal resolution of 2.2km. The time step used was 20s. There is no orography and the vertical extension of the model has no impact but permits to conduct different experiments on different model levels.

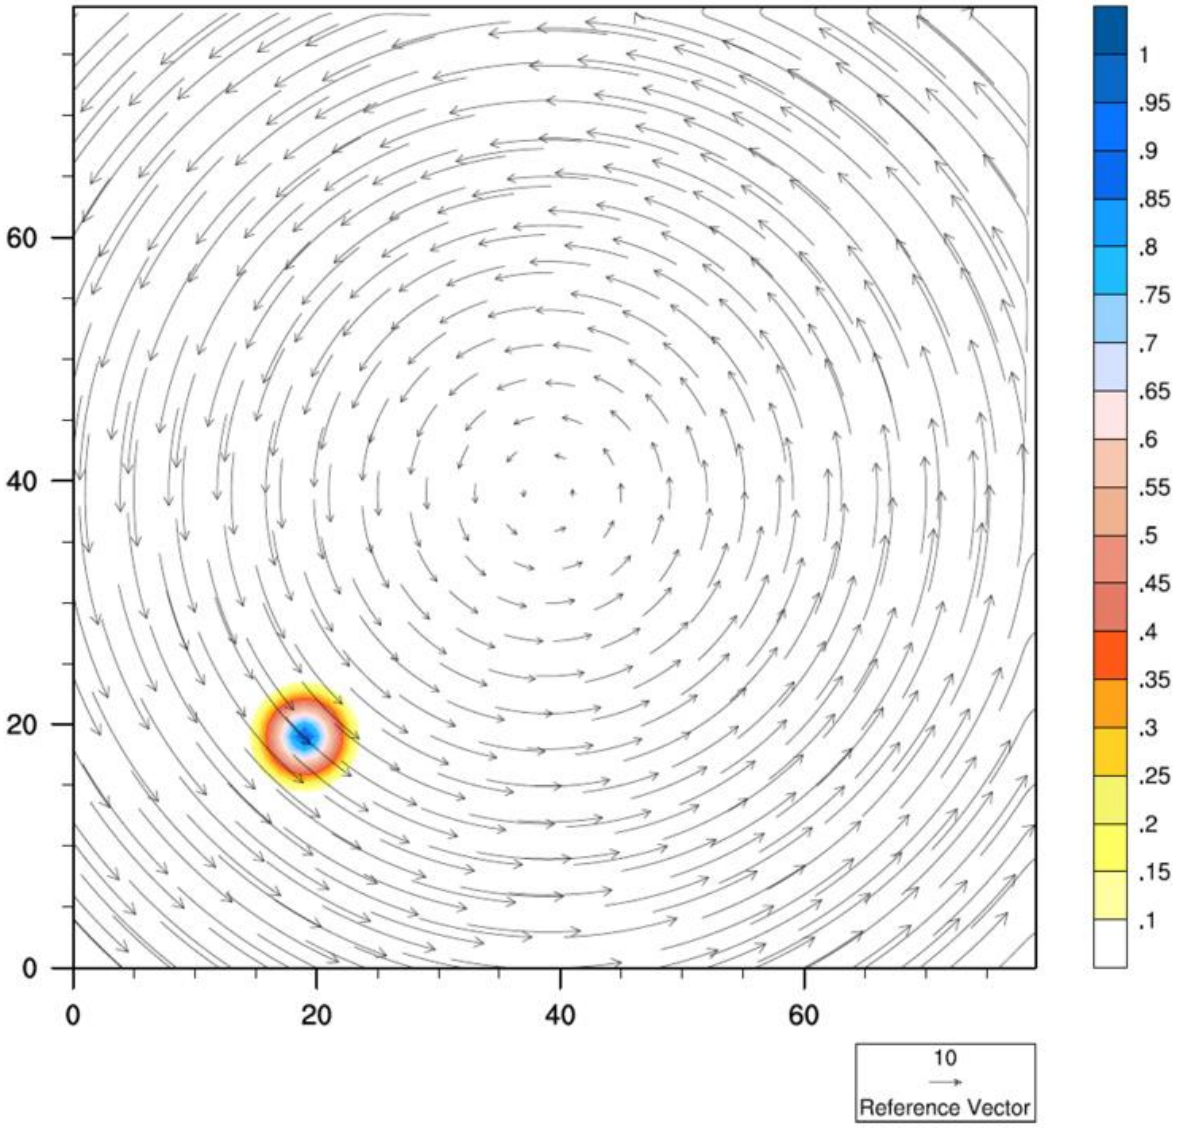

Figure 48: Rotating wind field in m/s over the whole computational domain with the starting tracer concentration (cone with base radius of 5 grid points) in colours centered at position (20,20).

Rotating cone test with 0 background As in the previous paragraph the specific cloud ice content q_i (in units of kg/kg) was used as a tracer and initialized to zero everywhere except

for a cone centered over the position $(i, j) = (20, 20)$ and with radius of 5 grid points and placed on the 10th level of the model so that we can write

$$q_i(i, j, 10) = \max(0.0, 1.0 - \sqrt{((i - i_{max})/5)^2 + ((j - j_{max})/5)^2})$$

where the maximum of q_i is 1 and is positioned on the grid point $(i_{max}, j_{max} = (20, 20)$. The rotating wind field is defined as

$$u(i, j, k) = -\omega(j - j_0) \quad v(i, j, k) = \omega(i - i_0) \quad w(i, j, k) = 0.0$$

where $\omega = 0.97m/s$, $u(i, j, k)$, $v(i, j, k)$ and $w(i, j, k)$ are the wind velocities in the i-, j- and k-direction and (i_0, j_0) is the mid point of the horizontal layer. The stationary winds and the distribution of the tracer at time 0 are shown in Figure 48.
The rotation period is 4h and the Courant number at the location of the tracer is about 0.3 but the maximum values are close to 0.5 in the corners of the domain.
The tracer should theoretically be transported without changing its shape and after 4h of computation it should be back in its starting position. To show the characteristics of the different schemes, the isolines of the tracer concentrations of the MPDATA method are drawn on top of the colored results of the Bott_2 scheme. Figure 49 displays 2 different settings of the MPDATA scheme. For MPDATA one can see that the maximum values have been reduced by 78% and 66% whereas Bott_2 has only been reduced by 50%. The results of the SL scheme are not shown but are very similar to the Bott_2 with a slightly better maximum value of 0.510. There is not only a reduction of the maximum but there is also a phase shift in the position of this value.

We compute the following statistical measures to quantify the results:

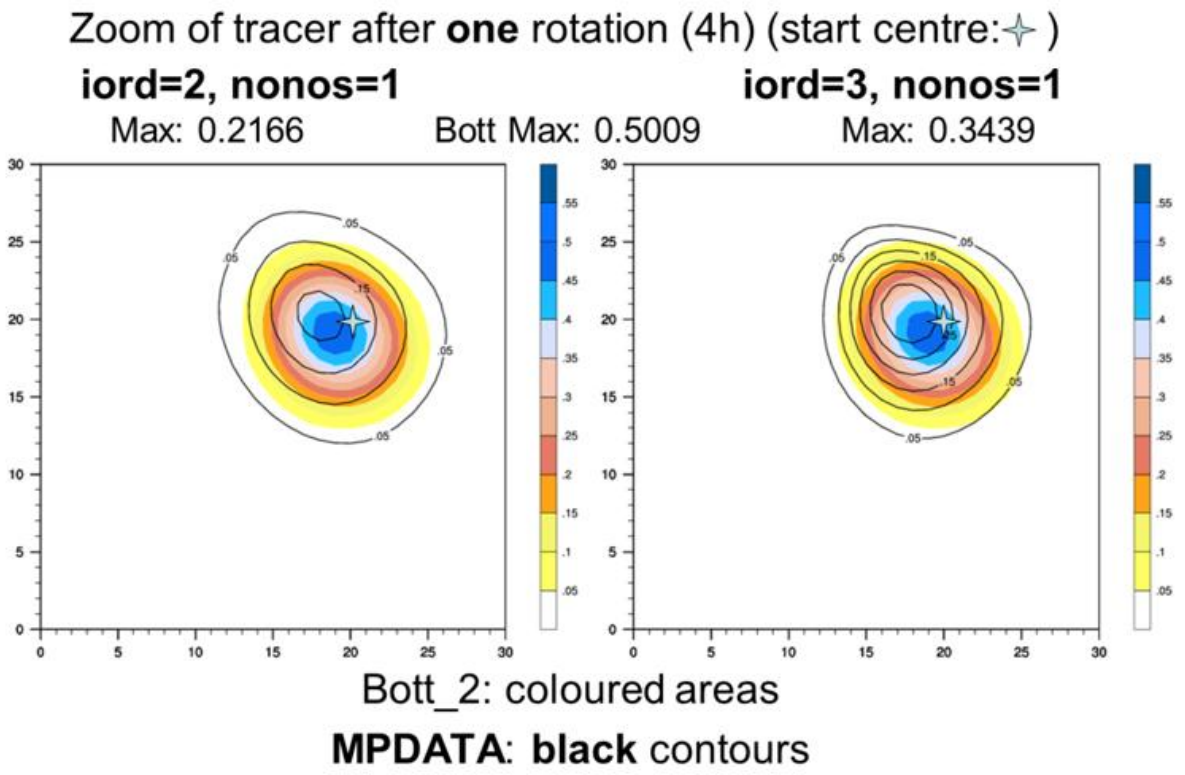

Figure 49: Zoom of the lower left domain with the tracer concentrations after one complete rotation of a cone with maximum of 1 and horizontal radius of 5 grid points centered at the position (20,20).

- the phase error E_{phase} is defined as the distance between the exact maximum position (i^{start}, j^{start}) and the computed one (i^{end}, j^{end}):

$$E_{phase} = \sqrt{(i^{start} - i^{end})^2 + (j^{start} - j^{end})^2} \tag{13}$$

- the diffusion error is

$$E_{diffusion} = \max(q_i^{start}) - max(q_i^{end}) \tag{14}$$

- the L2-norm is

$$E_{L2} = \sqrt{\sum_{i=1}^{N} A_i \cdot (q_i^{start} - q_i^{end})^2} \tag{15}$$

where N is the number of grid cells and A_i is the area of the grid cell.

Advection scheme after one rotation	L2-norm E_{L2}	Maximum value	E_{phase}	$E_{diffusion}$
Bott_2	3.068	0.501	1.414	0.499
Semi-Lagrange	3.147	0.510	1.414	0.490
MPDATA				
iord=2, nonos=0	5.798	0.219	2.000	0.781
iord=3, nonos=0	4.925	0.348	2.236	0.652
iord=2, nonos=1	5.795	0.217	2.000	0.783
iord=3, nonos=1	4.906	0.344	2.000	0.656

Table 8: Overview of the different schemes for the rotating cone test with 0 background.

All the results of the different experiments with the rotating cone are shown in Table 8. The smallest MPDATA diffusion error is given by the experiment with *iord* = 3 and *nonos* = 0 but its phase error is the largest and the overall smallest L2-norm is given by the Bott_2 scheme although its diffusion error is larger than the SL experiment.

Rotating cylinder test with non-zero background

In this test the tracer has a value of 0.3 over the whole domain and only in a radius of 5 grid points around the center position $(i, j) = (20, 20)$ does the tracer have a value of 1.0. The rotating wind field is the same as in the previous cone test. Figure 50 shows the same 2 settings of the MPDATA scheme on top of the Bott_2 solution as for the rotating cone test. Although we use the non-oscillating option for MPDATA local minima and maxima appear in the vicinity of the main tracer concentration. This is also the case for the Bott_2 but the trail behind the main concentration is much smaller than with MPDATA. For MPDATA one can see that the maximum values have been reduced by 37% and 26% whereas Bott_2 has only been reduced by 16%. This is much better than in the previous test but because of the local extrema the overall L2-norm is much larger in this experiment (see Table 9). The results of the SL scheme are not shown here because there is a boundary undershooting problem for this experiment.

All the results of the different experiments with the rotating cylinder are shown in Table 9. The smallest MPDATA diffusion error is again given by the experiment with *iord* = 3 and *nonos* = 0 with a maximum reduction of only 21% but its phase error is again the largest and the overall smallest L2-norm is again given by the Bott_2 scheme and its diffusion error is also the overall smallest.

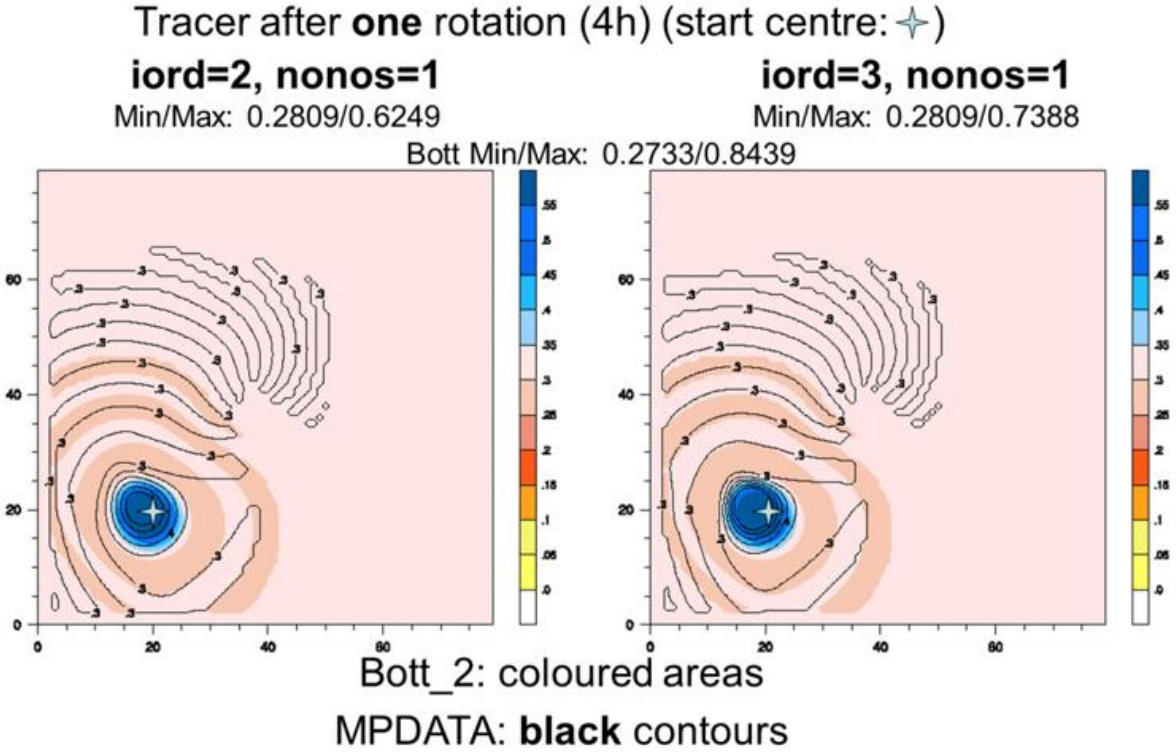

Figure 50: Tracer concentrations after one complete rotation (4h) of a cylinder of maximum 1 and horizontal radius of 5 grid points centered at the position (20,20) on top of a background value of 0.3.

Advection scheme after one rotation	L2-norm E_{L2}	Minimum value	Maximum value	Phase error	Diffusion error
Bott_2	5.233	0.273	0.844	1.414	0.156
Semi-Lagrange	12.574	0.125	0.843	1.414	0.157
MPDATA					
iord=2, nonos=0	6.907	0.261	0.633	2.000	0.367
iord=3, nonos=0	6.771	0.199	0.785	3.162	0.215
iord=2, nonos=1	6.882	0.281	0.625	2.000	0.375
iord=3, nonos=1	6.402	0.281	0.739	2.000	0.261

Table 9: Overview of the different schemes for the rotating cylinder test with non-zero background.

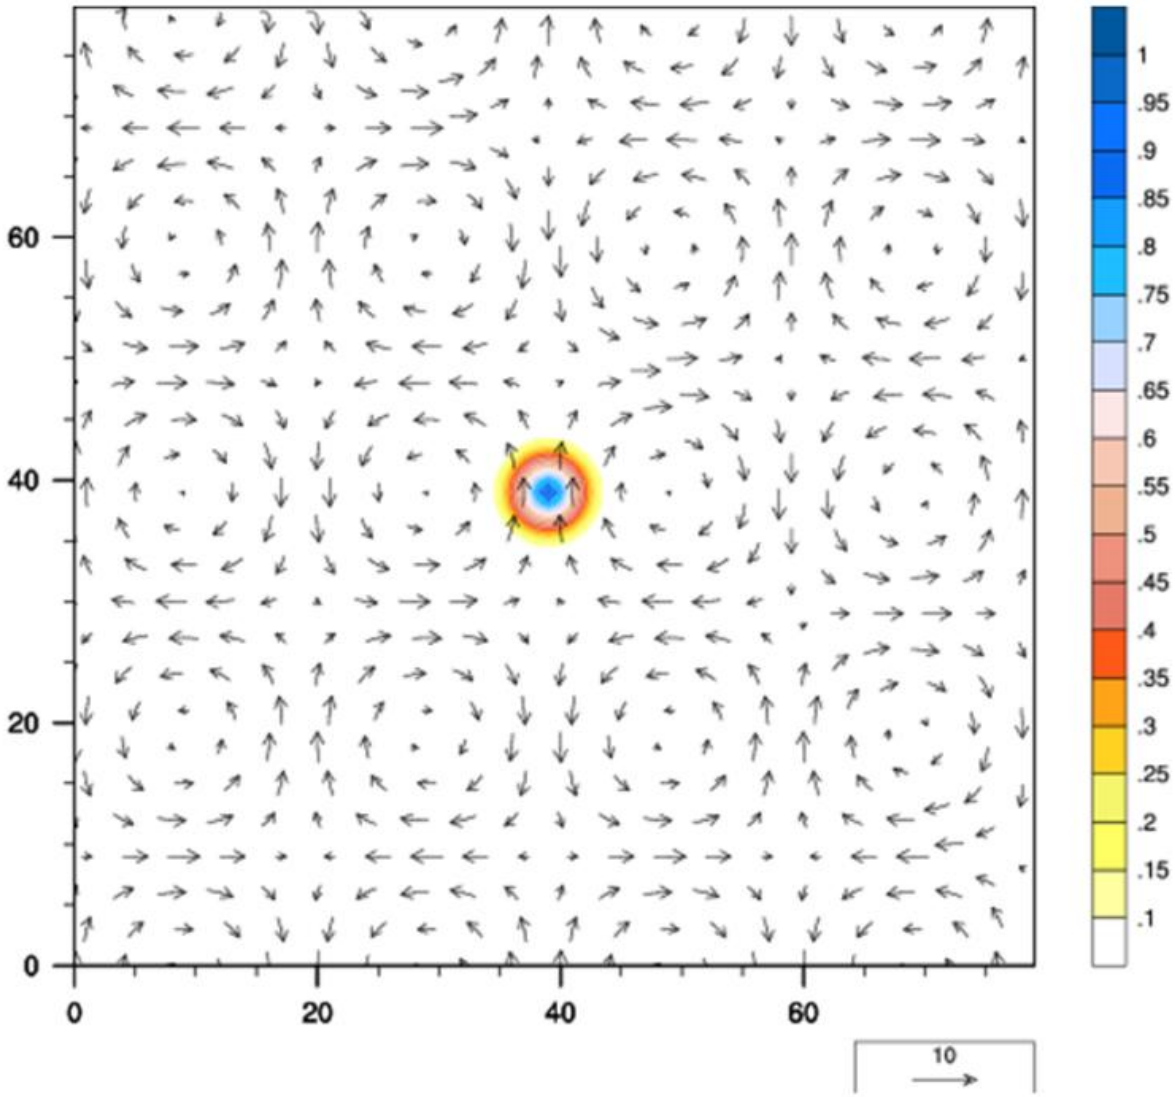

Figure 51: Wind field in m/s for the deformational flow test with the starting tracer concentration (cone with base radius of 5 grid points) in colours centered at position (40,40).

6.8 Deformation flow tests

The stability and the qualitative value of the different advection schemes can be best tested in this set-up because the splitting schemes have here the potential to fail. The wind field is now composed of series of symmetrical vortices with all neighbors rotating in opposite directions and the divergence is non-zero. Therefore the MPDATA switch $idiv = 1$ needs to be used for this test. The purely horizontal wind speed components ($w(i, j, 10) = 0$) are defined as follows

$$u(i, j, 10) = \frac{120.0 \cdot \pi}{80.0} \sin(\frac{4.0 \cdot \pi}{80.0} i) \sin(\frac{4.0 \cdot \pi}{80.0} j)$$
$$v(i, j, 10) = \frac{120.0 \cdot \pi}{80.0} \cos(\frac{4.0 \cdot \pi}{80.0} i) \cos(\frac{4.0 \cdot \pi}{80.0} j)$$

Similar to the first advection test, a cone tracer q_i of 5 grid point radius is placed on the 10th level at the centre of the domain $(i_{max}, j_{max}) = (40, 40)$ and every where else set to zero

$$q_i(i, j, 10) = \max(0.0, 1.0 - \sqrt{((i - i_{max})/5)^2 + ((j - j_{max})/5)^2})$$

The shear flow generated by the equations above is shown in Figure 51 where the initial distribution of the tracer at time 0 is exactly split in the middle by a counterclockwise and a clockwise rotating vortex. The tracer will therefore be transported first to the North reaching a strongly divergent zone (with a saddle point at the center of the top 4 complete vortices) where the tracer will be split in two parts, one going West and another going East. Near the tracer maximum the Courant number is 0.04. The time for the tracer to go round once depends on the starting position and as the fluid trajectories are not circles for a position close to the center of the domain the period can be analytically computed by $P_c = 2\pi/(k^2|A|) = L^2/(8\pi|A|)$ where L is the computational domain and A is the amplitude of the stream function which describes the wind field (see formula (12) in Staniforth et al. (1987)). This corresponds here to about 1500 time steps so that after 10 hours of simulation the tracer has gone round about 1.2 times.

Advection scheme	Maximum after 5h	Maximum after 10h
Bott_2	0.297	0.148
Semi-Lagrange	0.334	0.164
MPDATA		
iord=2, nonos=0	0.278	0.126
iord=3, nonos=0	0.299	0.149
iord=2, nonos=1	0.267	0.128
iord=3, nonos=1	0.287	0.146

Table 10: Maximum values of the cone tracer in a deformational flow field.

Figure 52 displays the tracer concentration with the Bott_2 and the SL scheme and they can be compared with 2 different settings of the MPDATA scheme in Figure 53. Although the setup is completely symmetric the results show some small asymmetry which can be perhaps explained by the Coriolis force which was not excluded. The maximum tracer values of the experiments are summarized in Table 10 and for the *iord* = 3 and *nonos* = 0 configuration of MPDATA the values are higher than for Bott_2 but the results for SL are overall best.

The test referred to in Smolarkiewicz (1982) and in Staniforth et al. (1987) is laid out in a larger domain with a square side of 100 grid points and starts with a cone with a radius of 15 grid points which interacts with six vortices. The amplitude of the stream function is also reduced from 30 to 8 so that the time needed to reach $3T/200$ ($T = 2637.6$) is of 32 hours. Three different advection schemes are shown in Figure 54 and can be compared to the analytical solution shown in Figure 4a of Staniforth et al. (1987). The overall symmetry of this setup is much higher than with the previous deformation flow test. The solution with the highest wall on the North side of the two central vortices and between these two vortices is the SL configuration. The MPDATA configuration maintains higher maximum values than the Bott_2 scheme and the advection of the tracer near the North saddle point produces far reaching 'horns' which are also in the analytical solution, but the southern tracer extension from the South saddle point is the smallest with MPDATA.

6.9 Conclusions

MPDATA is a 3-dimensional advection scheme which was introduced by Piotr Smolarkiewicz. It is based on the upstream scheme. The strong diffusion of the upstream scheme is reduced

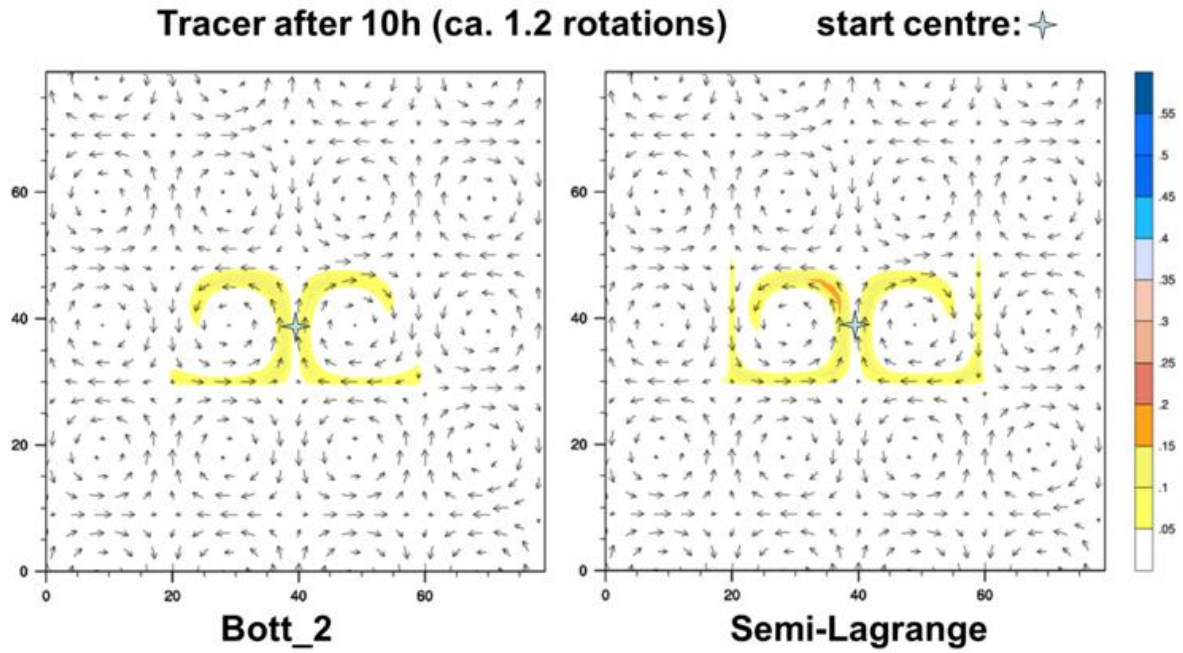

Figure 52: Tracer concentrations after more than a complete rotation of a cone with maximum of 1 and horizontal radius of 5 grid points centered in the middle of the domain for the Bott_2 (left) and semi-Lagrangian (right) advection scheme.

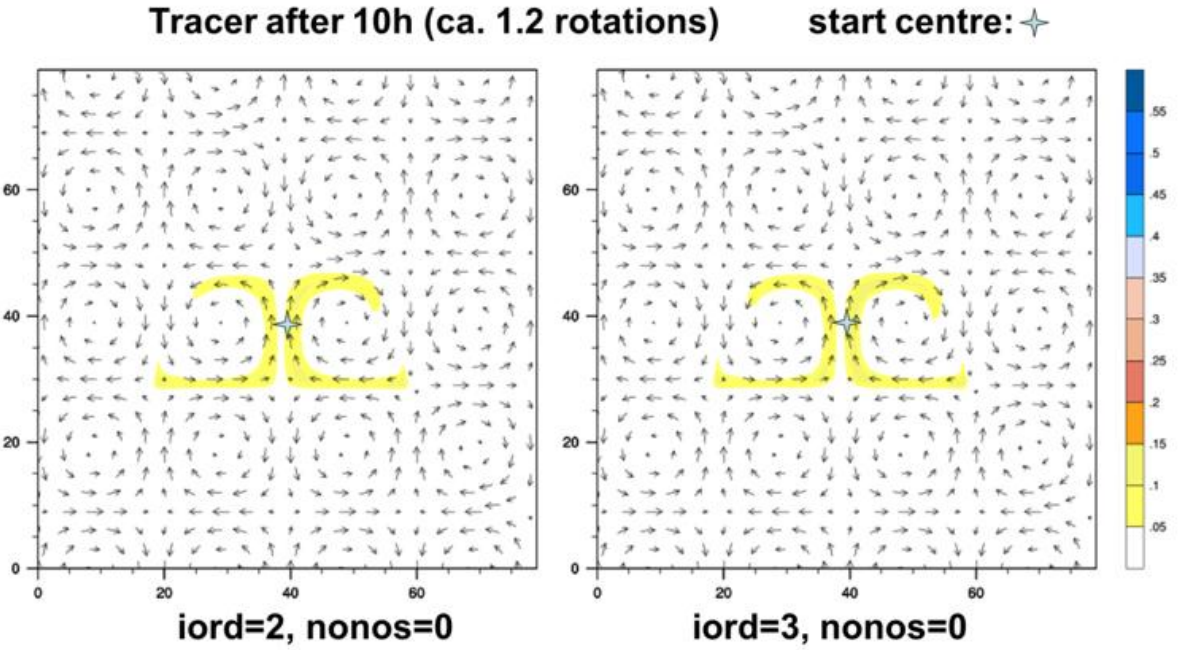

Figure 53: Same as Figure 52 but for 2 different settings of the MPDATA scheme.

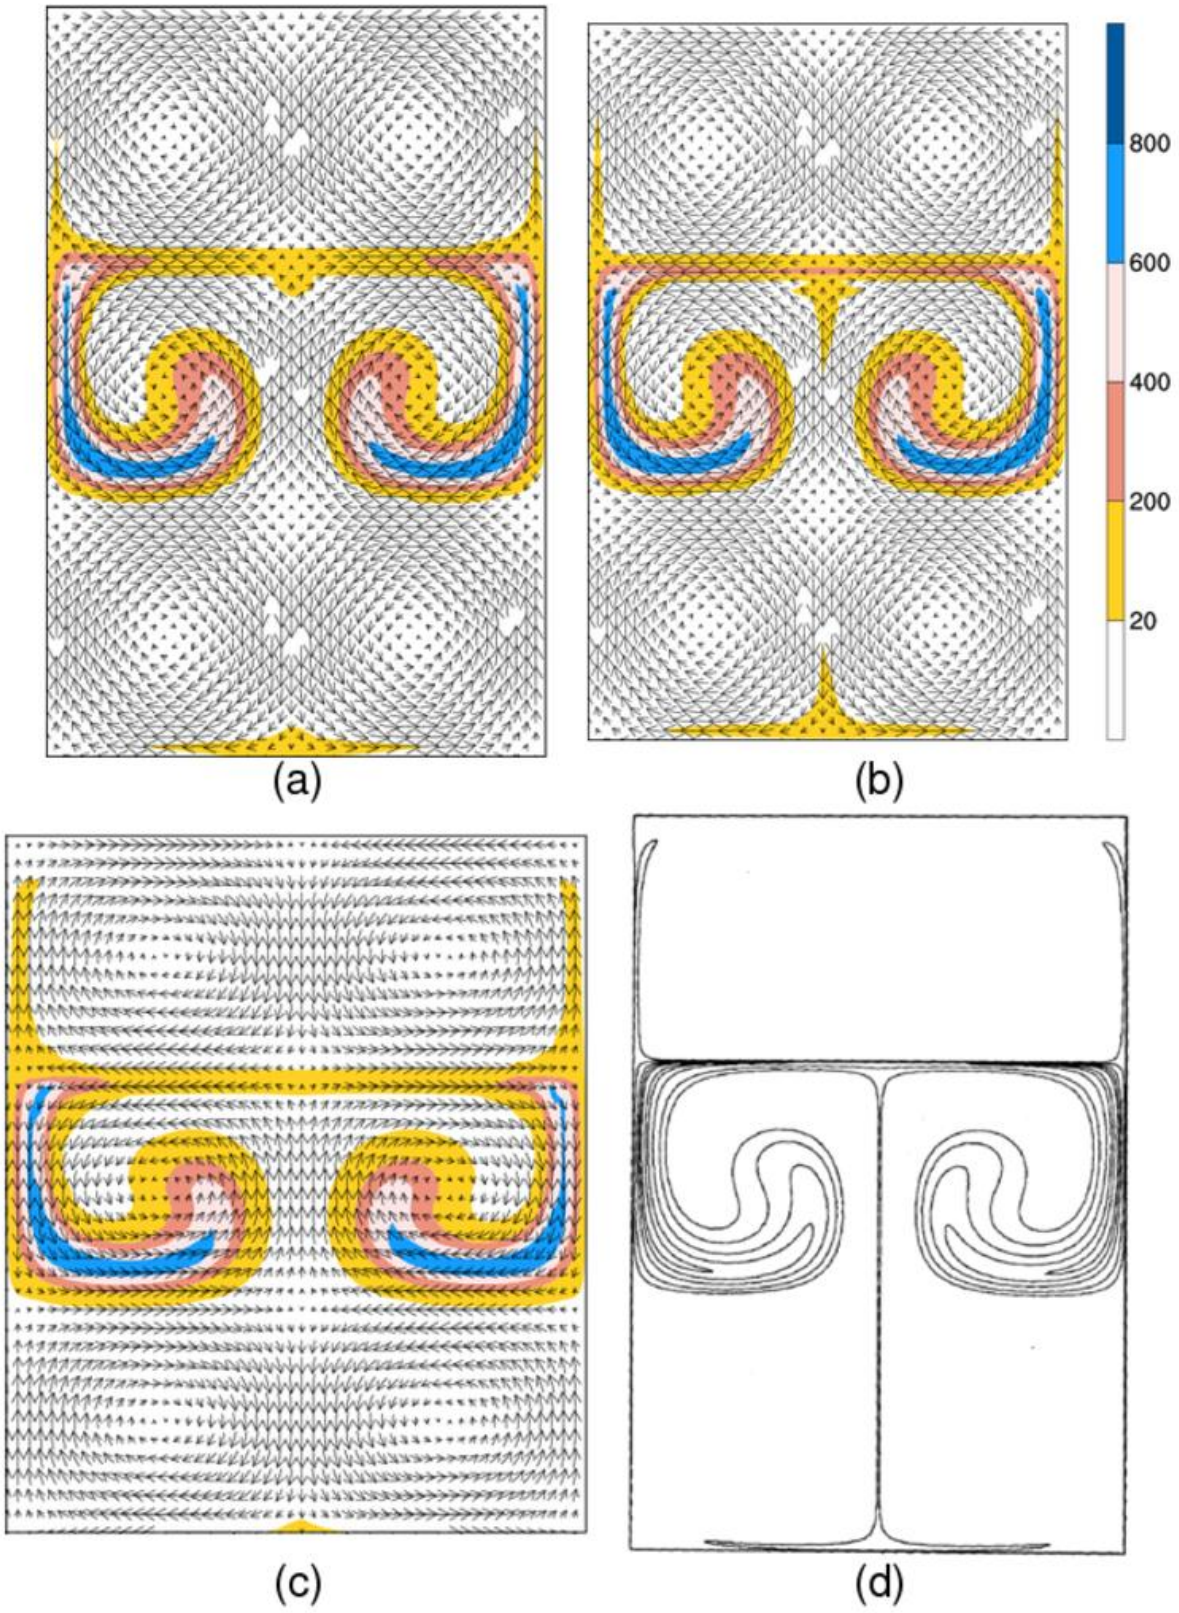

Figure 54: Tracer concentrations after 32 hours for (a) the Bott_2 scheme, (b) the SL scheme, (c) MPDATA scheme with *iord* = 3 and *nonos* = 1. (d) is the Fig. 4a of Staniforth et al. (1987) for $T/50$ with (T = 2637.6). All the isolines are 0.8 (not present in (a), (b) or (c)), 0.6, 0.4, 0.2, 0.02. Except for (d) the divergent flow field of the internal six vortices where the tracer is confined is also shown.

by iterating anti-diffusive steps.
Compared to splitted schemes, as the Bott-scheme, MPDATA has the advantage not to have the tendency to oscillate and is therefore more precise and as a fully 3-dimensional scheme it therefore can not empty a grid box in a single step. But MPDATA is more diffusive as the Bott_2 scheme or the 3-dimensional semi-Lagrangian scheme (SL). This was particularly the case in the solid body rotation tests because in the deformation flow tests the maximum values of MPDATA were better than for the Bott_2 scheme. To be fair a fully 3-dimensional test was not conducted so that the full advantage of MPDATA as a non-splitted scheme could not be completely compared to the Bott-scheme.
The computing time for MPDATA as used in this work is considerably larger than for Bott_2 or for the Semi-Lagrange scheme but no effort was undertaken to optimize the scheme as it is already done for the two other schemes which can be used for operations. For the moment MPDATA runs only on one processor and to operate weather forecasts one should consider to use a parallelised and optimized version of MPDATA and then to compare the results of the different advection schemes.

7 Normal mode analysis of anelastic and compressible equation sets

Michael Baldauf

Deutscher Wetterdienst, Germany

7.1 Introduction

Inspection of linear wave expansion properties is often one of the starting points in the investigation of a hyperbolic equation set. Such an analysis gives also a first impression about the accuracy of possible approximations made in an equation set. Here we will investigate the wave expansion properties of several anelastic approximations of the Euler equations. Such a study has already been done by Davies et al. (2003) and some of their results will be reproduced here. Contrariwise, the current COSMO model uses the fully compressible Euler equations with a split-explicit solver by Wicker and Skamarock (2002). This time-splitting approach needs a so-called divergence damping to be stable (Baldauf, 2010), which can be considered as an artificial additional term in the compressible Euler equations. It will be of interest in which manner such a term will change the wave expansion properties, too. In the frame of the CDC priority project, it is of particular interest to compare the divergence damping with the anelastic equations. This comparison is done here on the level of the analytic equations.

Such an investigation has been already performed by Baldauf (2011), where the anelastic approximation sets of Ogura and Phillips (1962), here denoted as 'OP62', Wilhelmson and Ogura (1972) ('WO72'), and Lipps and Hemler (1982) ('LH82') have been compared with a compressible equation set with the artificial 3-dimensional (3D) divergence damping. The equation set 'LH82' is used in the EULAG model (e.g. Smolarkiewicz and Prusa, 2005). This study extends those of Baldauf (2011) by considering additionally the anelastic equation set of Durran (1989) ('D89') and by comparing different versions (3D, 2D) of the divergence damping, too. The basic methodology again follows the normal mode analysis of Davies et al. (2003).

7.2 Derivation of the dispersion relations

In the following a steady atmosphere (no base flow $u_0 = 0$) is assumed for the base state. It is further hydrostatic ($\partial p_0/\partial z = -g\rho_0$) and fulfills the ideal gas law $p_0 = \rho_0 R T_0$. The sound velocity of the base state is $c_s = \sqrt{\frac{c_p}{c_v} R T_0}$.

We will use an equation for the pressure perturbation p' as in the COSMO-model, but a continuity equation to have a direct control about the anelastic approximations. The different anelastic equation sets are summarized e.g. in Nance and Durran (1994) and are therefore

not repeated here The linearization around the base state delivers

$$\frac{\partial u'}{\partial t} = -\frac{1}{\rho_0}\frac{\partial p'}{\partial x} + fv' + \alpha_D \frac{\partial D'}{\partial x}, \tag{16}$$

$$\frac{\partial v'}{\partial t} = -\frac{1}{\rho_0}\frac{\partial p'}{\partial y} - fu' + \alpha_D \frac{\partial D'}{\partial y}, \tag{17}$$

$$\frac{\partial w'}{\partial t} = -\frac{1}{\rho_0}\frac{\partial p'}{\partial z} - \sigma_{LH}\frac{1}{\rho_0}\frac{N^2}{g}p' - g\frac{\rho'}{\rho_0} + \alpha_{D,v}\frac{\partial D'}{\partial z} + \sigma_{dd2}\alpha_{D,v}D'\frac{1}{\rho_0}\frac{\partial \rho_0}{\partial z}, \tag{18}$$

$$\sigma_2\frac{\partial \rho'}{\partial t} + w'\frac{\partial \rho_0}{\partial z} = -\rho_0 D' - \sigma_{D89}\frac{\rho_0}{\Theta_0}\frac{\partial \Theta_0}{\partial z}w', \tag{19}$$

$$\frac{\partial p'}{\partial t} + \underbrace{w'\frac{\partial p_0}{\partial z}}_{=-g\rho_0 w'} = c_s^2\left(\frac{\partial \rho'}{\partial t} + w'\frac{\partial \rho_0}{\partial z}\right), \tag{20}$$

$$D' = \frac{\partial u'}{\partial x} + \frac{\partial v'}{\partial y} + \frac{\partial w'}{\partial z}. \tag{21}$$

Some switches $\sigma_{...}$ have been introduced whose values (0 or 1) are summarized in table 11. σ_{dd2} distinguishes two types of the artificial divergence damping in the 3D case: either the term $\alpha_D \partial D'/\partial z$ ('type 1', $\sigma_{dd2} = 0$) or the term $\alpha_D/\rho_0 \partial(\rho_0 D')/\partial z$ ('type 2', $\sigma_{dd2} = 1$). Type 2 is used in COSMO and MM5 because it can be coded more efficiently than type 1.
σ_2 is the main switch of the anelastic approximation. The additional term $\sim \sigma_{LH}$ only arises in the equation system of LH82. For its derivation one has to consider that LH82 are using $-c_p\nabla\Theta_0\pi' + \mathbf{g}\Theta'/\Theta_0$ for the pressure gradient and the buoyancy term instead of the correct term $-c_p\Theta\nabla\pi' + \mathbf{g}\Theta'/\Theta_0$ (Nance and Durran, 1994). In linear approximation the difference between these two terms is $-c_p\pi'\nabla\Theta_0$. Expressed by the variables used in the equation system above this can be approximated linearly by $-\frac{1}{\rho_0}\frac{N^2}{g}p'$. Alternatively, the D89 equation set uses $\nabla \cdot \rho_0\Theta_0\mathbf{v} = 0$ (for adiabatic processes) instead of $\nabla \cdot \rho_0\mathbf{v} = 0$ (used in OP62, WO72 and LH82). In linear approximation this delivers an additional term $\sim \sigma_{D89}$. The pressure equation is just the linearized adiabatic state equation $d\Theta/dt = 0$ which is used by all equation sets considered here. Furthermore, it should be mentioned that in this *linear* analysis there is no difference between the equation systems of OP62 and WO72.

equation system	σ_2	σ_{LH}	σ_{D89}	α_D	$\alpha_{D,v}$	σ_{dd2}
compressible	1	0	0	0	0	0
compressible, with 3D-div. damping, type 1	1	0	0	$\neq 0$	$= \alpha_D$	0
compressible, with 3D-div. damping, type 2	1	0	0	$\neq 0$	$= \alpha_D$	1
compressible, with 2D-div. damping	1	0	0	$\neq 0$	0	0
anelastic (OP62, WO72)	0	0	0	0	0	0
anelastic (LH82)	0	1	0	0	0	0
anelastic (D89)	0	0	1	0	0	0

Table 11: Switches for the different equation sets inspected in the normal mode analysis.

The coefficient functions of the linearized equations (16)-(21) are dependent on z. To reduce this z-dependency (the following Fourier transformation requires even constant coefficients) we perform a variable transformation by a function of the density according to Bretherton (1966, section 5):

$$\phi' = \left(\frac{\rho_0}{\rho_s}\right)^{\alpha} \cdot \phi_b. \tag{22}$$

where ρ_s is a constant reference value (e.g. at the bottom). The exponent is $\alpha = -1/2$ for the variables $\phi' = u, v, w, T'$ and $\alpha = +1/2$ for $\phi' = p', \rho'$. Insertion into eqns. (16)-(21) results in a quite similar system with additional terms proportional to the (inverse) scale height

$$\delta = -\frac{\partial}{\partial z}\left(\log\frac{\rho_0}{\rho_s}\right). \tag{23}$$

In the special case of an isothermal atmosphere ($T_0 = const.$) the density is purely exponential and therefore $\delta = g/(RT_0) = const.$ The result of this Bretherton transformation is that some coefficients (namely those $\sim 1/\rho_s$) become constant, whereas others like $\sim c_s^2$, $\sim T_0$, $\sim \delta$ remain dependent on z (they are only constant for an isothermal atmosphere). But this z-dependency is quite weak, therefore they can also be considered nearly as constant. This allows to extent the analysis to more realistic stratifications (see 'second stratification case' below).

It is convenient to introduce the acoustic cutoff frequency

$$\omega_a^2 = -\frac{g}{\rho_0}\frac{\partial\rho_0}{\partial z} \tag{24}$$

and therefore $\delta = \omega_a^2/g$, and the Brunt-Väisälä-frequency

$$N^2 = \frac{g}{\Theta_0}\frac{\partial\Theta_0}{\partial z} = \frac{g}{T_0}\left(\frac{\partial T_0}{\partial z} + \frac{g}{c_p}\right). \tag{25}$$

With the aid of the sound velocity, the ideal gas equation and the hydrostatic equation one can derive

$$\omega_a^2 = N^2 + \frac{g^2}{c_s^2}. \tag{26}$$

Now we can Fourier transform the equations by

$$\phi_b'(x,y,z,t) = \hat{\phi}_b(k_x,k_y,k_z,\omega)\, e^{i(k_x x + k_y y + k_z z - \omega t)}. \tag{27}$$

This leads to a system of the form $\mathbf{A}\cdot(\hat{u}_b,\hat{v}_b,\hat{w}_b,\hat{\rho}_b,\hat{p}_b)^T = 0$ with

$$\mathbf{A} = \begin{pmatrix} i\omega + \alpha_D(ik_x)^2 & f - \alpha_D k_x k_y & \alpha_D ik_x(ik_z + \frac{\delta}{2}) & 0 & -ik_x\frac{1}{\rho_s} \\ -f - \alpha_D k_x k_y & i\omega + \alpha_D(ik_y)^2 & \alpha_D ik_y(ik_z + \frac{\delta}{2}) & 0 & -ik_y\frac{1}{\rho_s} \\ \alpha_{D,v} ik_x K_d & \alpha_{D,v} ik_y K_d & i\omega + \alpha_{D,v}(ik_z + \frac{\delta}{2})K_d & -\frac{g}{\rho_s} & A_{35} \\ -ik_x\rho_s & -ik_y\rho_s & A_{43} & \sigma_2 i\omega & 0 \\ 0 & 0 & -\frac{\rho_s}{g}N^2 c_s^2 & -i\omega c_s^2 & i\omega \end{pmatrix} \tag{28}$$

and with the abbreviations

$$K_d = \left(ik_z + \frac{\delta}{2} - \sigma_{dd2}\frac{\omega_a^2}{g}\right), \tag{29}$$

$$A_{35} = -\frac{1}{\rho_s}\left(ik_z - \frac{\delta}{2}\right) - \sigma_{LH}\frac{1}{\rho_s}\frac{N^2}{g}, \tag{30}$$

$$A_{43} = -\rho_s(ik_z + \frac{\delta}{2}) + \rho_s\frac{\omega_a^2}{g} - \sigma_{D89}\rho_s\frac{N^2}{g}. \tag{31}$$

After an appropriate non-dimensionalization the requirement $\det A = 0$ leads to the characteristic equation for $\omega(\mathbf{k})$. This delivers the following dispersion relations:

The characteristic equation for the **non-hydrostatic, compressible equations** follows from the switches $\sigma_2 = 1$, $\sigma_{LH} = 0$, $\sigma_{D89} = 0$:

$$\begin{aligned}
&\omega^4 + \left[i\alpha_D(k_x^2 + k_y^2) + i\alpha_{D,v}\left(k_z - \frac{i}{2}\frac{\omega_a^2}{g}\right)^2 - \sigma_{dd2}\alpha_{D,v}\left(k_z - \frac{i}{2}\frac{\omega_a^2}{g}\right)\frac{\omega_a^2}{g} \right] \omega^3 \\
&- \left[c_s^2\left(k^2 + \frac{1}{4}\frac{\omega_a^4}{g^2}\right) + f^2 \right] \omega^2 \\
&+ \left[(k_x^2 + k_y^2)(\alpha_D - \alpha_{D,v})g\left(k_z - \frac{i}{2}\frac{\omega_a^2}{g}\right) - i\alpha_{D,v} f^2 \left(k_z - \frac{i}{2}\frac{\omega_a^2}{g}\right)^2 \right. \\
&\left. + \sigma_{dd2}\alpha_{D,v}\left(-i(k_x^2 + k_y^2)\omega_a^2 + f^2\left(k_z - \frac{i}{2}\frac{\omega_a^2}{g}\right)\frac{\omega_a^2}{g}\right) \right] \omega \\
&+ N^2 c_s^2 (k_x^2 + k_y^2) + f^2 c_s^2 \left(k_z^2 + \frac{1}{4}\frac{\omega_a^4}{g^2}\right) = 0.
\end{aligned} \tag{32}$$

For $\alpha_D = 0$ and $\alpha_{D,v} = 0$ we get the compressible solution (i.e. the 'true' solution), whereas the influence of the artificial divergence damping can be inspected by $\alpha_D, \alpha_{D,v} \neq 0$. Note, that this dispersion relation is identical to equations (15) and (18) of Gassmann and Herzog (2007), if the simplifications $f = 0$ and $\sigma_{dd2} = 0$ are made.

The different **anelastic approximations** follow from $\sigma_2 = 0$, $\alpha_D = \alpha_{D,v} = 0$ and the setting of the switches σ_{LH} and σ_{D89} (see table 11). This results in the dispersion relation

$$\left[c_s^2\left(k^2 + \frac{1}{4}\frac{\omega_a^2}{g}\right) + a_0 \right] \omega^2 - \left[c_s^2(k_x^2 + k_y^2)N^2 + f^2\left(c_s^2\left(k_z^2 + \frac{1}{4}\frac{\omega_a^2}{g}\right) + a_0 \right) \right] = 0 \tag{33}$$

with

$$a_0 = \begin{cases} \frac{N^2 c^2}{g}\left(ik_z - \frac{1}{2}\frac{\omega_a^2}{g}\right) & \text{for OP62, WO72,} \\ 0 & \text{for LH82,} \\ -N^2 & \text{for D89.} \end{cases} \tag{34}$$

All the anelastic approximations eliminates sound waves, only the two branches for gravity waves are contained.

In the following sections, we will evaluate and compare the dispersion relations (32) and (33) for several realistic parameters.

7.3 Discussion of the results

To get an impression about the behavior of waves we consider two stratifications. First an isothermal atmosphere with $T_0 = 260$ K. In this case the inverse scale height is $\delta \approx 1/7606.5$ 1/m, the sound velocity is $c_s \approx 323.2$ m/s, the Brunt-Väisälä-frequency is $N \approx 0.01919$ 1/s, and the acoustic cut-off frequency is $\omega_a \approx 0.03591$ 1/s. The second considered atmosphere also has a mean temperature of $T_0 = 260$ K but a Brunt-Väisälä frequency of $N = 0.01$ 1/s. We further consider wave expansion both in pure horizontal direction or in a direction which is tilted by 20 degrees against the horizontal.

For the compressible equations *with* divergence damping we choose values of $\alpha_D, \alpha_{D,v} = 50000$, 100000, or 150000 m^2/s, which are typical values for COSMO grid mesh sizes from about 2.8 km until about 10 km, respectively.

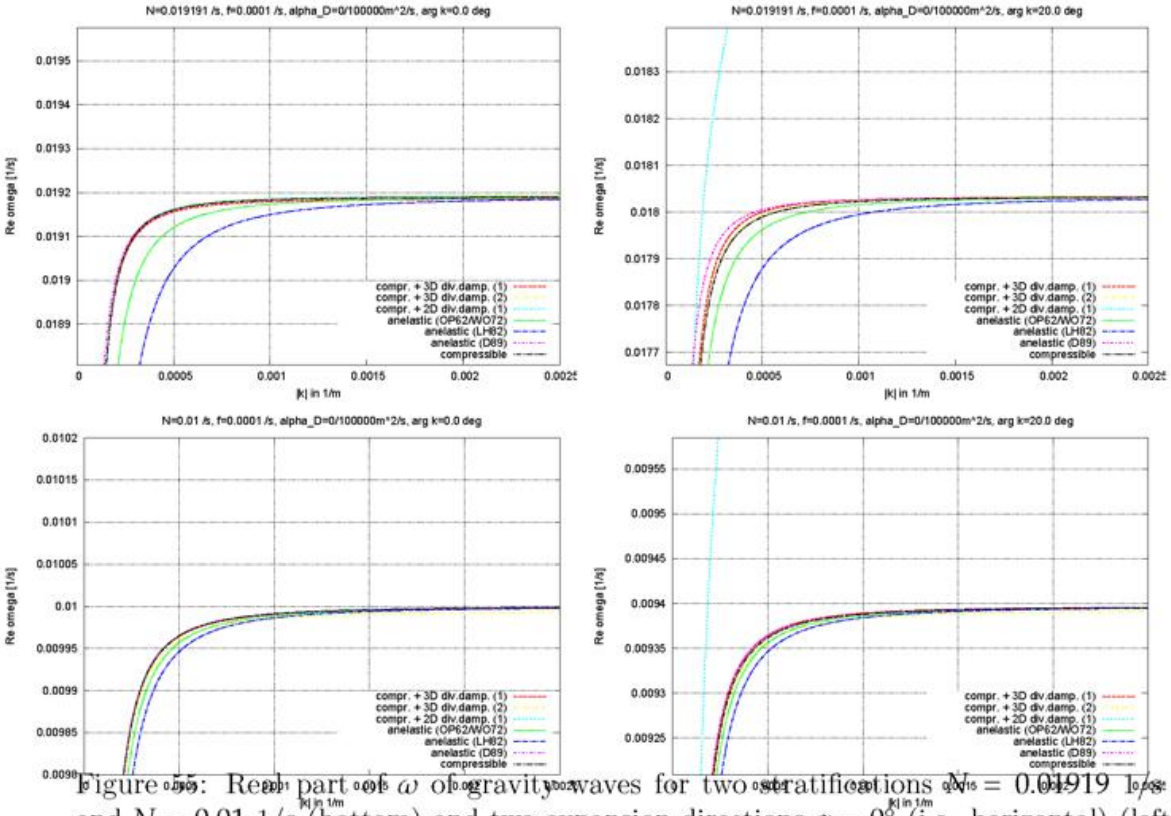

Figure 55: Real part of ω of gravity waves for two stratifications $N = 0.01919$ 1/s (top) and $N = 0.01$ 1/s (bottom) and two expansion directions $\alpha = 0°$ (i.e. horizontal) (left) and $\alpha = 20°$ (right). The different equation sets are distinguished by different colors and line types (see also table 11).

Short gravity waves. Figure 55 shows the positive real part of the gravity for the different equation sets. For very short gravity waves ($k = 0.003$ 1/m corresponds to a wavelength $\lambda = 2\pi/k \approx 2.1$ km) all equation sets show a quite good agreement with the 'truth', the dispersion relation of the compressible equations (black line). A closer examination shows that for the anelastic equation sets it holds indeed that $\omega \to \pm N$ for $k \to \infty$. The compressible 3D divergence damping versions do not exactly converge to the right value but the deviations are less than about 0.05 % and therefore are negligible. The 2D divergence damping has a quite strange behavior for tilted expansion, which is separately discussed below.

For longer waves (> 10 km) stronger deviations in the order of one percent are visible for the OP62 and WO72 system and even stronger for the LH82 system. In contrast, a remarkably good agreement with the compressible system is shown by the D89 equation set. The compressible sets *with* 3D-divergence damping are generally quite close to the compressible solution.

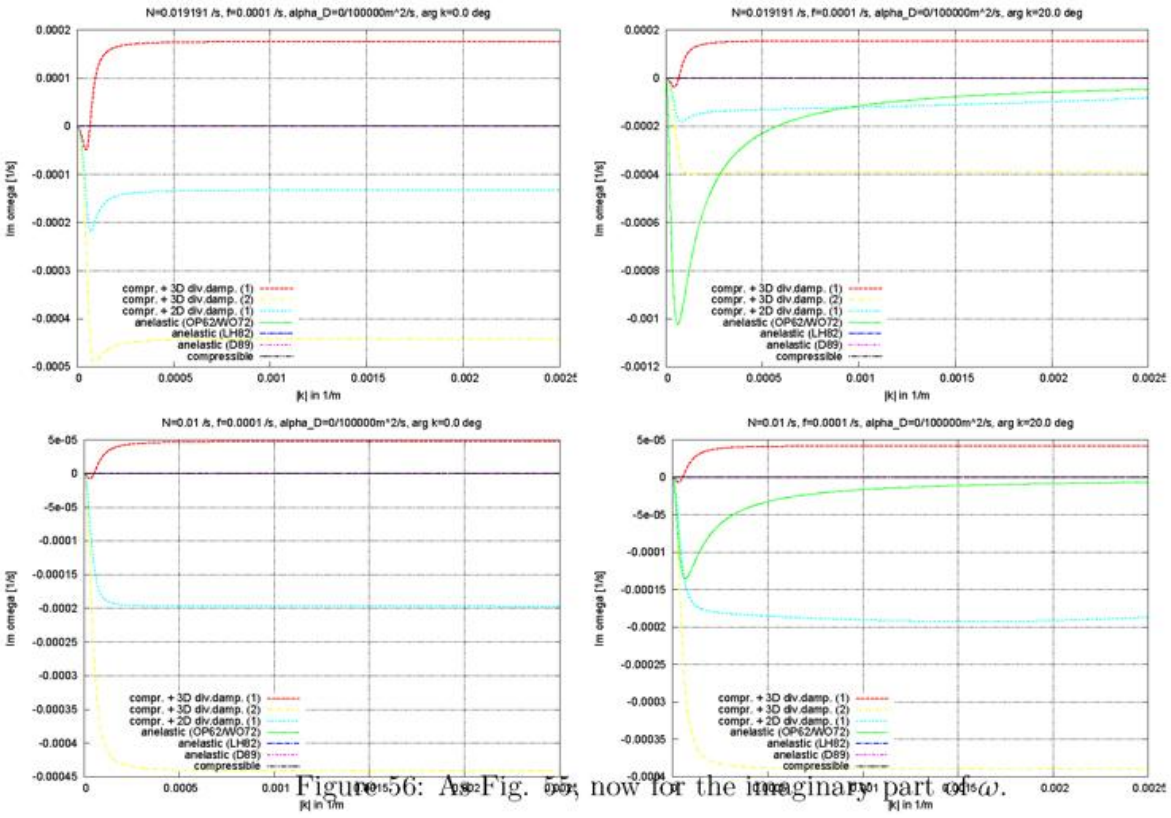

Figure 56: As Fig. 55, now for the imaginary part of ω.

The damping (i.e. the imaginary part of ω) is shown in Figure 56. The horizontal expansion of all anelastic sets has no damping. The same holds for tilted expansion in the cases LH82 and D89, however OP62 or WO72 show a certain damping for longer gravity waves. The compressible equations with 3D divergence damping type 2 show a damping of nearly all gravity waves. This is smaller for the 2D divergence damping. In contrast, type 1 even shows a weak amplification. This was also stated in Baldauf (2010, appendix), were it has been shown, too, that this behavior does not occur if the Bretherton-transformation is not performed.

Long gravity waves. The long gravity wave behavior is shown in Fig. 57 ($k = 0.0001$ 1/m corresponds to $\lambda \approx 63$ km). Obviously divergence damping has almost no influence to this wave type. The OP62 and WO72 systems are still relatively close to the compressible equations for wave lengths larger around 100 km. For even larger wave lengths the deviations become larger. A different behavior has LH82: here an intermediate range of long gravity waves show a larger deviation from the compressible solution, however, very long gravity waves ($\lambda > 300$ km) are well represented. Under all anelastic approximations considered here, such very long waves are worst represented by the D89 system. All these statements reduce in strength if the stratification becomes less stable. (lower figures in Fig. 57).

For the damping of long waves (Figs. 58) similar statements hold as for the shorter waves. For extremely long waves the influence of divergence damping decreases with increasing wave length.

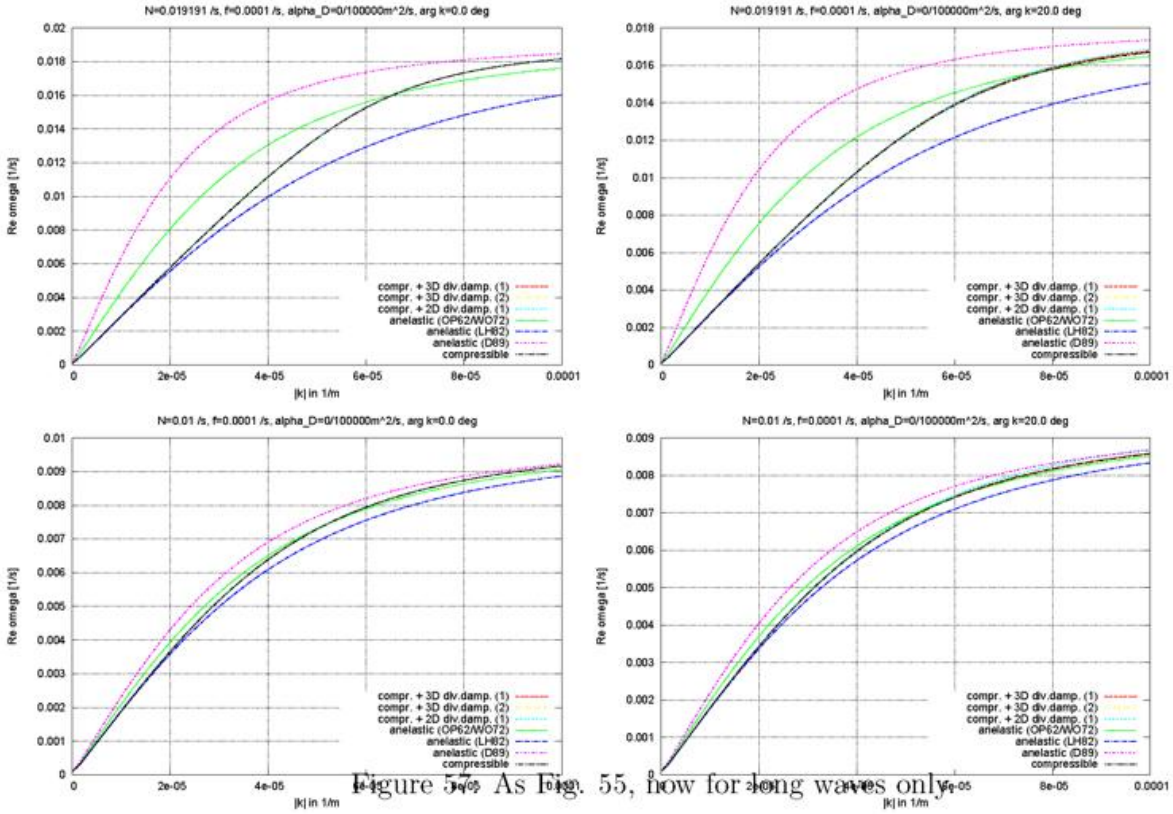

Figure 57: As Fig. 55, now for long waves only.

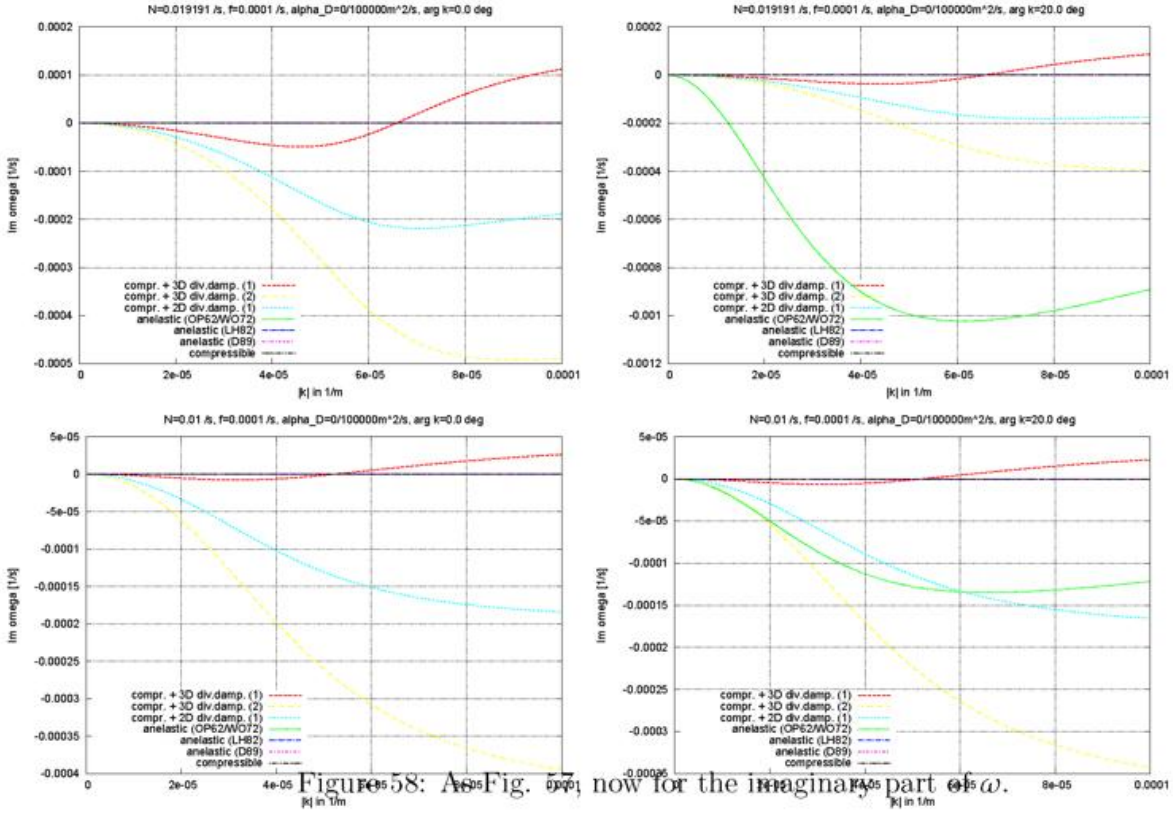

Figure 58: As Fig. 57, now for the imaginary part of ω.

Sound waves in the compressible systems. The compressible equations contain sound waves. The divergence damping increasingly reduces their phase velocity with decreasing wave length (Figure 59). However, for strong divergence damping the e-folding time is quite small, therefore only long sound waves will be simulated in the current COSMO dynamical core. In the case of tilted expansion (Figure 60), there is a small but relatively unimportant difference between the different types of divergence damping.

The temperature stratification has almost no influence to the expansion of sound waves. Therefore only results for $N = 0.01$ 1/s are shown.

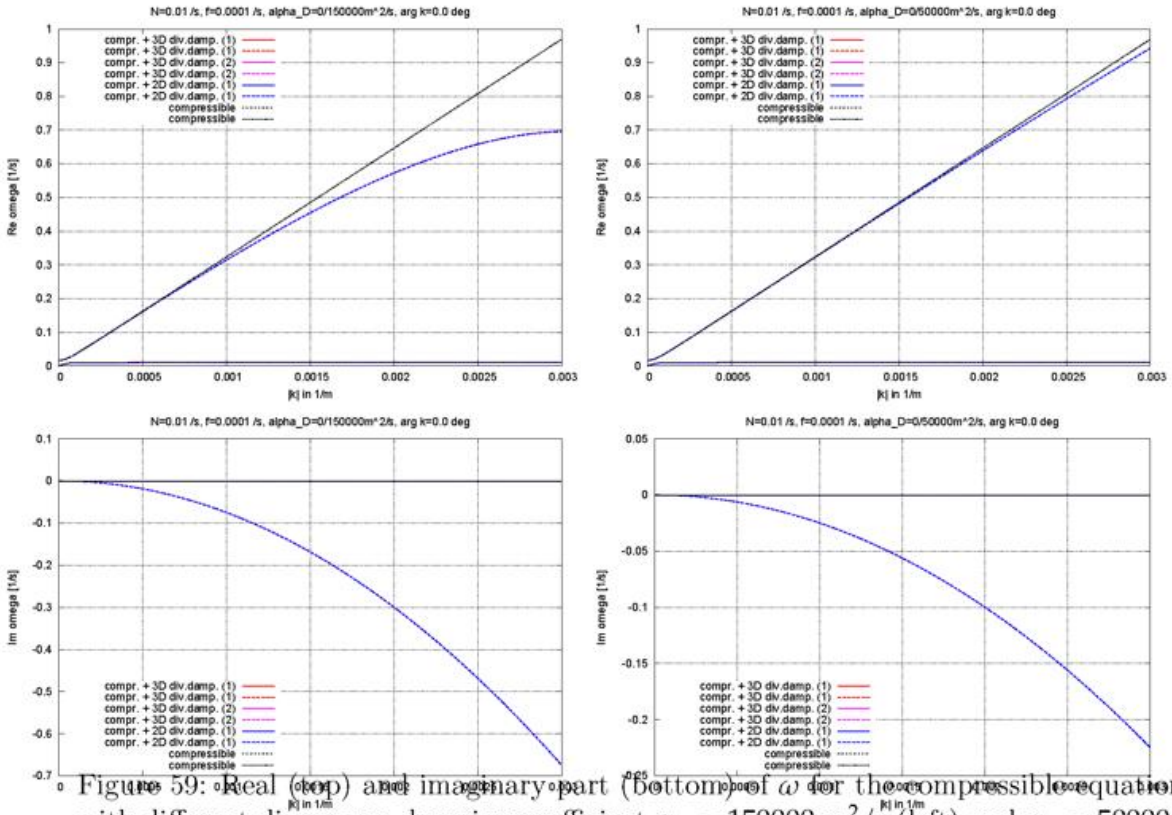

Figure 59: Real (top) and imaginary part (bottom) of ω for the compressible equation sets with different divergence damping coefficient $\alpha_D = 150000$ m^2/s (left) and $\alpha_D = 50000$ m^2/s (right). $N = 0.01$ 1/s, $\alpha = 0°$.

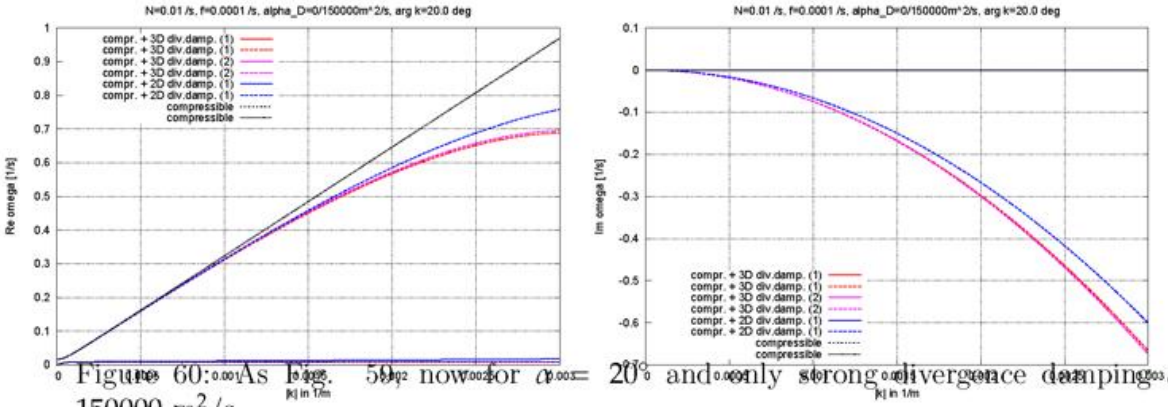

Figure 60: As Fig. 59, now for $\alpha = 20°$ and only strong divergence damping $\alpha_D = 150000\ \mathrm{m}^2/\mathrm{s}$.

Gravity waves in the compressible systems. In a section above we have already seen that the gravity waves are almost correctly treated by the 3D divergence damping. For the 2D divergence damping, this also holds only for purely horizontal expansion of gravity waves, whereas it shows a strange behavior for tilted expansion: the frequency obviously increases with decreasing wavelength instead of remaining constant. This behavior was already remarked by (Gassmann and Herzog, 2007, eq. (20)). Since in real case simulations and also in idealized tests this equation system behaves not so bad, a look to all the branches of the dispersion relation is advisable. Figure 61 shows that the positive frequencies ω are increasing with k. But the absolute values of the negative frequencies are *decreasing*. Physically this means that upward traveling gravity waves are faster then expected, whereas downward traveling gravity waves are slower than expected, so that their mean velocity is nearly the correct one.

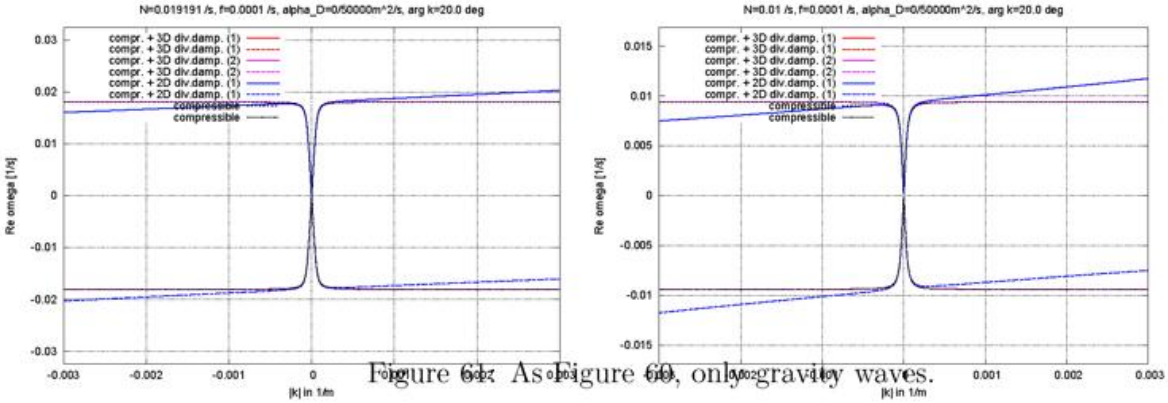

Figure 61: As Figure 60, only gravity waves.

7.4 Summary

The dispersion relations for several anelastic equation sets and compressible equations with several versions of the artificial divergence damping have been compared.

The general outcome is that the anelastic equation set is very well suited to simulate shorter gravity waves. The compressible systems with 'type 2' 3D-divergence damping treats the phase and group velocity of this wave type well, too, apart from a small damping. But

the 2D divergence damping, which is actually used in the COSMO model, exhibits a not completely satisfying behavior.

Concerning long gravity waves ($\lambda > 100$ km), the anelastic equation sets have some drawbacks. This probably reduces their applicability for global models a bit.

Sound waves are of course not contained in the anelastic equations, but also the shorter waves are heavily damped in the compressible equations by divergence damping. Only for rather long sound waves a reasonable realistic treatment can be expected.

Via Maiorise, 80143 Capua (CE), Italy

Summary

A flow solver for the Euler and Navier-Stokes equations in 3 dimensions has been written. Time integration is based on dual time stepping, spatial discretization on finite volumes. Second order central scheme with added artificial dissipation and fourth order scheme have been currently implemented. Convergence in dual time is improved by adopting residual averaging, local time stepping, preconditioning, multigrid. Tests with complex orography were carried out, they are meant to address the issues related with flow initialization, hydrostatic balance in the equations, inflow, outflow and upper boundary conditions. Some other test cases are reported, to demonstrate the capability of the present method to dial with typical basic phenomena.

8.1 Introduction

The general trend in numerical weather prediction is to increase the mesh resolution; consequences are the increase in amount of mesh cells, reduction of time step and steeper lower boundaries in regions with complex orography. In those regions mesh cells are more skewed, so horizontal and vertical components of velocity and pressure gradient (and numerical errors as well) are more strongly coupled.

Motivations for this work are the needs of improving numerical efficiency of the COSMO model, improving the conservation properties of the scheme and its capability to deal with steep orography.

Finite volume formulation has the capability of conserving the transported quantities, for this reason it is a good candidate for improving the conservation properties of the dynamical core. The dual time stepping procedure is very popular in the field of aerodynamics but it seems that was never tested for simulation of atmospheric flows. The aim of this work is to evaluate the performances of the scheme in comparison with the classical time splitting procedure, which is the standard time integration scheme of COSMO, in the perspective of using very small grid size and also very large time steps, those are required for climatological simulations. The main questions to answer are related to three aspects: equation set in conservative variables, the dual time stepping procedure and the finite volume schemes, whether they are suitable for numerical weather prediction.

8.2 Mathematical formulation

The unsteady Euler equations are cast in integral form for a region Ω with boundary $\partial\Omega$:

$$\frac{\partial}{\partial t}\int_{\Omega}\underline{\mathbf{W}}\,\mathrm{d}\Omega+\oint_{\partial\Omega}\underline{\underline{\mathbf{F}}}\cdot\underline{n}\,\mathrm{d}S=\int_{\Omega}\underline{\mathbf{B}}\,\mathrm{d}V \tag{35}$$

when the region Ω is fixed in time the above matrices are:

$$\underline{\mathbf{W}} = \begin{bmatrix} \rho \\ \rho u \\ \rho v \\ \rho w \\ \rho E \end{bmatrix}, \quad \underline{\underline{\mathbf{F}}} = \begin{bmatrix} \rho u & \rho v & \rho w \\ \rho u^2 + p & \rho uv & \rho uw \\ \rho uv & \rho v^2 + p & \rho w \\ \rho uw & \rho vw & \rho w^2 + p \\ \rho uH & \rho vH & \rho wH \end{bmatrix}, \quad \underline{\mathbf{B}} = \begin{bmatrix} 0 \\ 0 \\ 0 \\ \rho g \\ \rho gw \end{bmatrix}, \tag{36}$$

where $\underline{\mathbf{W}}$ is the vector of conserved quantities, $\underline{\underline{\mathbf{F}}}$ is the corresponding flux term, $\underline{\mathbf{B}}$ the source term, g the vertical component of the gravity vector $\underline{g}$ (usually the reference system z axis is oriented like -$\underline{g}$), $\underline{n}$ is the unit vector normal to the boundary surface and $\mathrm{d}S$ is the surface area element. We denote density and pressure as ρ and p, the velocity vector $\underline{\mathbf{u}}$=(u,v,w). For a perfect gas we can express the pressure from the total energy E

$$p = (\gamma - 1)\rho(E - \frac{\mathbf{u}^2}{2}) \tag{37}$$

the total enthalpy is defined by

$$H = E + \frac{p}{\rho}. \tag{38}$$

The integral form allows discontinuities in the flow field.

For computing the Navier-Stokes equations, viscous fluxes $\underline{\underline{\mathbf{G}}}$ are added to $\underline{\underline{\mathbf{F}}}$:

$$\underline{\underline{\mathbf{G}}} = -\begin{bmatrix} 0 & 0 & 0 \\ \sigma_{xx} & \sigma_{xy} & \sigma_{xz} \\ \sigma_{xy} & \sigma_{yy} & \sigma_{yz} \\ \sigma_{xz} & \sigma_{yz} & \sigma_{zz} \\ \underline{\mathbf{u}} \cdot \sigma_{ix} - \kappa\frac{\partial T}{\partial x} & \underline{\mathbf{u}} \cdot \sigma_{iy} - \kappa\frac{\partial T}{\partial y} & \underline{\mathbf{u}} \cdot \sigma_{iz} - \kappa\frac{\partial T}{\partial z} \end{bmatrix} \tag{39}$$

$\underline{\underline{\sigma}}$ is the stress tensor and its components are:

$$\begin{aligned} \sigma_{xx} &= \mu[2\frac{\partial u}{\partial x} - \tfrac{2}{3}(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z})] \\ \sigma_{xy} &= \mu(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}) \end{aligned} \tag{40}$$

the other components are obtained by exchanging the velocity gradient derivatives. μ is the kinematic viscosity, the heat flux is given by the thermal diffusion coefficient κ multiplied by the temperature gradient. In case of turbulent fluxes the turbulent viscosity μ_{tur} and turbulent thermal diffusion κ_{tur} are modeled and added to the thermodynamical (laminar) coefficients. Turbulent viscous flows were not simulated in this work.

Boundary conditions are different in case of inflow, outflow and rigid wall. Inflow conditions allow to set four variables and extrapolate one variable from inside the flow field. Usually momentum and density are set, and pressure is extrapolated. Outflow conditions allow to set one variable (usually pressure or normal momentum component) and extrapolate the others. Boundary conditions on rigid walls fix normal momentum component to 0 and extrapolate tangential components and pressure. Artificial dissipation also requires boundary conditions: usually zero artificial fluxes are set at the boundaries. In case of viscous computations all the momentum components at the wall can be set to 0 (no-slip boundary condition), and wall enthalpy or heat flux (enthalpy gradient) can be assigned. In case of inviscid flow the heat flux at the wall could be added as an external source to the ground layer.

8.3 Finite volume scheme and time integration

The equations are discretized by sub-dividing the flow domain in sub-domains (mesh cells), assuming the conserved quantities $\underline{\mathbf{W}}$ are known at the center of each mesh cell. In our case the domain is sub-divided in structured form, which means that each cell is stored in a 3-dimensional array and can be addressed by a 3-d index (i,j,k). Its 6 neighbors can be simply addressed by the indices (i+1,j,k), (i-1,j,k), (i,j-1,k), (i,j+1,k), (i,j,k-1), (i,j,k+1). The structured mesh arrangement allows more efficient algorithms for computing advective and diffusive fluxes, and more efficient data storage, since it is not necessary to keep informations for addressing the neighbor cells. The semi-discretization for a sub-domain of volume V leads to the equation:

$$V\frac{\partial(\underline{\mathbf{W}})}{\partial t} + \underline{\mathbf{R}}(\underline{\mathbf{W}}) = 0 \tag{41}$$

where

$$\underline{\mathbf{R}}(\underline{\mathbf{W}}) = \underline{\mathbf{Q}} - \underline{\mathbf{D}} - \underline{\mathbf{B}}. \tag{42}$$

$\underline{\mathbf{R}}$ represents the sum of the net flux out of the sub-domain $\underline{\mathbf{Q}}$, the artificial dissipative flux -$\underline{\mathbf{D}}$ (that is required for numerical stability) and the source term -$\underline{\mathbf{B}}$, which are balanced by the rate of change of $\underline{\mathbf{W}}$. The net flux out of the cell m is given by the sum over the six cell faces k

$$\mathbf{Q}_{\mathrm{m}} = \sum_{\mathrm{k}=1}^{6} \underline{\underline{\mathbf{F}}}_{\mathrm{mk}} \cdot \underline{n} S_{\mathrm{mk}} \tag{43}$$

Fluxes $\underline{\underline{\mathbf{F}}}$ are approximated at the cell face centers by averaging the quantities between the cell m and its neighbors k,

$$\underline{\underline{\mathbf{F}}}_{\mathrm{mk}} = \frac{\underline{\underline{\mathbf{F}}}_{\mathrm{m}} + \underline{\underline{\mathbf{F}}}_{\mathrm{k}}}{2} \tag{44}$$

S_{mk} is the area of the face between cells m and k, and $\underline{n}$ the unit vector normal to the cell face pointing outward. The artificial dissipation $\underline{\mathbf{D}}$ is proportional to the fourth derivative of the conserved variables:

$$\underline{\mathbf{D}} = \nu\nabla^4(\underline{\mathbf{W}}). \tag{45}$$

It can be expressed in flux form as the sum of the third derivative over the cell faces, in order to keep the conservation properties of the scheme.

Time derivatives are discretized by a second order backward formula, where the upper index n indicates the current time step. Volume for our system is constant in time and can be taken out of the time derivative:

$$\frac{\partial(\underline{\mathbf{W}})}{\partial t} = \frac{3\underline{\mathbf{W}}^{n+1} - 4\underline{\mathbf{W}}^{n} + \underline{\mathbf{W}}^{n-1}}{2\Delta t} \tag{46}$$

This formula is implicit, as it contains the variables $\underline{\mathbf{W}}$ at the time step n+1. It is A-stable and damps the highest frequency. In principle there are no limitations to Δt due to numerical stability. The dual time stepping procedure (Jameson, 1992) consists in solving the following system by inner iterations which advance in pseudo-time τ to steady state:

$$\frac{\partial(\underline{\mathbf{W}}^{n+1})}{\partial \tau} + \underline{\mathbf{R}}^{*}(\underline{W}^{n+1}) = 0 \tag{47}$$

where

$$\underline{\mathbf{R}}^{*}(\underline{W}^{n+1}) = \frac{3\underline{\mathbf{W}}^{n+1} - 4\underline{\mathbf{W}}^{n} + \underline{\mathbf{W}}^{n-1}}{2\Delta t} + \underline{\mathbf{R}}(\underline{W}^{n+1}) \tag{48}$$

An explicit multistage Runge-Kutta time marching scheme with variable local $\Delta\tau$, residual averaging, preconditioning and multigrid is implemented to advance the system in dual time, until a norm of the dual time derivative is smaller than a given small value. It should be noted that the backward implicit time derivative is second order accurate only when the residuals of the dual time equations are driven to 0. A technique based on prediction can be adopted, in order to keep the second order accuracy also in case of non perfect convergence of the dual time iterations: the flow variables are initialized at the beginning of the dual time iterations by an appropriate prediction formula, second order accurate in time. It has been shown that the dual time iterations do not destroy the second order accuracy of the prediction formula.

The convergence rate of iterative solvers for compressible Euler or Navier-Stokes equations is limited in case of low Mach number flows, because of the large difference between the velocities of the advective fluxes and the pressure perturbations (acoustic waves). Usual technique is to modify the acoustic speed in order to make the local Mach number large enough almost everywhere in the flow domain. It has essentially two functions: the first one is to improve the convergence rate, the second one is to modify the relative influence of the artificial dissipation term, which would affect the physical solution for very small Mach numbers. The basic idea is to pre-multiply the time derivatives of the flow variables (without artificial dissipation) by an appropriate matrix, which performs the scaling of the acoustic speeds with respect to the flux velocities. More details are in Turkel et al. (1996). Preconditioning can only be applied when we are interested to obtain a steady solution, since it destroys the time accuracy of the governing equations. In our procedure the physical time derivatives are treated as source terms and they are concealed in the right hand side of the equations set, while the dual time derivatives are relaxation terms.

8.4 Atmosphere at rest

The test case with atmosphere at rest (i.e. zero velocity components and no fluxes from the boundaries) is useful to highlight the numerical issues related to the large vertical gradient of pressure and density in case of a deformed mesh. Discretization errors in the computation of the pressure gradient for tilted cells can produce non-zero horizontal components. Even the little displacement of a single mesh point in the interior of a perfectly regular rectangular mesh on flat orography can produce spurious velocity and disturbances in the flow solutions. When pressure is a function only of the vertical coordinate z, a density field exists that allows a steady solution with zero velocity. But the spatial discretization of the pressure gradient is affected by metric terms. The discrete Euler flow equations for a cell m in case of atmosphere at rest simplify to:

$$\frac{\partial \rho}{\partial t} = 0 \tag{49}$$

$$\frac{\partial \rho u}{\partial t} + \frac{1}{V}\sum_{k=1}^{6} p_{mk} n_x S_{mk} = 0 \tag{50}$$

$$\frac{\partial \rho v}{\partial t} + \frac{1}{V}\sum_{k=1}^{6} p_{mk} n_y S_{mk} = 0 \tag{51}$$

$$\frac{\partial \rho w}{\partial t} + \frac{1}{V}\sum_{k=1}^{6} p_{mk} n_z S_{mk} = \rho g \tag{52}$$

$$\frac{\partial \rho E}{\partial t} = 0 \tag{53}$$

p_{mk} is the pressure averaged at the face between the cells m and k:

$$p_{\mathrm{mk}} = \frac{p_{\mathrm{m}} + p_{\mathrm{k}}}{2} \tag{54}$$

n_x, n_y, n_z are the Cartesian components of the unit vector normal to the face, S_{mk} is the face area. The set of discrete equations in case of zero velocity is a system of $3\mathrm{N}_c$ linear equations in $2\mathrm{N}_c$ unknowns p, ρ, constant in time, where N_c is the total amount of mesh cells. So it is not possible to find discrete solution for the atmosphere at rest with generic 3 dimensional meshes: only additional constraints on mesh coordinates could allow a solution for the equilibrium of the horizontal pressure gradient components. The resulting horizontal accelerations produce spurious motions.

A reference pressure and density field p_{ref} , ρ_{ref} in hydrostatic equilibrium is subtracted from the momentum equation to reduce the amount of spurious accelerations. By assuming that:

$$\nabla p_{\mathrm{ref}} = \rho_{\mathrm{ref}} g \tag{55}$$

$$p' = p - p_{\mathrm{ref}} \tag{56}$$

$$\rho' = \rho - \rho_{\mathrm{ref}} \tag{57}$$

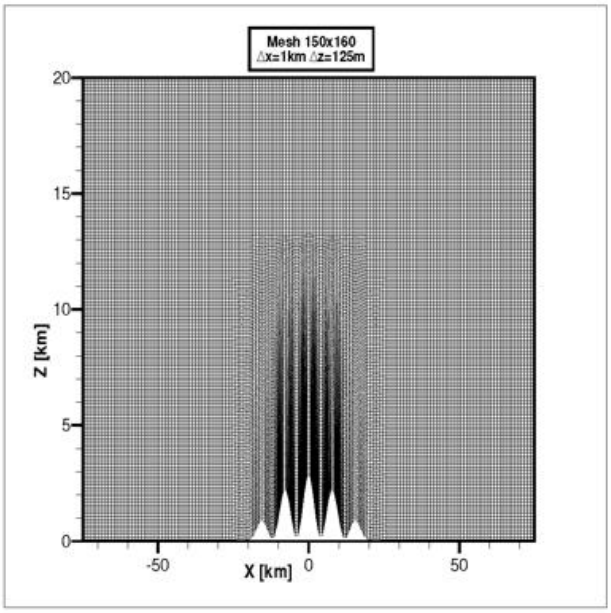
the momentum equations in discrete form can be written as follows:

$$\frac{\partial \rho u}{\partial t} + \frac{1}{V} \sum_{\mathrm{k}=1}^{6} p'_{\mathrm{mk}} n_x S_{\mathrm{mk}} = 0 \tag{58}$$

$$\frac{\partial \rho v}{\partial t} + \frac{1}{V} \sum_{\mathrm{k}=1}^{6} p'_{\mathrm{mk}} n_y S_{\mathrm{mk}} = 0 \tag{59}$$

$$\frac{\partial \rho w}{\partial t} + \frac{1}{V} \sum_{\mathrm{k}=1}^{6} p'_{\mathrm{mk}} n_z S_{\mathrm{mk}} = \rho' g \tag{60}$$

Since the pressure perturbation p' is usually 10 to 100 times smaller than full pressure, the spurious acceleration is also smaller. Pressure and density perturbations are adopted for computing the artificial dissipation terms. In order to evaluate the performances of the numerical scheme, a skewed mesh was produced on a simplified orography with highest mountain of 3 km (Fig. 62). The mesh contains 150 cells in horizontal direction and 160 in vertical direction, with Δx = 1 km and Δz= 125 m. The mesh levels are flat above 13.5 km.



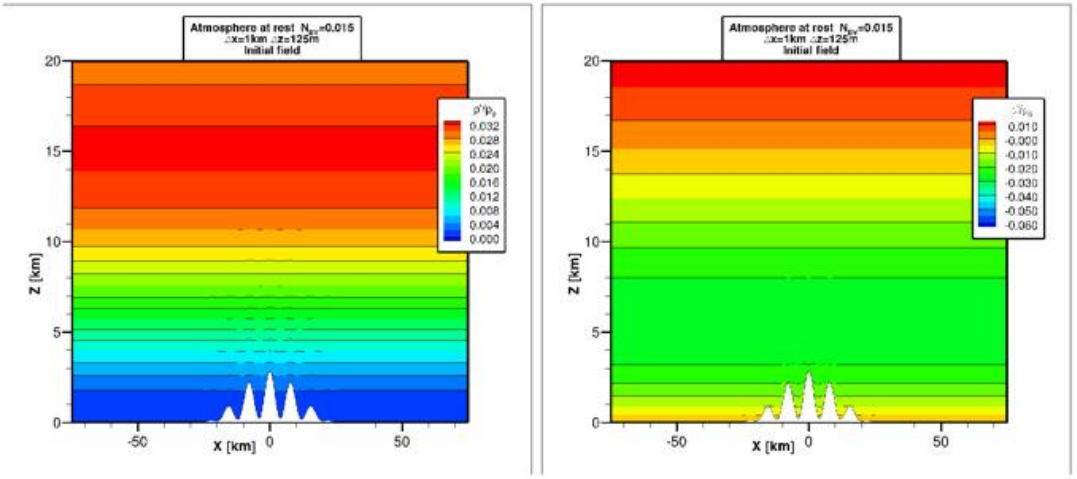


Figure 62: Mesh for testing the atmosphere at rest

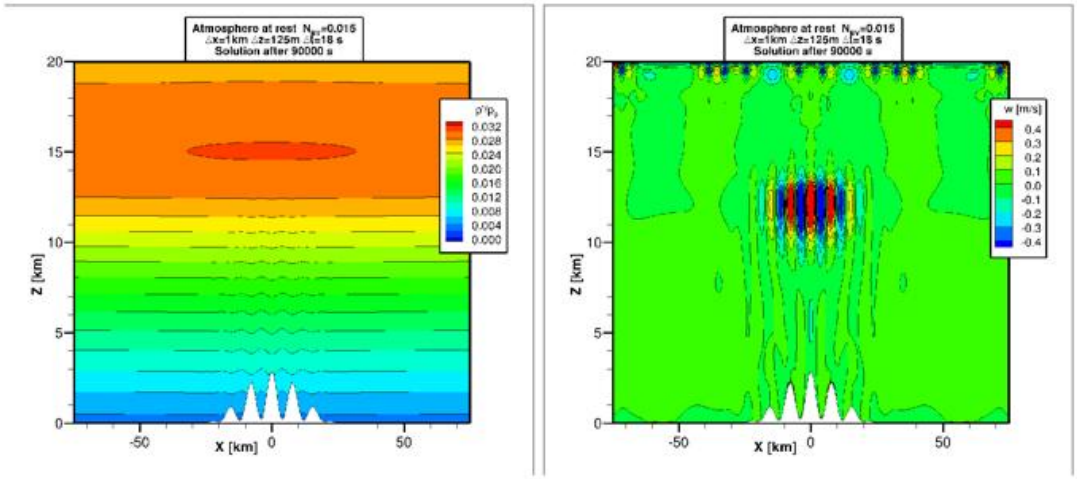
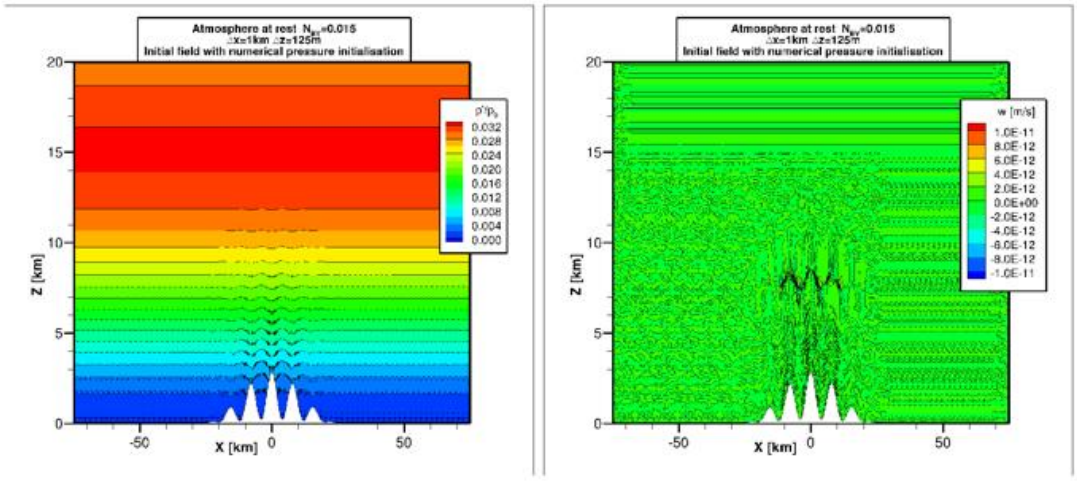


The reference pressure and density field is defined with constant Brunt-Väisälä frequency N_{BV}=0.01 1/s, and the initial field is defined with N_{BV}=0.015 1/s, so the initial pressure and density perturbations are computed as the difference between the two fields (Fig. 63). The flow field computed after 90000 seconds is shown in Fig. 64.

(a) Initial pressure perturbation

(b) Initial density perturbation

Figure 63: Initial perturbation field for atmosphere with N_{BV}=0.015 1/s



(a) Pressure perturbation (b) Vertical velocity component

Figure 64: Velocity components after 90000 s

The magnitude of the spurious velocity field is affected by the artificial viscosity ν: near the ground it damps the oscillations, at the higher levels the mesh stretching in vertical direction increases the artificial fluxes. This effect calls for a more appropriate formulation of the artificial dissipation and for a smoother mesh clustering in vertical direction.

An exact solution of the discrete equations for the atmosphere at rest can be obtained in 2D cases on generic meshes: the pressure field can be computed from the equation for the horizontal component (equilibrium of the horizontal component of the pressure forces acting on the four sides of each cell): the pressure depends upon the metric terms. After the pressure has been computed, the density field can be readily derived from the equilibrium in vertical direction. An example of such a 2D solution for a skewed mesh shown in Fig. 65.

(a) Pressure perturbation (b) Vertical velocity component

Figure 65: Exact solution of the discrete equations for 2D atmosphere at rest: pressure field computed from the equilibrium in horizontal direction

By comparing the numerical solution of pressure and density fields with the mathematical solution (horizontal stratification) the effect of a deformed mesh can be seen: it is clear that a mesh deformation induces disturbances in the field in such a way that pressure is increased where the mesh density decreases (i.e. in correspondence of the valleys). The resulting

velocity field is balanced.

8.5 Pressure gradient correction

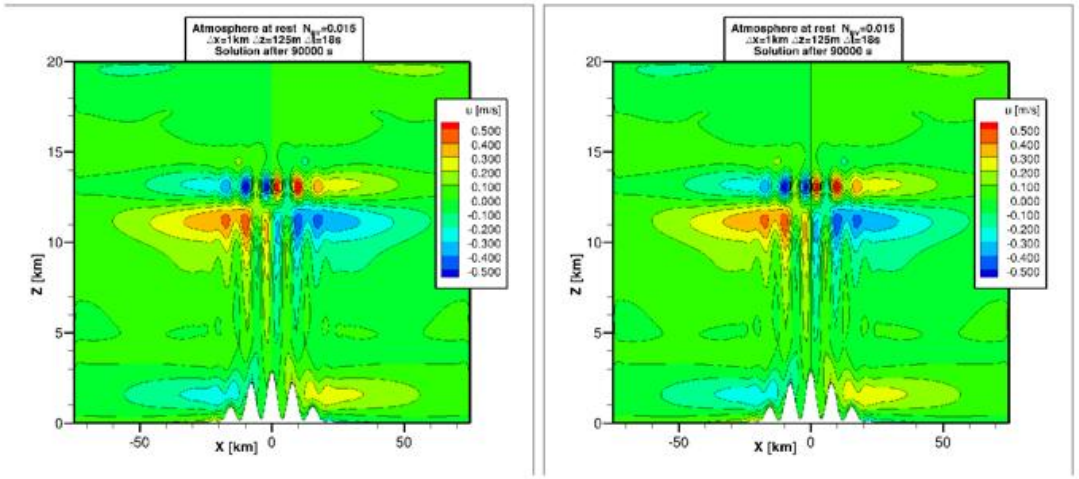
A correction of the pressure gradient terms has been tested, in order to reduce the spurious velocity for the atmosphere at rest. This seems to improve the convergence rate of dual time iterations as well. The basic idea is to add a first order correction to the pressure averaged at the cell faces, by considering the vertical pressure gradient ρg, when the face center has different vertical coordinate from the cell center. Two different approaches were tested and compared. In the first case the density is considered to be constant inside a mesh cell. The averaged pressure at the face between cells m and k is computed as follows:

$$p'_{mk} = \frac{p'_m + (\frac{\partial p'}{\partial z})_m \delta z_m + p'_k + (\frac{\partial p'}{\partial z})_k \delta z_k}{2} \tag{61}$$

where δz_k is the difference between the z coordinate of the cell face center and the k cell center.

$$(\frac{\partial p'}{\partial z})_k = \rho'_k g \tag{62}$$

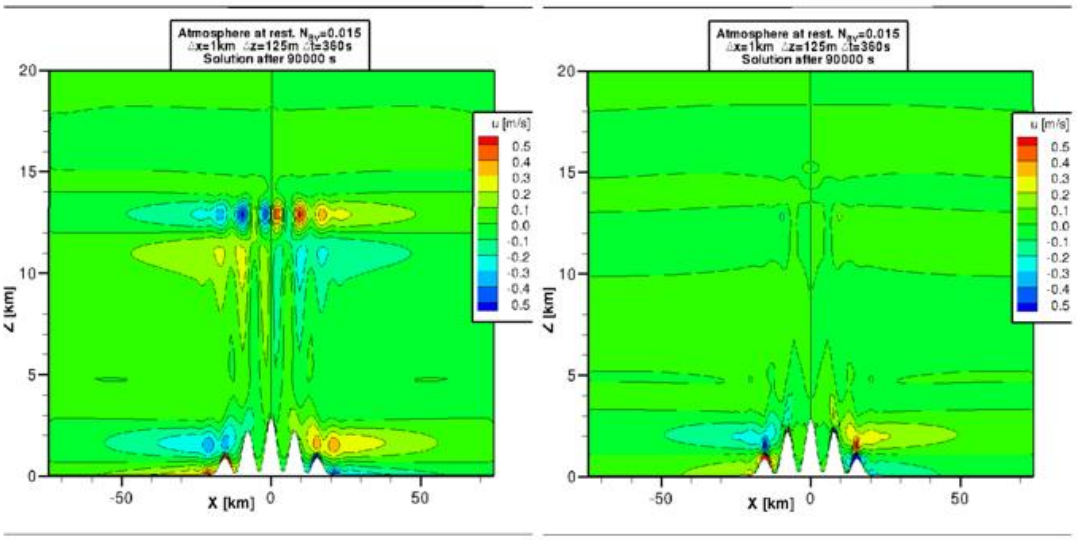
The second approach considers a vertical gradient of the density perturbation inside the cell, related to the pressure gradient by the isentropic relation:



$$(\frac{\partial p'}{\partial \rho'}) = \gamma p/\rho = c^2 \tag{63}$$

It means that entropy is assumed to be constant inside a cell, rather than density. Both the averaged pressure and density are modified by adding the following corrections like in eq.(61):

$$(\frac{\partial p'}{\partial z})_k = \frac{\rho'_k g}{1 + \frac{\delta z_k}{c^2}} \tag{64}$$

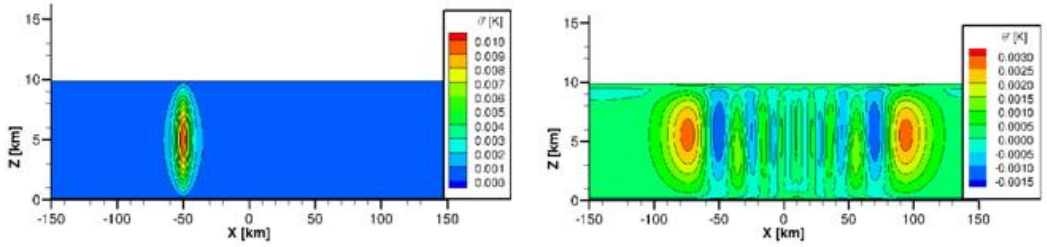


$$(\frac{\partial \rho'}{\partial z})_k = \frac{\rho'_k g}{c^2 + \delta z_k} \tag{65}$$

The perturbation fields after 90000 seconds are compared in Fig. 66 and show similar behavior, with smaller velocities near the ground. Finally, the effect of reducing the artificial viscosity is shown in Fig. 66(d). The flow computations of the atmosphere at rest were carried out with time steps ranging from 18 to 750 seconds, without significant differences in the results.

(a) Pressure correction approach 1

(b) Pressure correction approach 2



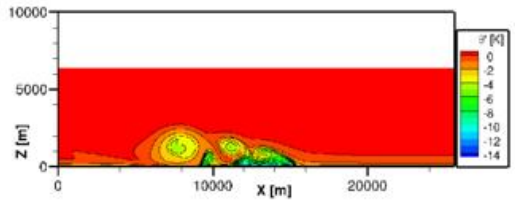
(c) No pressure correction

(d) Pressure correction and reduced artificial viscosity

Figure 66: Comparison of horizontal velocity components after 90000 s with different pressure correction approaches

8.6 Gravity wave

The test case is described in Skamarock and Klemp (1994), it shows the capability of the present scheme to simulate the time evolution of gravity waves produced by potential temperature perturbations. The flow field is initialized with constant Brunt Väisälä frequency N_{BV}=0.01 1/s in a channel of length 300 km and height 10 km, with rigid free-slip upper and lower boundaries. A small perturbation of potential temperature is located at x=-50 km (Fig. 67(a)). The wave is advected by a uniform stream of 20 m/s. The perturbation of total temperature is implemented as a perturbation of density. The mesh is made of 1200x40 cells, Δx=Δz=250m. Initial disturbance of potential temperature and solution computed after 3000 s are shown in Fig. 67. Time steps from 0.25 s to 50 s were tested, although details of the solution deteriorate when the time step is larger than 3 s.



(a) Initial potential temperature perturbation (b) Potential temperature perturbation after 3000 s

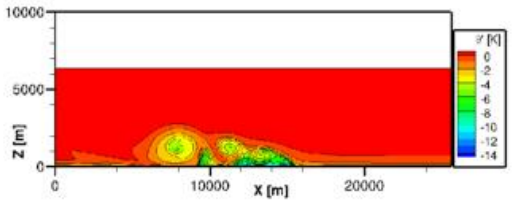


Figure 67: Gravity wave. Mesh with Δx=Δz=250 m, time step 1 s

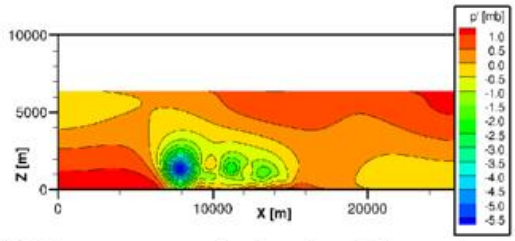
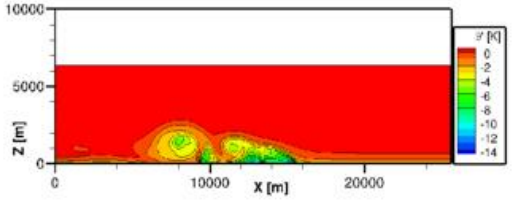
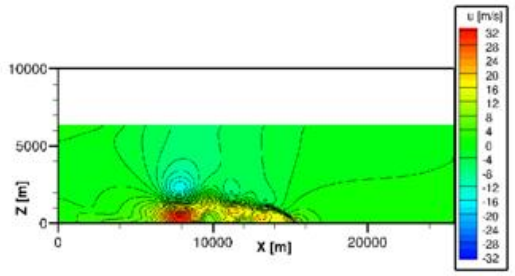
8.7 Density current



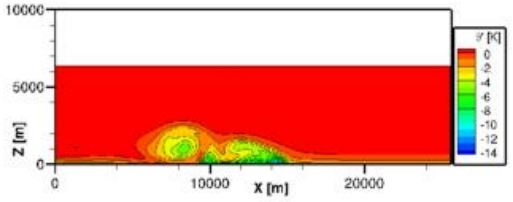
The test case is described in Straka et al. (1993). The equation set is completed by viscous fluxes (momentum and internal energy diffusion), with constant diffusion coefficient. Different mesh sizes (from Δx = Δz= 200m to 12.5m) and time steps between 0.25 and 10 seconds were tested. The complete flow field was simulated, without symmetric boundary condition in x=0. The solution is affected by the time step when Δt is larger than 1 second: it seems that larger time steps introduce a sort of viscosity, so that local maxima of the flow variables are smoothed and velocity is smaller. Mesh size below 50 m is sufficient to obtain grid-converged solutions. In Fig. 68 the solution obtained with the finest mesh is shown, together with a comparison of the potential temperature obtained with different mesh density and time step.



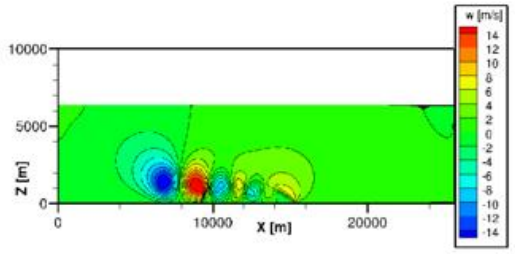
(a) Potential temperature Δx=12.5 m, Δt=1 s ν=1/160



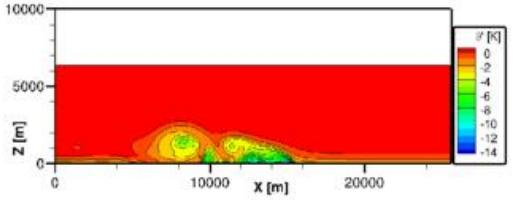
(b) Potential temperature Δx=50 m, Δt=1 s ν=1/160



(c) Pressure perturbation Δx=12.5 m, Δt=1 s ν=1/160



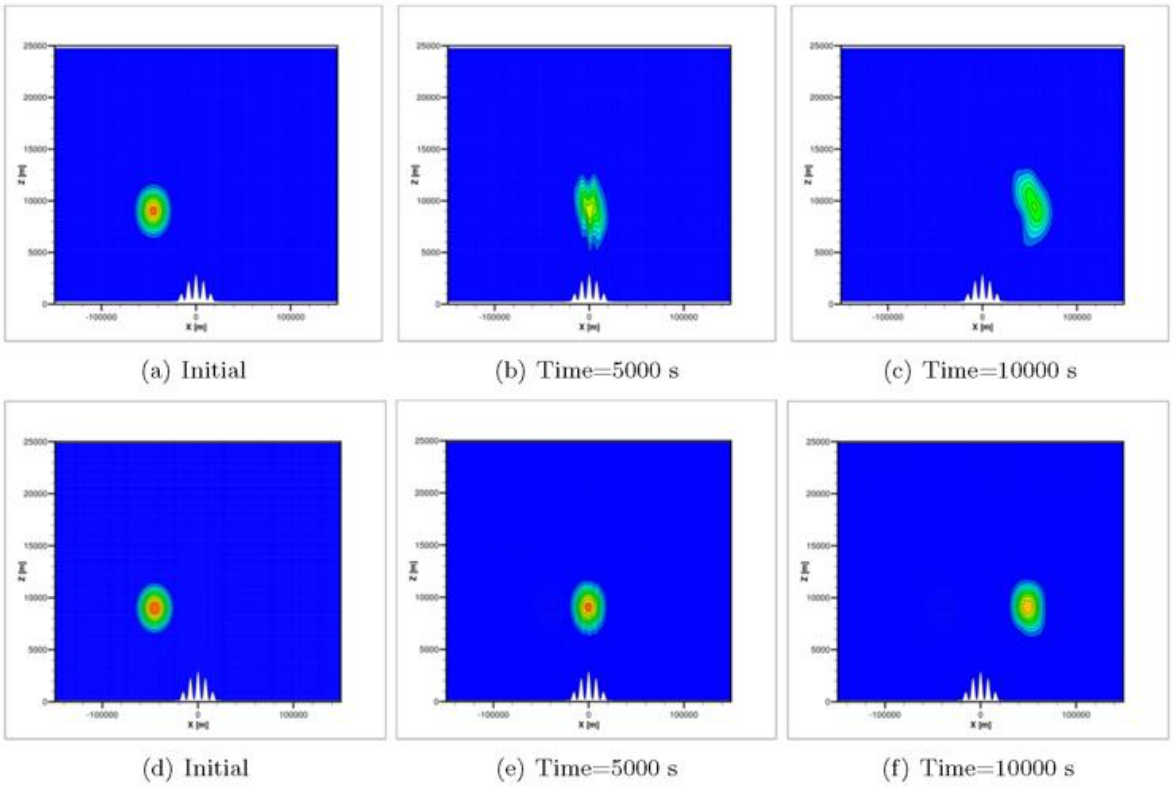
(d) Potential temperature Δx=100 m, Δt=1 s ν=1/160



(e) Horizontal velocity Δx=12.5 m, Δt=1 s ν=1/160

(f) Potential temperature Δx=100 m, Δt=10 s ν=1/160

(g) Vertical velocity Δx=12.5 m, Δt=1 s ν=1/160

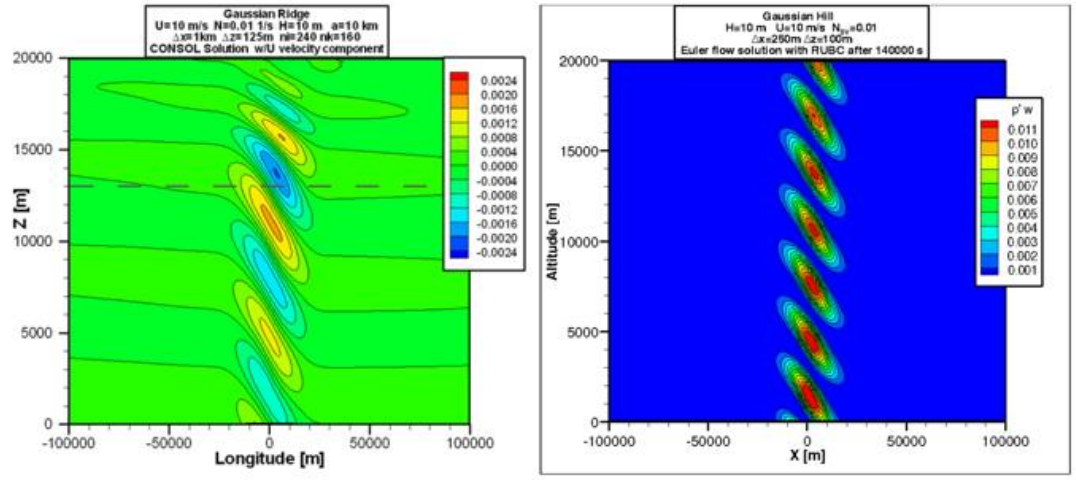


(h) Potential temperature Δx=100 m, Δt=1 s ν=1/80

Figure 68: Density current. Results after 900 s. Left: mesh with Δx=12.5 m. Right: effect of mesh density, time step, artificial dissipation ν

8.8 Advection

The test case is described in Schär et al. (2002). A scalar quantity contained in a circular bubble is advected accross a highly skewed mesh. The inflow velocity is 0 below the altitude of 4 km and rises smoothly to 10 m/s between 4 km and 5 km. Two different meshes were tested: the first one contains 300x50 cells with Δx=1 km and Δz=500 m, the second one has twice the number of cells in both directions with Δx=0.5 km and Δz=250 m (Fig. 69). A time step of 50 s was adopted in both computations. An attempt was made to implement and test the fourth order scheme described in Kok (2009), without significant improvements.



(a) Initial (b) Time=5000 s (c) Time=10000 s

(d) Initial (e) Time=5000 s (f) Time=10000 s

Figure 69: Advection of a conserved quantity in a deformed mesh. Above: coarse mesh 1. Below: mesh 2

8.9 Hydrostatic mountain flow

A classical hydrostatic test case is the flow simulation of a reference atmosphere with Brunt Väisälä frequency N_{BV}=0.01 1/s over a Gaussian shaped hill 10 m high, with free stream velocity of 10 m/s. The gravity waves produced above the mountain are stationary and momentum is transported in vertical direction. In order to avoid spurious reflection of the waves against the upper boundary, two techniques can be adopted: a damping layer in the upper atmosphere, where vertical velocities are smoothly damped, or a radiative upper boundary condition, that allows the wave energy to cross the boundary without reflection. In the first case (Fig. 70 a) about one third of the flow field is affected by an artificial damping term, that modifies the global momentum budget. In the second case (Fig. 70 b) the boundary condition has to be tuned to the local flow conditions, in order to be effective.

(a) Rayleigh damping: velocity field. The dashed line shows the lower side of the damping layer

(b) Radiative upper boundary condition: energy flux

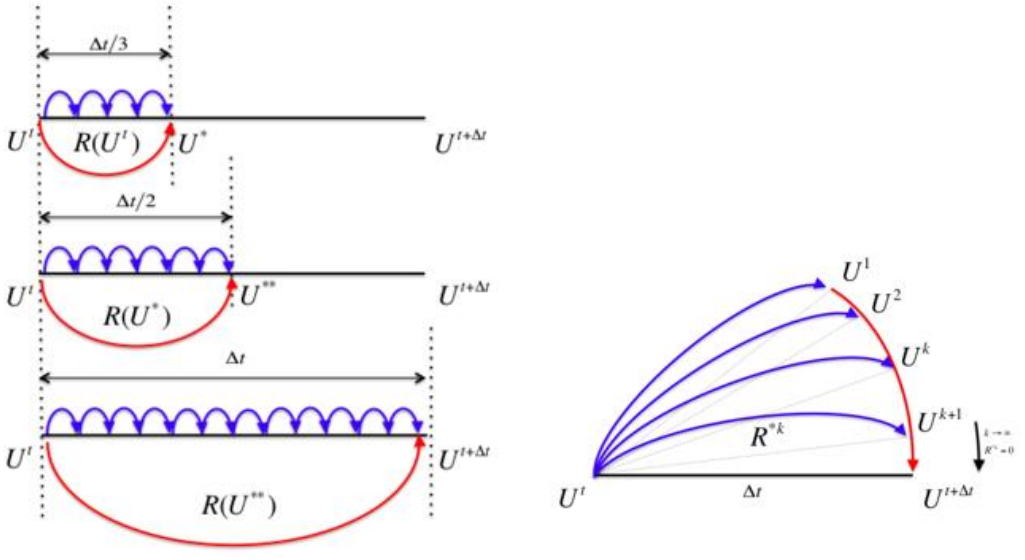
Figure 70: Hydrostatic flow computed with different upper boundary conditions

8.10 Conclusions

The CONSOL flow solver, based upon second order central finite volume schemes and implicit time integration with dual time stepping, is capable to simulate the test cases considered in the present work. A wide range of time steps can be adopted, as it is not limited by numerical stability, that could be an advantage when time accuracy is not an issue. It is not possible at this moment to draw a conclusion about the numerical efficiency with respect to other schemes, since the solver is not optimized yet. More complex 3D test cases should be simulated.

8.11 Implementation of a time integration procedure based upon dual time stepping in COSMO

The time integration procedure based upon dual time stepping was implemented in a test version of COSMO, by replacing the Runge-Kutta scheme currently adopted. This preliminary study was meant to assess the possibility to use the scheme in the dynamical core of COSMO. It seems that the dual time stepping was never used in the field of numerical weather prediction, despite its popularity in aerodynamics. The idea was to keep the equations set with the spatial discretization schemes adopted in COSMO, and to replace only the time integration scheme. Main difference is that the time splitting procedure operates in physical time, by advancing the flow solution with smaller time steps for the fast processes and larger steps for slow processes. The dual time stepping computes all processes with the same time step, and iterates in order to improve the evaluation of the flow variables and the time derivatives using the 'dual' time as relaxation parameter. The dual time relaxation is a pseudo-steady problem, which does not require time accuracy and can be solved with any convergence acceleration technique, like local time stepping, implicit residual averaging and preconditioning. As the scheme is implicit, in theory there is no limitation to the physical time step due to stability.



Defining the prognostic variables in the COSMO solver as $\underline{\mathbf{U}} = (u,v,w,p',T')$ and the model equations as

$$\frac{\partial \underline{\mathbf{U}}}{\partial t} = -R(\underline{\mathbf{U}}) \tag{66}$$

where $R(\underline{\mathbf{U}})$ denotes the right hand side of the model equation for $\underline{\mathbf{U}}$, the Runge Kutta integration takes the form of three steps to advance a solution $\underline{\mathbf{U}}(t)$ to $\underline{\mathbf{U}}(t + \Delta t)$:

$$\begin{aligned} \underline{\mathbf{U}}^{*} &= \underline{\mathbf{U}}^{t} - \frac{\Delta t}{3} R(\underline{\mathbf{U}}^{t}) \\ \underline{\mathbf{U}}^{**} &= \underline{\mathbf{U}}^{t} - \frac{\Delta t}{2} R(\underline{\mathbf{U}}^{*}), \\ \underline{\mathbf{U}}^{t+\Delta t} &= \underline{\mathbf{U}}^{t} - \Delta t R(\underline{\mathbf{U}}^{**}) \end{aligned} \tag{67}$$

where Δt is the time step for the slow-frequency modes (the model time step), and superscripts denote time levels. The time-splitting technique integrates fast modes with smaller time steps; terms associated with horizontally propagating modes are integrated explicitly, while terms associated with vertically propagating modes are integrated implicitly. The implicit integration component alleviates the severe Courant number restriction, arising from vertically propagating acoustic modes when using grids with large aspect ratios $\frac{\Delta x}{\Delta z}$, at the cost of a simple tridiagonal matrix inversion. The Figure 71a shows the three stages of the Runge-Kutta time integration procedure, where the blue arrows represent the small time steps used to advance the fast tendencies of the governing equations, while the slow tendencies are kept constant in each stage, represented by the red arrows.

(a) Runge-Kutta time integration

(b) Dual time stepping integration

Figure 71: Time integrations in COSMO: 3 stages Runge-Kutta and Dual time stepping

In the dual time stepping procedure (see equations 47 and 48) the residual at the dual iteration k is computed as follows:

$$\underline{\mathbf{R}}^{*k} = \underline{\mathbf{R}}(\underline{\mathbf{U}}^{k}) + \frac{3\underline{\mathbf{U}}^{k} - 4\underline{\mathbf{U}}^{t} + \underline{\mathbf{U}}^{t-\Delta t}}{2\Delta t} \tag{68}$$

we evaluate $\underline{\mathbf{R}}(\underline{\mathbf{U}}^k)$ using the spatial schemes already implemented in the dynamical core of COSMO for computing the time derivatives. The dual time derivative

$$\frac{\partial \underline{\mathbf{U}}^k}{\partial \tau} = -\underline{\mathbf{R}}^{*k} \tag{69}$$

is integrated to the steady state (see Fig. 71b). A flow chart of the implementation is shown in Fig. 72.

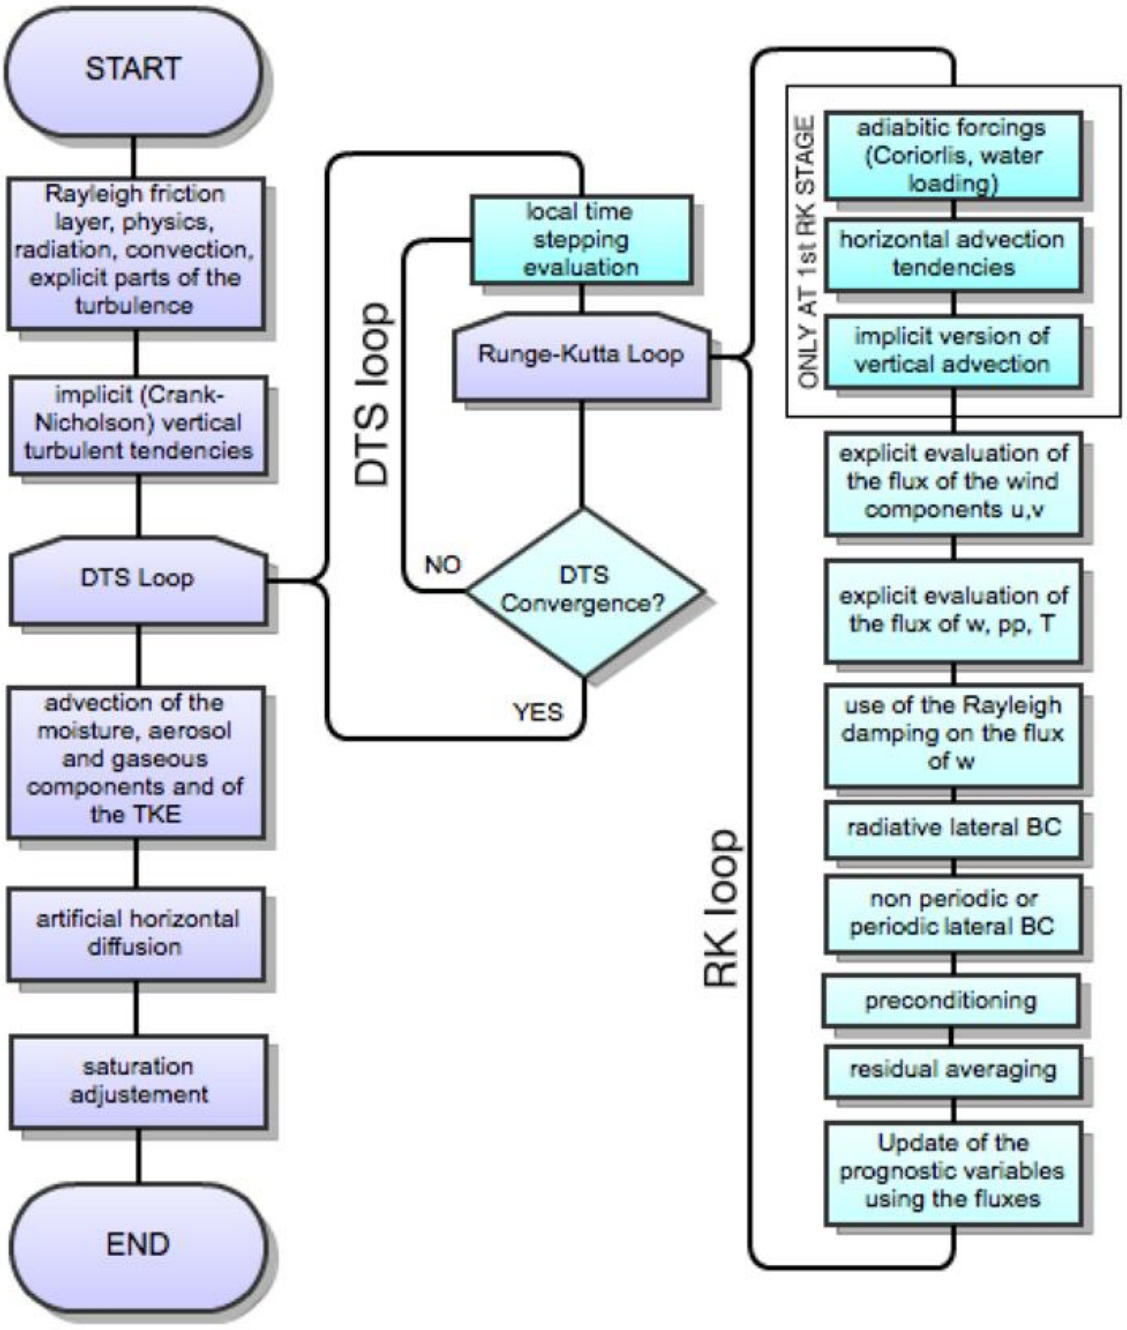


Figure 72: Flow chart of the Dual time stepping implementation in COSMO

Idealized test cases were computed, like mountain flow and inertia-gravity waves, which have

shown that the scheme is capable to give similar results to the original COSMO model, as reported in Petrone (2012). Larger time steps can be adopted. Applications to real test cases would require further work to be completed.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction

The latter Winter Olympic Games were hold in Sochi, Russia. Sochi–2014 region is very complicated for numerical modeling because of the mosaic surface properties determined by the close proximity of the Black Sea coast line combined with the mountainous terrestrial conditions. The local mesoscale circulation causes numerous weather phenomena at the differently oriented mountain slopes and valleys. It requires high resolution numerical model, particularly COSMO-Ru model, which was selected for meteorological support of the Games. The model should have to be able to predict meteorological conditions in the region with highly variable terrain. Specificity of physical variables had to be predicted for different sporting events on the basis of large amount of observational and forecasting data.

Annually registered number of weather hazards is very high in the Northern Caucasus, especially in winter. The high variability of local small-scale conditions (differently oriented slopes, valleys, significant high gradients) and proximity of non-freezing Black Sea generating medium-scale energy fluxes require the ensemble approach, improvement of model resolution to the scale of relief features, i.e. in the case of COSMO weather forecasting model the grid step had to be lesser than existing 2.2 km. It also required the improvement of the postprocessing methods of forecasting certain meteorological characteristics (wind, snow cover, visibility, humidity, etc.).

CORSO project was proposed to enhance and demonstrate the capability of COSMO-based systems of numerical weather prediction in winter conditions for mountainous terrain and to assess the effect of practical use of meteorological information in support of Sochi–2014 Olympic Games. The peculiarity of the Sochi region justified the development and adaptation of the available COSMO technologies. The insurance of the best performance of the COSMO system at the Sochi-2014 Olympics was required. It assumed a development of modeling techniques including. data assimilation for near-surface and land-surface parameters, model physics and dynamical core. Ensemble forecasting, applied post-processing and downscaling, comprehensive verification and other predictive components were crucially important for the enhancement of the Sochi-2014 meteorological services.

Significantly the PP CORSO for preparation and providing the meteorological services for Olympics Sochi-2014 is based on solving the tasks determined in the COSMO Science PLAN 2010-2014, where it stated (p. 11): "From the scale of the targeted processes it becomes clear that the mesh-size of the model system has to be of the order of 1–2.2 km. The COSMO Steering Committee decided to focus on the development of a model-system for the short to very short range forecasting considering convective-scale resolution".

In the region of the Sochi–2014 the additional observational network was developed since the end of 2011. It includes the automatic stations for near-surface measurements, meteorological radar, and aerological stations. This additional information could be used as a new source for data assimilation, model verification and for testing and adaptation of certain algorithms.

The improvements introduced to the COSMO system during this activity widened its applicability to regions with complex terrain characterized by frequent severe weather events, which could benefit COSMO as a whole.

CORSO project can be considered as a COSMO-related part of FROST–2014 project (FROST — Forecast and Research in the Olympic Sochi Testbed), initiated by WMO (Kiktev et al., 2017)..

2 Actions proposed

Development of the COSMO model version adjusted for the region with complex terrain, improvement of operational forecasts based on the COSMO-Ru7/So2 model and development of the version of this model with resolution approximately 1 km. Identification of the gaps, adaptation of data assimilation techniques, analysis of numerical aspects using the high resolution and modification of parameterization schemes (Task1).

Development and adaptation of approaches for post-processing downscaling and possible forecasters feedback (Task 2).

Adjustment of the COSMO EPS's techniques (COSMO-LEPS) for the Sochi area and to specific requirements of winter Olympics. Development of COSMO-RU-EPS system (Task 3).

All developed systems and technologies had to be validated and made available to forecasters during trials well before the Olympics. Forecast products were transferred to Olympic forecasters via web-based tools.

Available expertise within COSMO

COSMO-LEPS (ARPA–SIMC);
High-resolution modeling and post-processing for the Alps (DWD, MeteoSwiss, ARPA-SIMC);
Experience of MeteoSwiss and of DWD in meteo-support of winter sporting events in the mountains;
Developed tools ("nudging-process", Fieldextra, VERSUS);
Experience of Torino–2006 Olympics (ARPA Piemonte).

Links to other projects or work packages

Cooperation with all working groups will be required (as needed), during the lifetime of the project. Some activities are supposed to include expansion of actions considering the results and experience obtained within the framework of PP COLOBOC (external parameters, snow cover investigations), verification tools (VERSUS2), improvement of turbulence schemes (UTCS).

3 Tasks, brief description

3.1 TASK1 "High resolution COSMO-modeling for mountainous regions", *(TL G. Rivin)*

Motivation:

The pre-operational version of COSMO-RU07/So2 (resolution 2.2 km) for the North-Caucasian region was developed in Roshydromet in 2010–2011 (nested into OSMO-Ru07 (without regional DAS). OSMO-Ru07 is based on the use of the initial data, received from the GME modeling system (30 $\longrightarrow$ 20 km) of DWD and external parameters prepared as an output of the COSMO EXPAR system (2.2 km)).

Preliminary tests sometimes showed a presence of significant errors in meteorological fields predicted by the COSMO-RU07/So2 near land surface (primarily in air temperature, and as a consequence, conditions of boundary layer stability and the precipitation phase).

It was detected that certain inaccuracies in determining of initial values of T2m, snow-properties (the mask and water equivalent WE), as well as some external (geographic) parameters, such as mask and absolute height.

The goal of the starting actions of TASK1 is the identification of contribution of regional data assimilation for COSMO-RU07 forecasting based on comparison of skill scores of COSMO-RU and COSMO-EU (with assimilation) for the area of COSMO-RU, including the region of Sochi-2014. In parallel, inclusion of nudging continuous cycle using all available data for both (COSMO-RU7 and nested COSMO-RU/So2) is expected. It will be based on the standard network measurement and new additionally added observational network in the Sochi 2014 region. The techniques of correction of temperature in upper soil levels was based on T2m measurements. This technique was previously developed in Roshydromet. It should be coupled with nudging continuous cycle and corrected snow mask from satellite observations.

The more precise modeling of the near surface meteorological parameters taking into account the fractional relation of snow cover and stable and mosaic thermal stratification is one of the problems of numerical weather forecasting. It was obvious for Sochi-2014 weather forecasting support. Previously, based on a study of the COSMO-RU model forecasts for the large winter periods for the entire domain of COSMO-Ru07 it was revealed that the model produces the highest T2m errors in case of heating over the partial snow cover and some modification of TERRA was proposed and tested. TASK1 was expended to develop and test the modified algorithms of TERRA and to propose the modification of algorithms for turbulent diffuse parameterization scheme to improve the forecasts for certain cases.

The perspective plan of COSMO for 2014 stipulated the development of 1-km modeling techniques. Some results were obtained by DWD, MeteoSwiss and ARPA-SIMC. The united efforts of COSMO partners focus on the activities, which could potentially accelerate the development of 1-km COSMO techniques. The collaboration and coordination between DWD, MeteoSwiss, ARPA-SIMC, and Roshydromet is expected.

Task1 consists of two subtasks:

Subtask 1.1:"Improvement of technology of deterministic forecasting of weather conditions with model resolution 2.2 km for the North-Caucasian area (Sochi-2014), (including the operational support)",

Subtask 1.2: "Development of COSMO-So-1km"

Goals RDP:

Develop 1km version for Sochi-2014.

The strategy depends of available technical resources and results obtained by participants.

Deliverables:

Research technology COSMO-So1 with horizontal resolution ≈ 1 km (RDP).

3.2. TASK2 "Downscaling/post-processing for Sochi area and applications", *(TL I.Rozinkina)*

Motivation:

The local mesoscale circulation in the Sochi-2014 area causes multiple weather phenomena at the mountain slopes and valleys. The local values of meteoparameters for this region, including area of Olympics venues (coastal or mountainous clusters) may be identified considering the processes of the scales not modeled explicitly even at high resolution.

Forecasting for the Olympic Games may be complicated by the necessity to predict parameters, which are not explicitly included in the models output (i.e., visibility, wind chill, hill fog, katabatic winds). Furthermore it is requested that the exceeding of certain thresholds are accurately predicted (precipitation amount, fresh snow amount, visibility, wind, temperature, humidity, wind chill) in order to assess whether to confirm or to cancel open air competitions.

This implies the development and implementation of downscaling and post-processing methods. The goals are the following:

- Improve the skill of numerical forecasting and obtain reliable results for the specific points of the venues, the clusters, or the entire Sochi-2014 area;
- Target on the specific parameters needed for organizing committee and the assessment of the critical thresholds for different competitions.

In the Sochi-2014 region, the information from additional automatic stations for near-surface measurements of T, V, Q, precipitation, visibility, and snow parameters can be used as an additional source for development of algorithms for downscaling.

The following algorithms are presently available at Roshydromet: linear regression of COSMO-SIB-14 output for Altay mountains (trial period: 2 weeks), MOS on IFS/GFS (experimentally used also with COSMO-RU-7/WRF), trial period: 2 years, empirical rules based on manual weather classification for forecasting of significant weather phenomena. This experience allows to develop the new techniques for the region of interest with shorter (several days) training period, i.e Kalman Filter techniques firstly for improvement of T2m measurements at observational points. The experience of COSMO-countries in utilizing the Kalman-filter correction techniques with mountain weather conditions (Firstly, Switzerland) is very important. The data sets - rows "model – measurements"for some points for the area with similar geographical conditions (subtropical mountains near sea) are also useful to obtain the statistics for large variety of weather phenomena in stage of development and tuning of Kalman-filter algorithms. (In particular the data obtained in the Greek mountain areas could be useful for obtaining flexible algorithm).

The implementation of the automated weather classification systems together with climatological series of local observations can be used for forecasting relevant phenomena in the Sochi-2014 region. Furthermore, the project will take the opportunity to use the practical experience of the COSMO countries in their meteorological support to winter sports in

mountainous regions. The previous results obtained in WG4 in the domain of conditional verification and the interpretation of model results will also be used.

The collaboration with MeteoSwiss and HNMS is expected.

Task2 consists of two subtasks:

Subtask 2.1. (FDP): "Adapted downscaling techniques for winter conditions in the mountains and IOC requirements"

Subtask 2.2. ($FDP + RDP$): "Determination of typical COSMO model inaccuracies for typical climatological / synoptic situations"

3.3. TASK3 "Development and adaptation of COSMO EPSs for the Sochi region", *(TL E.Astakhova and A. Montani)*

Motivation:

Accurate assessment of probabilities of High-Impact Weather (HIW) events is the main challenge for regional ensemble prediction systems (EPS). For the winter Olympics, HIW are not necessarily linked with very intense or extreme meteorological phenomena. For outdoor sport events HIW forecasting also includes accurate representation of cross-zero temperature transitions (especially critical for cross-country skiing), precipitation phase and other sensible weather changes with respect to the prescribed decision-making thresholds. Development and demonstration of various HIW-related specific products is part of the ensemble component of the project CORSO.

COSMO-LEPS is an ensemble prediction system developed by the COSMO consortium. In the past years, COSMO-LEPS proved to be a valuable tool for the generation of probabilistic predictions of high-impact weather over complex topography and it is envisaged that it can be successfully used for the SOCHI region and provide useful support to bench forecasters during the Olympics. A 7-km COSMO-LEPS system for the Sochi region (COSMO-FROST-LEPS) is to be developed within the framework of the project and will be used for operational support of Sochi-2014 Olympics.

EPS with higher than 7-km resolution is desirable for better probabilistic prediction over the complex Caucasus terrain. Within the RDP part of Task 3 CORSO, the development and testing of COSMO-RU-LEPS 2.2 km is suggested.

COSMO-RU-SO-2.2 for the North-Caucasian region already runs operationally at Roshydromet. This technology is nested to OSMO-Ru07. On the other hand, COSMO-FROST-LEPS (also with 7-km resolution) will run daily during pre-trials, trials and Olympics and can provide initial and boundary conditions (ICs and BCs) for a higher-resolution ensemble system. This gives a possibility to develop a 2.2 km EPS based on COSMO-RU-SO-2.2 and ICs and BCs from SOCHMEL.

In collaboration and coordination with ARPA-SIMC

Task3 consists of two subtasks:

3.1. Adaptation of COSMO LEPS 7 km to the Sochi region and to specific requirements of winter Olympics. Operational ensemble forecasts during the Olympics (FDP)

3.2. Development and verification of COSMO-RU-LEPS 2.2 km for the Sochi region (with ICs and BCs from SOCHMEL7)

Goals:

Subtask 3.1 (FDP):

Development of a COSMO-LEPS system with a resolution of 7 km adapted to the Sochi region and to specific requirements of winter Olympics (SOCHMEL7) and operational support of the Sochi-2014 Olympics with COSMO-based 7-km ensemble forecasts:

- Adaptation of COSMO-LEPS 7 km to the Sochi region and to specific requirements of winter Olympics (SOCHMEL7). Organization of data transfer from ARPA -SIMC to RHMC.
- Development of visualization, interpretation and verification tools for SOCHMEL7. Coupling with post-processing techniques.
- COSMO-FROST-LEPS forecasts during the pre-trial (from 10 Dec 2011 to 31 Marh 2012) and trial (from 01 Dec 2012 to 31 Marh 2013) periods and their verification. Assessment of the effect of practical use of these forecasts.
- Operational ensemble forecasts during the Olympics and their verification. (The use of VERSUS with included EPS-verification tools is expected)

Deliverables (FDP):

A COSMO-LEPS system with 7 km resolution adapted to the Sochi region and to specific requirements of winter Olympics (SOCHMEL7). Operational ensemble forecasts during the Olympics. Technology of presentation and interpretation of the COSMO-FROST-LEPS results in operational mode.

Subtask 3.2 (RDP):

Investigation of the capability of high-resolution (2.2-km) ensemble system in forecasting over a complex terrain.

- Development of COSMO-RU-LEPS 2.2 km for the Sochi region (with ICs and BCs from SOCHMEL7)
- COSMO-RU-LEPS 2.2 km forecasts during trials and forecasts verification (if feasible).
- Comparison of capability of high-resolution (2.2-km) ensemble system with SOCHMEL7.
- COSMO-RU-LEPS 2.2 km forecasts during the Olympic Games (if feasible). Analysis of the results.

Deliverables (RDP):

COSMO-RU-LEPS 2.2 km for the Sochi region (with ICs and BCs from SOCHMEL7)

4 Development of High resolution COSMO-modeling for mountainous regions *(G. Rivin, M. Shatunova, D. Blinov, D. Majewski, J. Förstner, J. Helmert, U. Schättler, C. Schraff, M. Arpagaus, G. de Morsier, P. Steiner)*

4.1 Data assimilation system (DAS) based on the nudging scheme for the Sochi region *(G. Rivin, D. Blinov, C. Schraff)*

DAS activities

(a) **The new version of COSMO-Ru7/2 operational technology including the nudging- assimilation was developed for Caucasian and Central regions.** The analysis of skill of forecasts of T2m, Td2m, winds at 10m, PMSL showed the essential improving of models results **for the first 3–6 hours** for the version with nudging-assimilation (Fig.1)

(b) The realization of continuous model runs based on continuous assimilation cycles has allowed organizing the optimal time of starts of operational runs of COSMO-Ru1, nested into COSMO-Ru7/2, adapted to the timetable of work of Olympic Organizing Committee.

(c) RDP: The module of correction of initial values of T at the low model levels and of soil based on the T2m observations was realized and tested. After the coupling with COSMO-Ru domestic research version it was detected the more realistic results for the forecasts of vertical profiles of temperature during all period of short-range forecasts and the little decreasing of the models precipitations. **The module is ready for coupling with operational technology and for nudging-cycles**, but needs the further testing for accumulation of larger statistics of forecasts for different synoptic situations and seasons.

4.2 Development of High resolution COSMO-modeling for mountainous regions *(G. Rivin, M. Shatunova, D. Majewski, J. Förstner, J. Helmert, U. Schättler, D. Blinov, M. Arpagaus, G. de Morsier, P. Steiner)*

4.2.1 Model installation (and domain size selection)

Version of the COSMO model with horizontal resolution 1.1 km, named COSMO-Ru1, was installed on cluster-based architecture Tornado in Roshydromet. First COSMO-Ru1 version was released for domain size 450 x 450 grid points with lateral boundary conditions (LBC) from COSMO-Ru2SFO (with grid step 2.2 km for Southern Federal Region) for the same initial time run. COSMO-Ru1 is nested into COSMO-Ru2 but rotated grids of these models have different pole.

Model run time on cluster-based architecture Tornado for 24 hours forecast using 18 processors (244 cores) was approximately 50 min.

Because of limited computing resources and taking into account timing of the all COSMO-Ru models it was decided to reduce COSMO-Ru1 domain size for future operational use.

Forecasts for two versions of simulation domains were evaluated. Specifications of COSMO-Ru1 for experimental runs are presented in Table 2; positions of two domains are shown in Fig.2 along with COSMO-Ru2SFO domain.

Table 2: Specifications of COSMO-Ru1 experimental version

Domain size (grid points)	200 x 200 // 450 x 450
Horizontal grid spacing (degree / km)	0.01 / 1.1
Number of layers	50
Time step (seconds)	5-10
Forecast range (hours)	24-48
Initial time of model runs (UTC)	00, 06, 12, 18
Lateral Boundary conditions	COSMO-Ru2SFO
LBC update frequency (hours)	1
Initialization	none
COSMO version	4.27
Hardware	RSK Tornado
No. of cores used	224 (of 1152)

Assessment of the temperature at 2 m and precipitation forecasts showed that changes of domain size had greater effect on precipitation forecast than on temperature forecast. The difference in T2m forecast for two different domains would not exceed 0.5° (see Fig.3) while for precipitation forecast, especially for heavy precipitation cases, the difference varies from 30 % (for 24 h accumulated precipitation) to 100 % (for 1 h sums).

It is evident that change of the simulations domain size lead to changes in spatial (see Fig.4) and temporal (see Table 3) distribution of predicted precipitation. Assessment of results for two domains by comparison 3h and 24 h accumulated precipitation with observed values does not allow a definite conclusion about preferable domain.

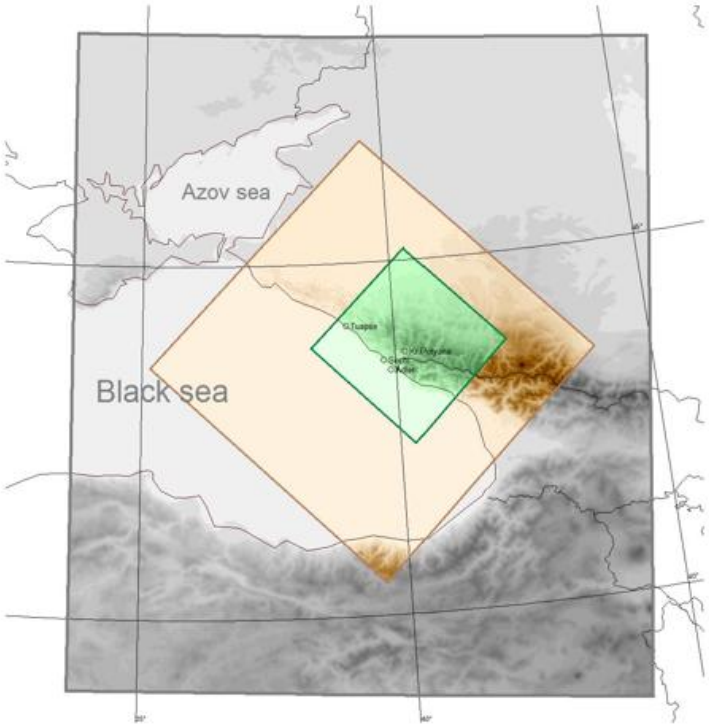

Figure 2: Location and size of COSMO-Ru2 domain (outer grey rectangle) and COSMO-Ru1 domains used in experiments: 450 x 450 grid points (brown-colored square) and 200 x 200 grid points (inner green-colored square)

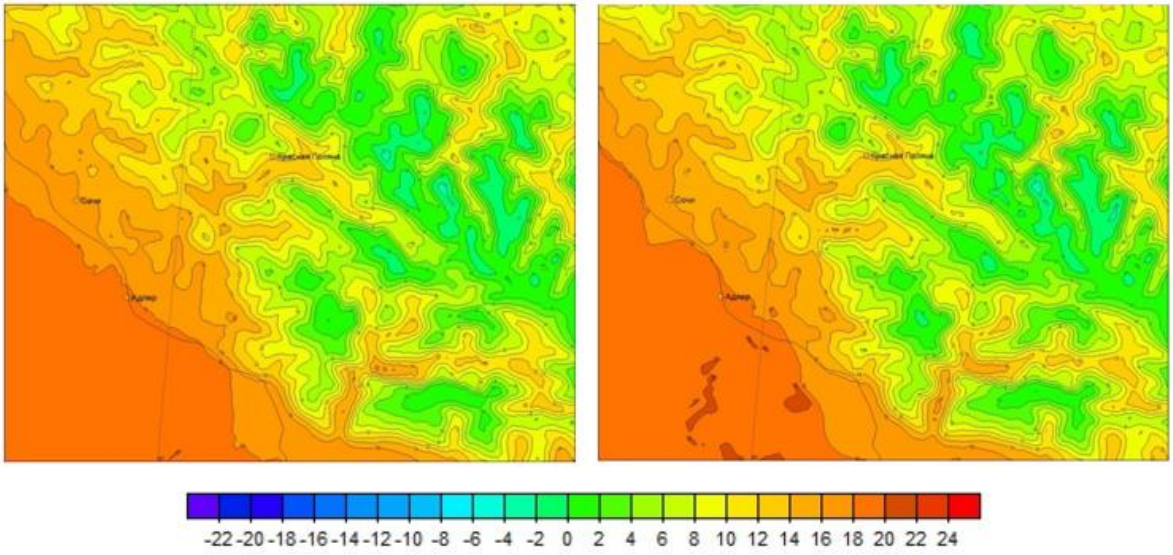

Figure 3: T2m 12 h forecasts from 24.09.2013, 00 UTC obtained in experiments with simulations domain 200 x 200 grid points (left) and 450 x 450 grid points (right)

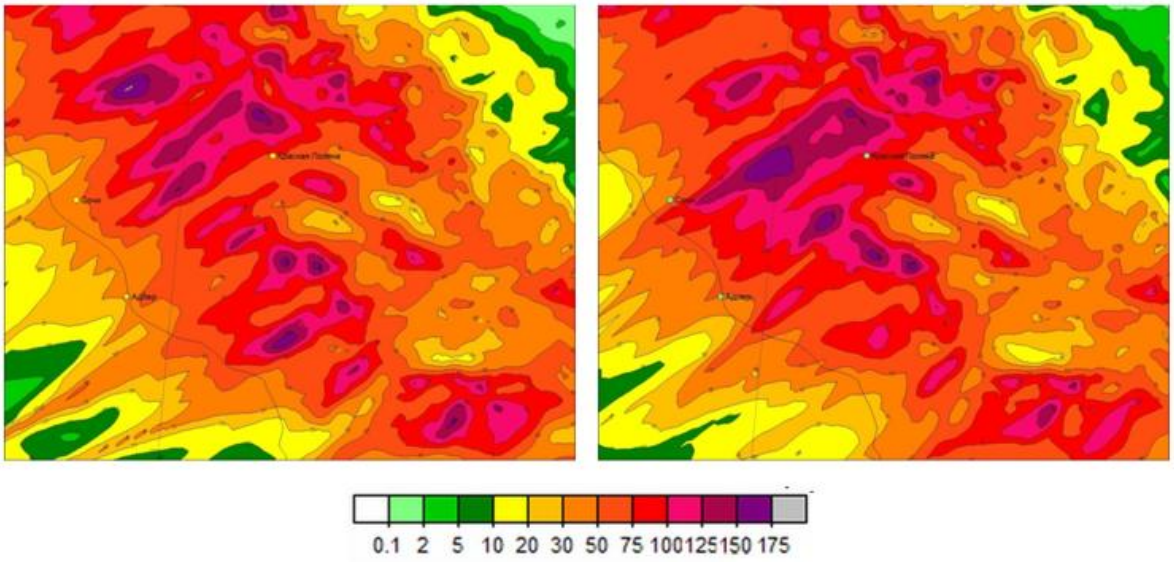

Figure 4: The same as figure 3 but for 12h precipitation sum

4.2.2 COSMO-Ru1 model orography options

Initially COSMO-Ru1 model orography was based on GLOBE *(The Global Land One-km Base Elevation Project)* data (NOAA/NGDC) (http://www.ngdc.noaa.gov/mgg/topo/globe.html). Great differences between height of observation points and height of the nearest model grid nodes forced us to check model orography by comparison with high-resolution ASTER *(Advanced Spaceborne Thermal Emission and Reflection Radiometer)* data (METI/NASA) (http://asterweb.jpl.nasa.gov/gdem.asp) that has resolution 1"($\sim 30\ m$). This comparison revealed a discrepancy between model orography and "real"one that reached 500 m for some nodes.

In December 2013, new orography data from EXTPAR based on ASTER GDEM2 became available and replaced COSMO-Ru1 model orography. The following orography filters were used: $ilow_pass_oro = 4$, $ilow_pass_xso = 5$, $rxso_mask = 625$.

Numerical experiments shown a positive effect of new orography data on the temperature, wind and precipitation forecast. Some errors in ASTER data locations discovered by EXTPAR developers later were insignificant for forecast quality.

Difference between observation site height and height of corresponding grid node became smaller. That lead to better agreement between observed and predicted values of T2m and wind speed (see Fig.5). For Gornaya Karusel height difference reduced to -32 m (previously -568 m), for Krasnaya Polyana 7 m (previously 248 m), for Aibga -194 m (previously -443 m). Improvement of T2m forecast was below 3° for some sites depending on weather conditions.

Model orography replacement affected also the predicted precipitation spatial and temporal distribution. Fig.6 shows forecasts with different model orography in comparison with observations for two sites: Gornaya Karusel-1500 and Krasnaya Polyana. Both sites are located within the mountain valley, height changes of the model grid node are mentioned above. Impact of new orography on forecasted accumulated precipitation can be seen better on the bottom graphs where differences "forecast – observation"for two variants of the model orography are presented. For Gornaya Karusel-1500 errors are the same: overestimation for the 4 first and the 4 last hours of the event and large underestimation of the accumulated precipitation at 2 (first maximum of the event) and 6 UTC 19.10. However, for the period

Table 3: Observed and predicted 3h precipitation sum for 24.09.2013

	Period, h								
	00–03	03–06	06–09	09–12	12–15	15–18	18–21	21–00	00–24
Krasnaya Polyana									
Observations	0.6	3.8	17.1	30.6	13.6	25.4	19.1	4.6	114.8
COSMO-Ru1 (200 x 200 g.p.)	13.0	29.1	11.9	12.1	31.9	28.9	3.8	0.8	131.5

Gornaya Karusel-1500									
Observations	0.5	10.5	28.7	34.6	16.6	20.1	20.2	1.7	132.9
COSMO-Ru1 (200 x 200 g.p.)	8.2	31.1	11.9	20.9	8.6	17.7	3.5	1.5	103.4
COSMO-Ru1 (450 x 2450 g.p.)	8.4	35.8	26.9	24.2	18.7	13.9	3.6	0.0	131.5
COSMO-Ru2	5.7	25.6	26.1	15.9	19.5	15.1	4.2	0.1	112.2
Roza Khutor-4									
Observations	0.5	9.7	19.0	33.0	31.8	29.6	26.4	4.4	154.4
COSMO-Ru1 (200 x 200 g.p.)	7.2	31.4	30.5	50.3	19.6	25.6	3.1	1.1	168.9
COSMO-Ru1 (450 x 2450 g.p.)	7.5	43.2	41.4	36.6	33.5	32.2	3.9	0.0	198.4
COSMO-Ru2	1.4	10.9	16.7	18.5	22.3	22.3	4.6	0.1	96.6
Roza Khutor-7									
Observations	0.3	10.5	25.9	34.1	26.1	28.0	25.0	5.0	154.9
COSMO-Ru1 (200 x 200 g.p.)	5.3	24.7	31.1	48.4	21.6	28.6	3.5	0.9	164.2
COSMO-Ru1 (450 x 2450 g.p.)	5.6	29.9	36.5	33.7	29.2	31.4	3.3	0.0	169.7
COSMO-Ru2	2.7	17.7	26.1	24.7	26.4	21.9	2.8	0.1	122.4

7-18 UTC forecast with new orography is better, errors have opposite sign. For Krasnaya Polayna forecast improvement is not obvious, errors are mostly the same or even greater.

4.2.3 COSMO-Ru1 operational use and verification

From January 29, 2014 COSMO-Ru1 run in operational mode is conducted 4 times a day. In order to perform forecast delivery schedule to forecasters COSMO-Ru1, COSMO-Ru2 and COSMO-Ru7 models run as priority tasks on additional cluster-based architecture ICE-X in Roshydromet during Olympics/Paralympics. Specifications of COSMO-Ru1 for operational use are presented in Table 4.

COSMO-Ru1 used initial and boundary conditions from COSMO-Ru2SFO from previous start-time (Fc-06h). The preliminary experiments demonstrated the capability of COSMO-Ru1 to produce satisfactory forecast with lead-time until 36 hours. It made possible to create operational forecast technology, which meets the requirements of forecasters, taking

into account time difference (UTC+4) and need to provide forecast for the current day to forecasters on 5 a.m. local time (1UTC).

COSMO-Ru1 forecast were used by forecasters along with COSMO-Ru2 during SOCHI-2014 Olympic Games. Model output parameters were produced in form of forecast charts of individual meteorological characteristics or combination of them and those produced in form of meteograms. Forecast charts were prepared for the three regions with varying order of detail: for whole simulations domain, for the Sochi coastal region and for mountain cluster (see examples in Fig.7).

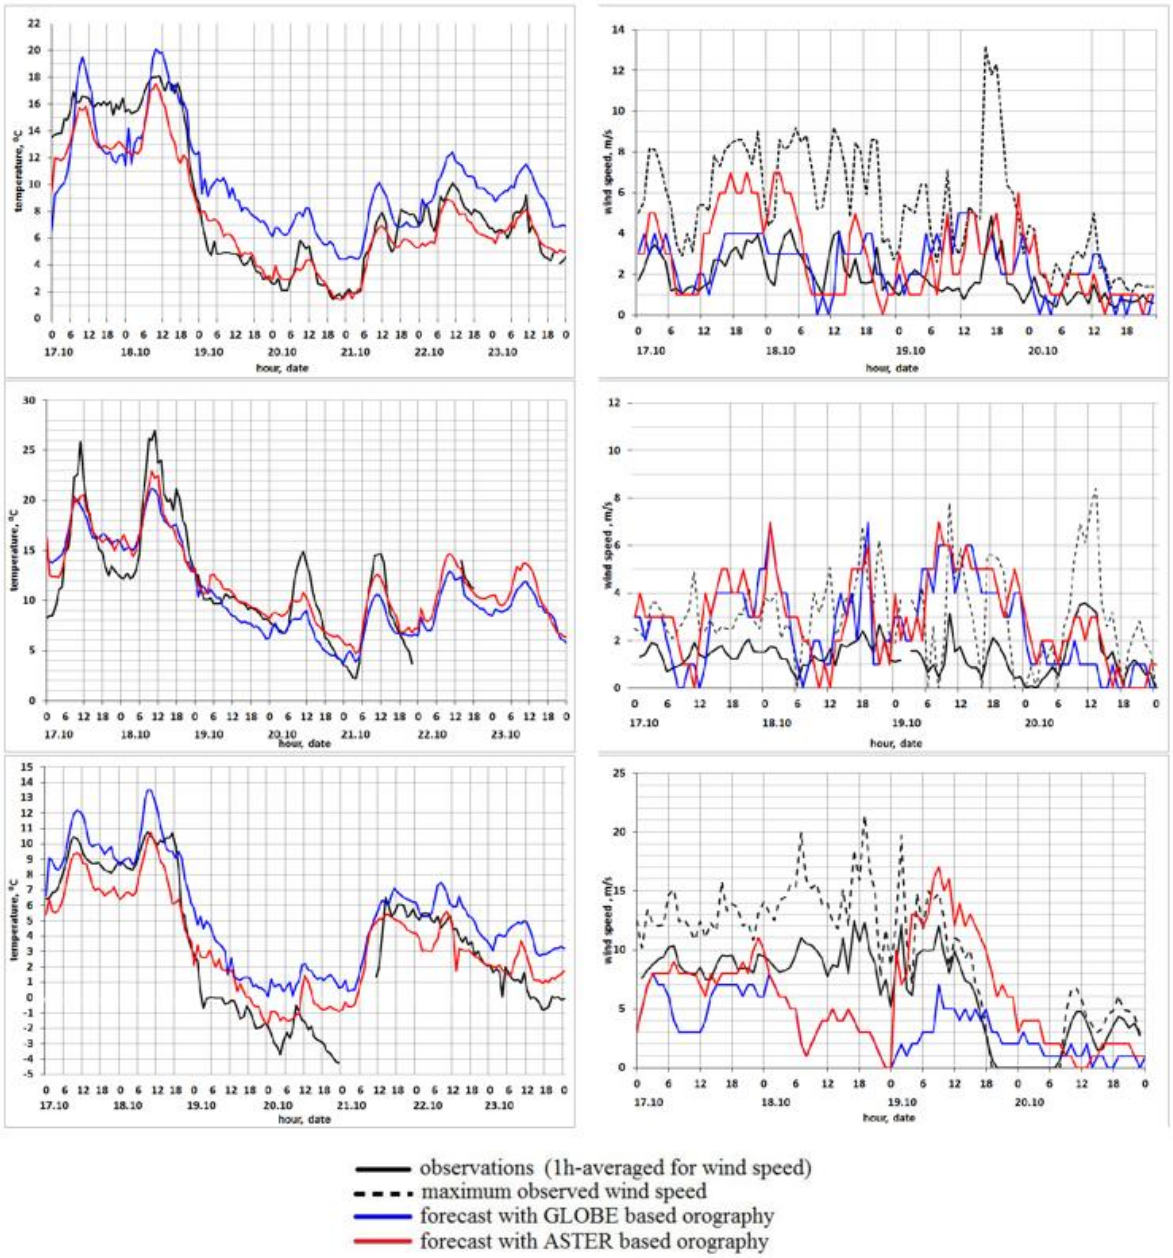

Figure 5: Series of 24 h forecasts for T2m (left) and wind speed at 10 m (right) from 00 UTC, for the period October, 17-23, 2013 (for T2m) and October, 17-20 (for wind) and observation data at Gornaya Karusel (top), Krasnaya Polyana (middle) and Aibga (bottom) for the same period

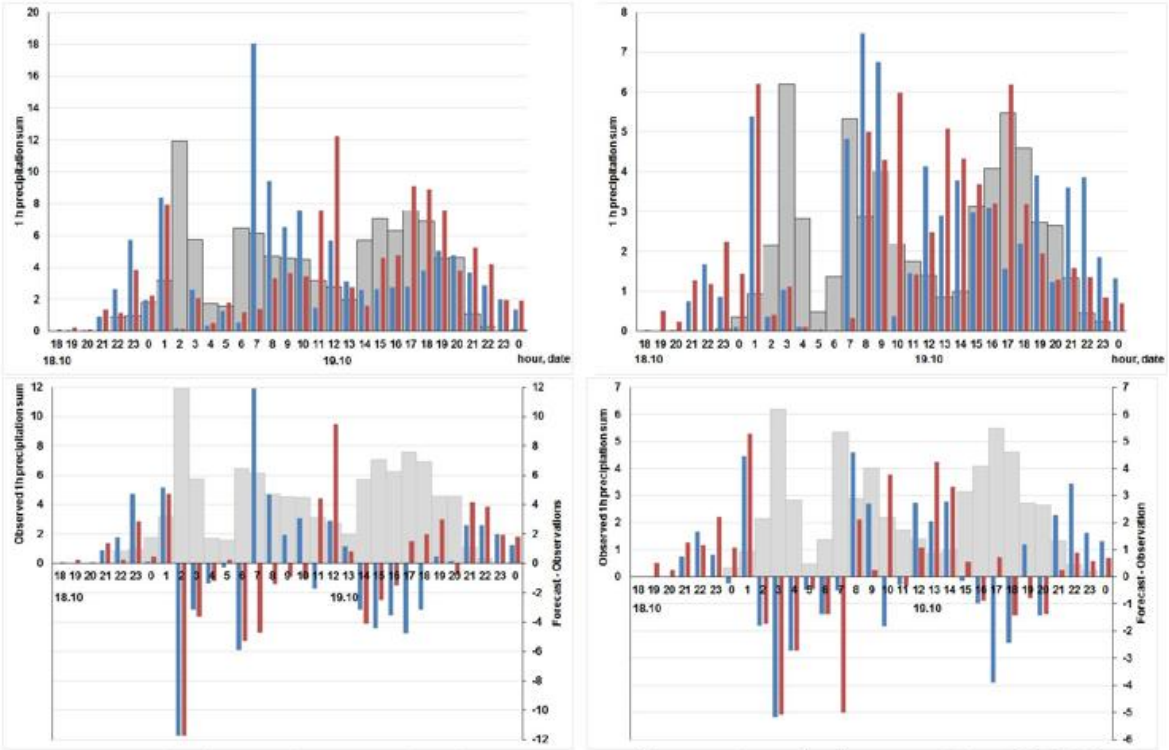

Figure 6: 1 h observed accumulated precipitation (grey column), forecasted by COSMO-Ru1 with different model orography: based on GLOBE data (blue) and ASTER data (red) for Gornaya Karusel-1500 (left) and Krasnaya Polyana (right). Comparison of 1h accumulated precipitation (top) and difference of two forecasts (bottom)

Table 4: Specifications of COSMO-Ru1 operational version during Olympics/Paralympics

Domain size (grid points)	190 x 190
Horizontal grid spacing (degree / km)	0.01 / 1.1
Number of layers	50
Time step (seconds)	5
Forecast range (hours)	36
Initial time of model runs (UTC)	00, 06, 12, 18
Lateral Boundary conditions	COSMO-Ru2SFO
LBC update frequency (hours)	1
Initialization	none
COSMO version	5.0
Hardware	SGI ICE-X
No. of cores used	660 (of 720)

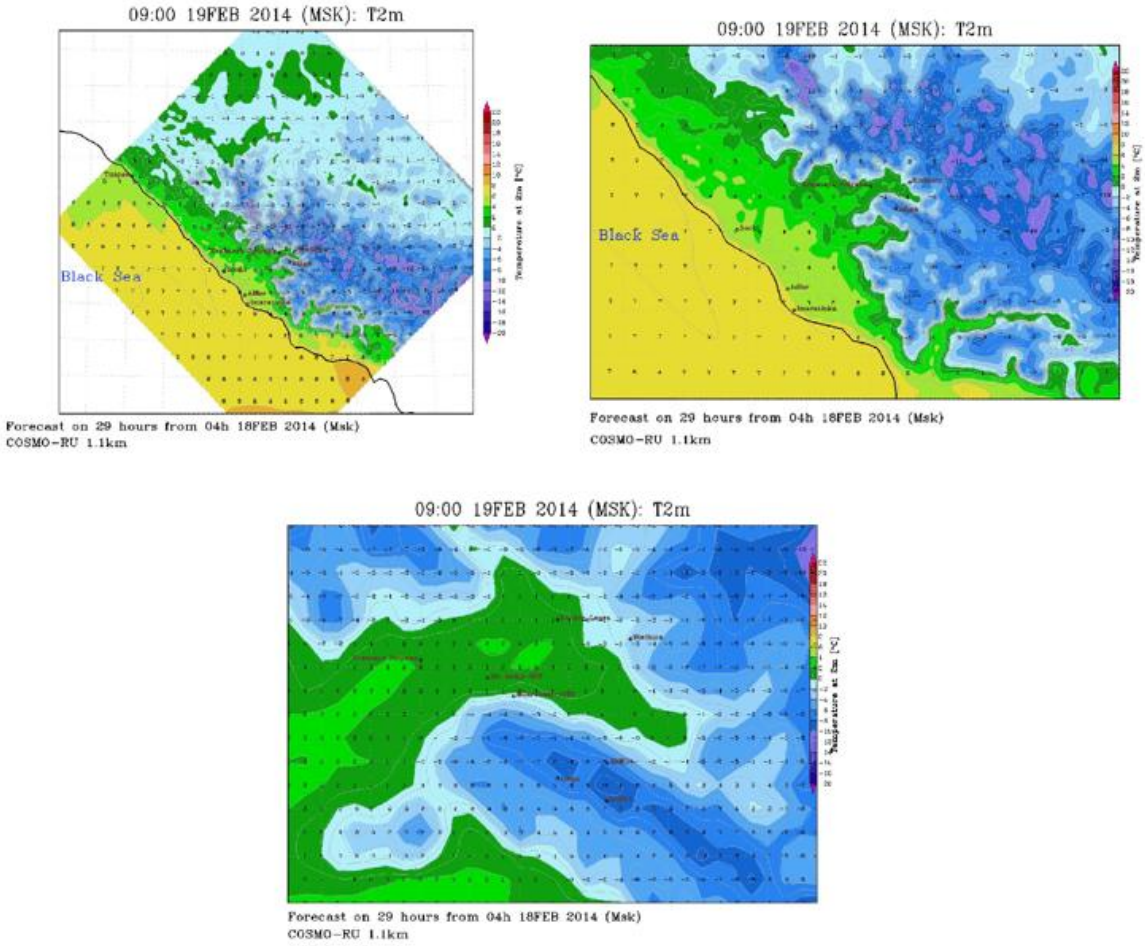

Figure 7: COSMO-Ru1 output presentation example. T2m forecast for the entire simulation domain (upper left), the Sochi region (upper right) and mountain cluster (bottom)

COSMO-Ru1 results were verified by VERSUS for the period of the Olympics/Paralympics along with COSMO-Ru2 and COSMO-Ru7. Some results for 00 UTC run are presented in Fig.8 *(by courtesy of Anastasia Bundel and Alexander Kirsanov)*. Verification made for 39 stations located at different altitudes in the mountain and coastal clusters for the period 29.01.2014 15.03.2014.

As for subjective verification, forecasters favored COSMO-Ru1 less than COSMO-Ru1 because COSMO-Ru1 began to run operationally just before the Olympics and they had no experience using products of this model. However COSMO-Ru1 forecasts for mountain cluster, such as combined charts "RH + streamlines", proved to be very popular and useful in the preparation of synoptic forecasts.

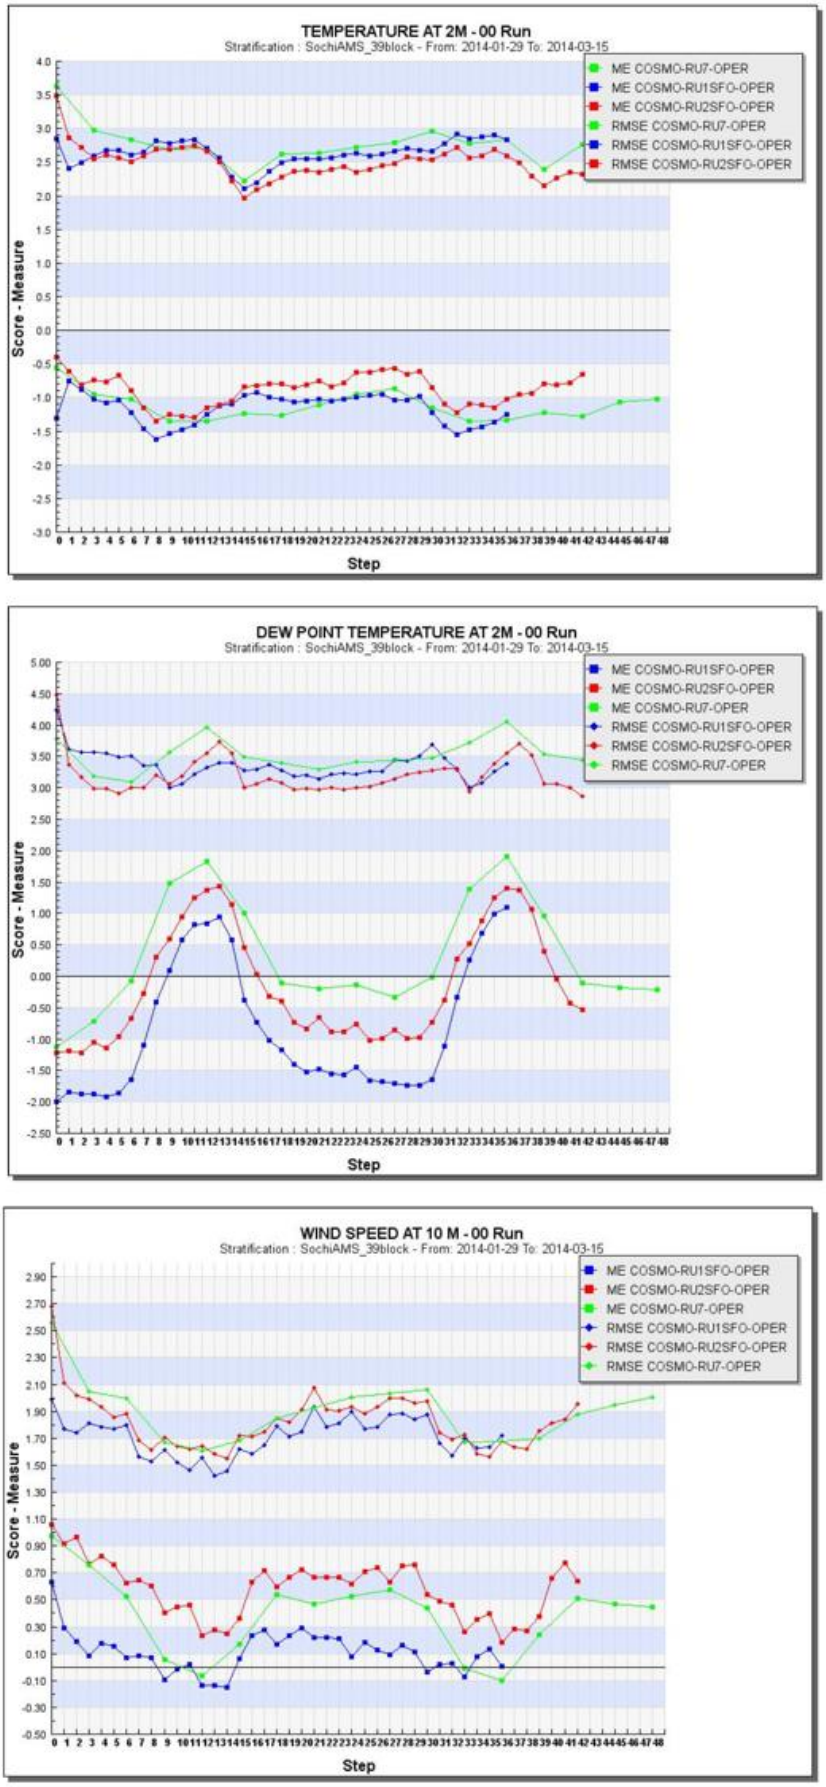

Figure 8: Verification COSMO-Ru1 (blue), COSMO-Ru2 (red) and COSMO-Ru7 (green) results for the 39 stations located at different altitudes in the mountain and coastal clusters for the period 29.01.2014 15.03.2014

4.2.4 Case study

The presence of observation data of different kinds and increasing of AMS numbers in the Sochi region during pre-Olympics period allowed to conduct several case studies. Satellite images, radars and profilers'data, as well as AMS data of high temporal resolution used to investigate COSMO-Ru1 model behavior in different synoptic conditions. List of weather events along with several NWP models behavior in appropriate situations was prepared by forecasters on the basis of their experience obtained during Sochi-2014 Olympics. Two events in the list related to low visibility cases have been studied. Detailed description of these cases is presented in (Shatunova, Rivin, Rozinkina, 2015).

5 Downscalling/post-processing for Sochi area and applications *(I. Rozinkina, E. Kazakova, M. Chumakov, A. Bundel, A. Muravev, D. Blinov, A. Kirsanov, P. Eckert, G. Rivin, A. Euripides, E. Kukanova)*

5.1 T2m correction *(I. Rozinkina, D. Blinov, G. Rivin)*

The goal: To realize the updated software of Fieldextra with inclusion of calculations of subgrid values of T2m based on the forecasts of vertical temperature gradient and to provide the software of 1-D correction of T2m forecasts based on the forecasts of vertical T gradient ("h-correction").

Method:

1. Determine the difference in heights of the model gridpoint and the height at the station Δh.
2. Find the vertical temperature gradient in the planetary boundary layer dT_{pbl}.
3. Find an amendment of temperature to the height as a product of the gradient and the difference in heights. The value of the amendments added to the model temperature at 2 meters. $T2m_hcorr = T2m + \Delta h \times dT_{pbl}$

Technology: The algorithm was tested in RHM and was operationally used during the Olympic Games in 2014. The vertical profiles of temperature from FieldExtra were used to find the vertical temperature gradients in PBL . As a result, the corrected temperature appears in the text and graphic 1D meteograms.

Outcome: Description of 1-D algorithm of h-correction of T2m.

The examples of results in using the proposed algorithm in COSMO-model are presented in the next sections of this chapter.

5.2 Kalman filtering application for correction of T2m COSMO-Ru-So forecasts *(M. Chumakov, E. Kazakova, I. Rozinkina, P. Eckert)*

It is a commonly acknowleged that Numerical Weather Prediction (NWP) models exhibit systematic errors in the forecasts of near surface weather parameters. This is a result not only of deficiencies of the physical parameterizations, but also of the inability of these models to handle successfully sub-grid phenomena. Furthermore, forecasts for the areas that are not in close proximity to the model grid points are usually based on interpolation of model output parameters, which also increases the 'noise' in the final forecast products.

Well known that the 2m-temperature, is one of the most commonly biased variable, where the magnitude of this bias depends, among other factors, on the geographical location and the season. So for better forecast result some correction algorithm should be used.

One of the most common approache to the above mentioned problems is the use of Kalman filtering (Kalman, 1960). This technique gives excellent results in the correction of systematic errors in any type of prediction, based on the recursive combination of recent forecasts and observations. The main advantage is the easy adaptation to any changes in the data being used (Galanis, Anadranistakis, 2002).

5.2.1 Description of the method

At Hydrometcenter of Russia Kalman filtering and height T2m correction algorithm (through vertical gradient) are implemented in COSMO-Ru2 (the Sochi region) (station locations are shown in the map in Fig.9). The technology works operationally since February 2015.

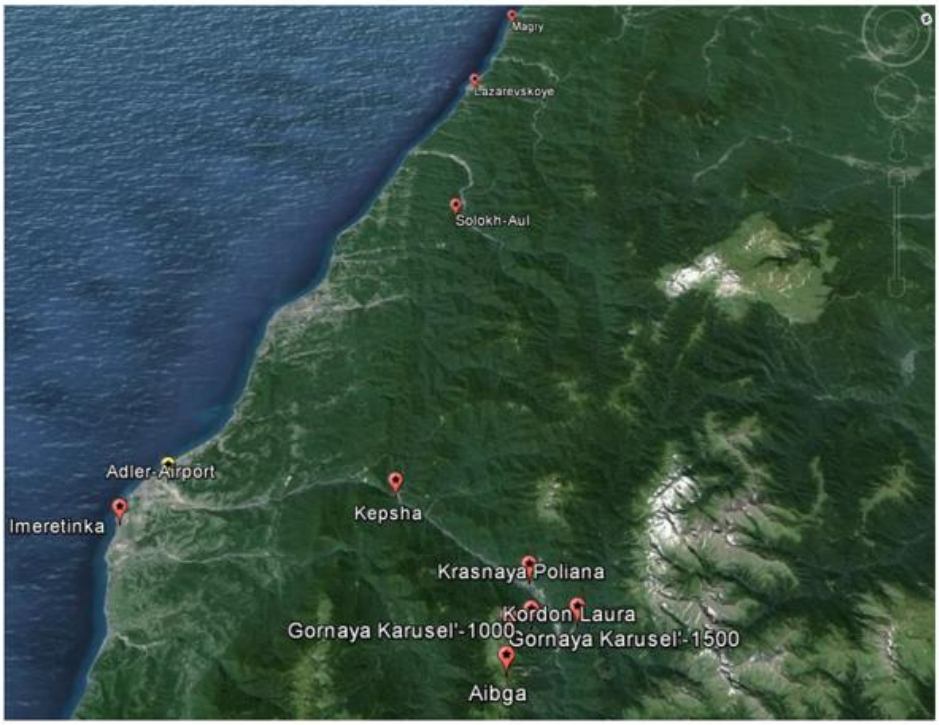

Figure 9: Station locations in the Sochi region

Describe briefly the main features of the implemented Kalman filtering. Suggest that there are two T2m observations T_1 and T_2 which can be represented as:

$T_1 = T_{true} + g_1$

$T_2 = T_{true} + g_2$

where T_{true} — true value of T2m, g_1, g_2 — stochastic variables (connected with measurement or forecast errors). As a rule, it is impossible to know exactly the value of T_{true}. But T_1, T_2 can be specified through reducing noise components g_1, g_2.

Consider that g_1, g_2 obey the normal distribution law and following conditions for mathematical expectation M and variance D are relevant:

$$\begin{aligned} M(g_1) = 0, M(g_2) = 0 \\ D(g_1) = \sigma_1^2, D(g_2) = \sigma_2^2. \end{aligned} \tag{1}$$

At this assumptions the best fit (best estimator), T_{cor}, of the true value of T2m would be written as:

$$T_{cor} = \alpha_1 T_1 + \alpha_2 T_2, \tag{2}$$

where α_1, α_2 are some unknown weight coefficients which has one important feature:

$$\alpha_1 + \alpha_2 = 1. \tag{3}$$

Take into account (3) we may rewrite (2) in following form:

$$T_{cor} = (1 - \alpha)T_1 + \alpha T_2, 0 \leq \alpha \leq 1. \tag{4}$$

In general case to assess the quality of it should be introduced some cost function $f(\varepsilon)$. Let the cost function has the form

$$f(\varepsilon) = \varepsilon^2 = (T_{true} - T_{cor})^2. \tag{5}$$

Such form of cost function is convenient for estimation of assessment quality since it has one minimum where derivative exists and equals to zero. This feature gives opportunity to find analytical form of T_{cor}.

Generally speaking function ε is a random variable as errors g_1, g_2 are changing from measurement to measurement, what lead to change of T_{cor} value at the same algorithm of measurements' processing. That's why quality criterion should be chosen in the way that algorithm gives minimum in average function $f(\varepsilon)$, i.e. assessment error variance P must tend to zero:

$$P = M\{(T_{true} - T_{cor})^2\} \longrightarrow 0. \tag{6}$$

Take into account (1) and (4) we obtain analytical formula for P:

$$P = (1 - \alpha)^2 D(g_1) + \alpha^2 D(g_2). \tag{7}$$

From the condition

$P = \frac{dP(\alpha)}{d\alpha} = 0$

we find optimal value of α, so Kalman filter is written as:

$$T_{cor1} = T_1 + K \cdot (T_2 - T_1), \tag{8}$$

where $K = \frac{P_1}{\sigma_2^2}$ — amplification factor. P_1 — variance of estimation which is calculated as:

$$P_1 = \frac{D(g_1) \cdot D(g_2)}{D(g_1) + D(g_2)} = 0. \tag{9}$$

This formula is easily extended to the case when there are more than two measurements.

It gives opportunity employ this algorithm for correction current forecast values using results of the preceding forecasts in assumption that variance of current forecast error is equal to value which was calculated using value of error during a few previous days.

Scheme of using COSMO-model (2.2 km) forecast series for the Sochi region is presented in Fig.10. This figure shown, for example, for correction result of 15-hour forecast T2m from 00 UTC of any day may be used forecast result for this time from 00, 06, 12 and 18 UTC of previous day.

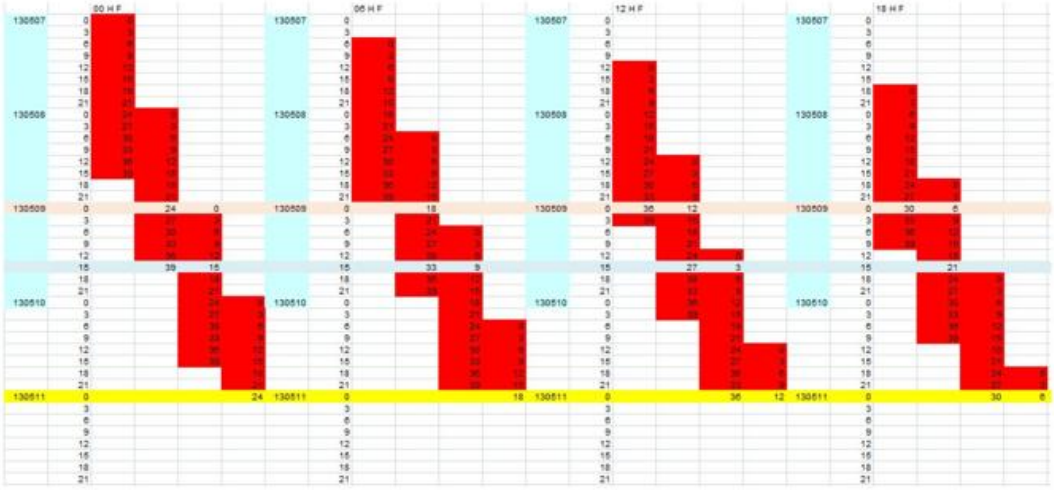

Figure 10: Scheme of COSMO-Ru2 forecast series for the Sochi region

Testing of the algorithm was done for station Adler (Sochi) for May 2013 with the use of COSMO-Ru2 version. Results are presented in Table 1. As can be seen, significant reduction of T2m RMSE values was observed for 3-hour, 9-hour and 15-hour lead time model forecasts starting from 06 UTC. It may be supposed that it is related to the quality of forecasted values, which were used in correction or statistical characteristics of forecast errors at this time.

It will be appreciated that only strict implementation of the conditions (1) ensures successful operation of Kalman filtering. Unfortunately forecast's values of T2m not always satisfy these conditions. As a result of studies it was determined that the Fourier coefficients are more relevant.

Thus, modification of Kalman filter algorithm application was done by using discrete Fourier transform. T2m forecast series on particular date can be treated as a real time-dependent function f. Thus suppose that we sample f at N equally spaced time intervals of length Δ seconds starting at moment t_0. Consequently:

$SEQ_i = f(t_0 + (i-1)\Delta) i = 1, ..., N.$

Table 5: RMSE values for T2m COSMO-Ru2 forecasts with Kalman filtering application for station Adler for period of May 2013

Forecast, hour	Start 00 h		Start 06 h		Start 12 h		Start 18 h	
	Filtered	Ref.	Filtered	Ref.	Filtered	Ref.	Filtered	Ref.
03	1.3	2.0	1.3	2.3	0.9	1.4	1.1	2.0
06	1.4	1.1	1.4	1.6	1.3	1.3	1.7	1.8
09	1.3	1.3	1.6	2.7	1.1	1.5	1.7	2.1
12	1.5	1.4	1.3	1.5	1.7	1.9	1.6	1.2
15	1.3	1.6	1.1	1.9	1.7	2.1	1.3	1.2
18	1.4	1.3	1.7	1.8	1.1	1.1	1.4	1.4
21	1.1	1.5	1.7	2.0	1.3	1.1	1.2	1.6
24	1.7	1.9	1.1	1.1	1.5	1.3	1.3	1.3

Note. In colors: orange improvement, red significant improvement, blue measurement error.

Discrete Fourier transform of this function can be written as:

$$SEQ_i = \frac{1}{N}[c_1 + 2\sum_{n=2}^{(N+1)/2} c_{2n-2}cos[\frac{2\pi(n-1)(i-1)}{N}] - 2\sum_{n=2}^{(N+1)/2} c_{2n-1}sin[\frac{2\pi(n-1)(i-1)}{N}]]. \tag{10}$$

For obtaining sufficient number of Fourier coefficients synoptic period (7 days) must be used. Each Fourier coefficient (c_i) can be represented as an independent temperature measurement. Accordingly Kalman filtering (KF) algorithm mentioned above can be applied to these coefficients.

5.2.2 Operational results and verification

Since the mid February 2014 Kalman filtering was implemented in operational mode for COSMO-Ru2 Sochi domain at Hydrometcentre of Russia. Meteograms were produced for 11 stations situated in the region, which sent standard regular SYNOP measurements (example is presented in Fig.11). Height corrected temperature forecasts (authors of the algorithm — I. Rozinkina, D. Blinov) were used as T2m COSMO-Ru2 forecasts.

Thus, Kalman filtering was applied to the value of corrected T2m COSMO-Ru2 forecasts and observations at meteorological stations. It could work for other COSMO-Ru domains and when using standard T2m COSMO-Ru forecasts.

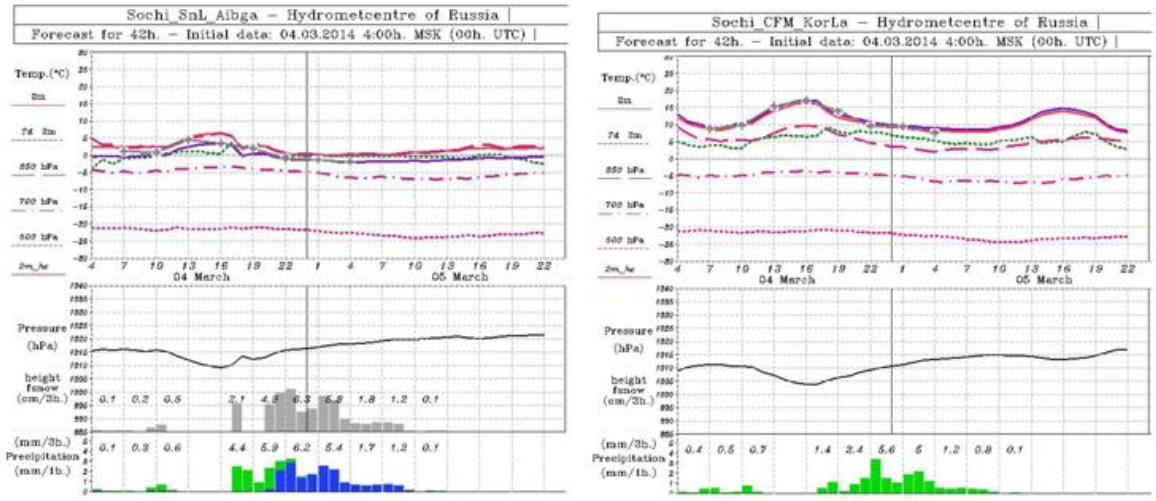

Figure 11: Example of meteograms obtained from integration of COSMO-Ru2 for station Aibga (left) and Kordon Laura (right). Start 00 UTC 4 March 2014. Height corrected temperature is presented by a violet curve, 2m temperature — pink line, result of KF application — gray dots. Grey columns show hourly accumulated depth of fresh snow, numbers above — its 3-hour sums. Blue columns indicate hourly accumulated precipitation in the form of snow, green — in the form of rain

Kalman filtering (with using corrected COSMO-Ru2 T2m forecasts) provides more accurate T2m forecast in mountain region rather than operational version of COSMO-Ru2 (improvement is about 2° C in RMSE) and in most cases — better than using only height correction algorithm for T2m (Fig.12-13). Improvement of T2m forecasts with the use of KF is observed not only for mountain areas, but also for the coastal stations. Comparison between T2m forecasts for the period up to 24 hours was done for these statiuons with start time 00

and 18 UTC — RMSE absolute values were close. The accuracy of KF and T2m corrected algorithm is comparable.

Sochi Adler (0 m)

forecast. hour	RMSE oper	RMSE cor	RMSE KF

Figure 13: RMSE for T2m COSMO-Ru2 forecasts for stations in the Sochi region. Start 18 UTC. 1 March — 30 June 2014

According to Kalman filtering approach, most T2m picks during spring period in 2014 were predicted in a good correspondence with measurements (Fig.14).

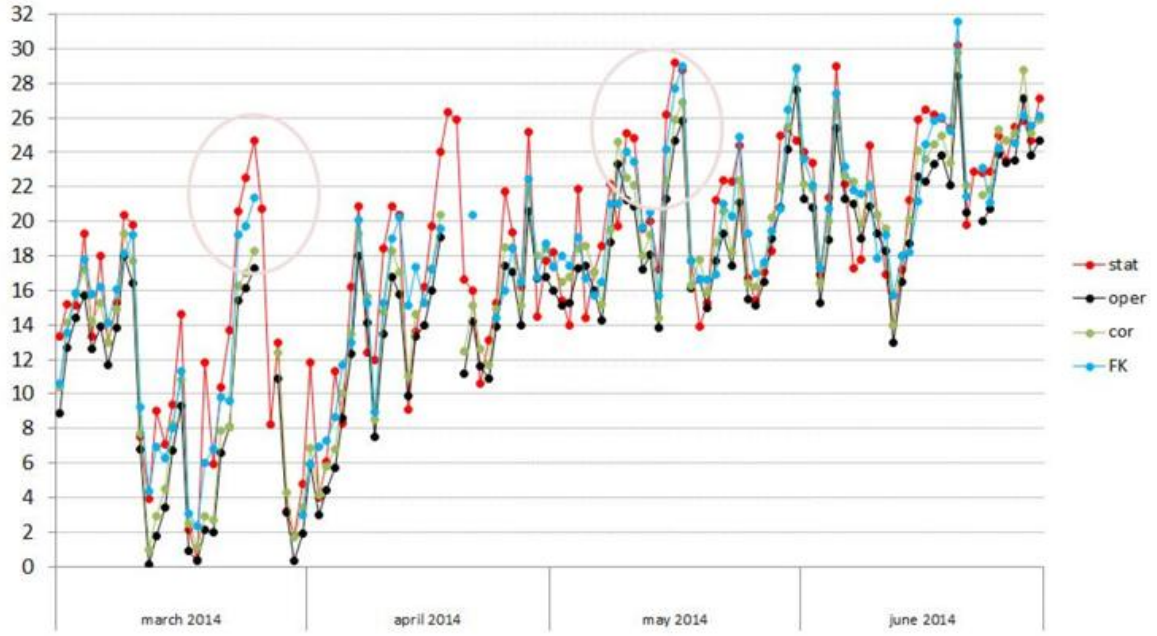

Figure 14: Example of T2m 12h forecasts by COSMO-Ru2 for station Krasnaya Polyana. Start 00 UTC. 1 March — 30 June 2014. Red line observations, black — operational forecast, green — T2m correction algorithm, blue — Kalman filtering

In future we plan to perform a series of experiments to develop the technology of using Kalman filtering in case of the partial absence of forecast data.

5.3 Fresh snow depth postprocessing example for COSMO-Ru-So *(E. Kazakova, M. Chumakov, I. Rozinkina)*

Model precipitation is considered to be a mass of water, which reached earth surface (taking into account its phase state) for given time period, i.e. accumulated water equivalent. According to WMO regulations, information about fallen precipitation is received from synoptic observational network in the same terms as the general-purpose weather forecasts are made.

Due to determined structure "data numerical forecast general-purpose weather forecast", in case of falling of solid or mixed precipitation, users (transportation, electricity supply networks, community facilities, organization of winter sports events, etc.) are not provided with greatly demanded information about depth of snow layer after snowfall which has already taken place or predicted.

As a rule, for fresh snow depth determination simple empirical dependences based on assumption of constant values of its density are used in operational synoptic practice. Use of more valid difficult dependencies should be provided on the basis of automated technology.

Snow depth measurements are held at hydrometeorological stations (HMS) and sent once a day through communication link to international exchange. Such a discreteness of measurements is not satisfactory for exact determination of snow depth in the train of snowfalls, since during this period of time snow cover could experience significant changes (snow could dense, melt, be blown by wind). In some regions there are automated meteorological stations (AMS), for example, in the Sochi region in Russia, which measure snow depth with high time

discreteness (once in 10 minutes). Yet, as the practical usefulness of these measurements has been demonstrated, these data should have pass quality control because reliability of these data is very sensitive to accuracy of setting, operation conditions and regularity of technical service of AMS. Thus the information about snow from AMS can't always be directly used in operational practice.

The main goal of the project was to provide users of mesoscale forecasting system COSMO-Ru output with a new type of information snow increment for several hours. In order to achieve this goal a number of algorithmic and technological issues needed to be resolved.

Forming of suggestions and testing of algorithm for fresh snow density calculation (hence, its layer thickness) referred to algorithmic tasks, combination of calculation of this characteristic from existing elements of postprocessing of COSMO-Ru operational system to technology application. Additional task was analyzing a success of fresh snow depth calculation received from direct COSMO-Ru forecasts (with the proposed algorithm included into its postprocessing) versus direct snow observations at AMS and HMS of North-Caucasian region during the period of winter Olympic Games Sochi-2014. Technological aspects consist of combining the calculations according to the proposed module with operationally functioning postprocessing systems of COSMO-Ru.

While forming meteograms, fresh snow depth could be calculated on the basis of elements' values included in the table. The peculiarity of technological changes during present work was the fact that in the framework of preparation of meteorological support for Sochi-2014 at Hydrometcenter of Russia algorithm of model air temperature (2 meters) correction for mountain region based on moving amendments connected with differences between model and actual relief heights (for points for which meteograms are prepared) was proposed and implemented. Its obvious that when big differences occur, such a temperature amendment should be taken into account in calculations of fresh snow depth, especially at temperatures close to zero.

For output processing in grid nodes the program module of universal postprocessing FieldExtra was developed in COSMO consortium. One of the tasks of the present work was to adapt and implement the proposed algorithm of fresh snow depth calculation based on air temperature data in FieldExtra tool, which in future could allow providing users with calculated information in form of maps.

5.3.1 Description of fresh snow depth calculation algorithm and its testing

Calculation of fresh snow depth is based on the formulas which are used in the snow model SMFE (see COSMO Newsletter, Kazakova, Chumakov, Rozinkina, 2013). For fresh snow depth $h_{s,f}$ (mm) calculations of accumulated precipitation (observed or prognostic) p_s (mm) and fresh snow density $\rho_{s,f}$ (kg/m^3) are needed:

$h_{s,f} = \frac{p_s \cdot \rho_w}{\rho_{s,f}}$,

where $\rho_w = 1000\ kg/m^3$ - water density.

For testing of the proposed method it was checked against several assumptions:

- linear dependence on air temperature at 700 hPa from (McGurk, Azuma, Kattelmann, 1988);
- formula for fresh snow density calculation in TERRA of the COSMO-model, depending on temperature of the model lowest atmospheric level (Doms et al., 2011);

– constant density value equal to 100 kg/m^3, which is mostly used in synoptic practice while making weather forecast for conversion of precipitation sums into snow depth.

For quality assessment of unique observations of several snowfalls in January 2013 at the station Gornaya Karusel (1500 m) was conducted (Fig.15). As shown, the proposed fresh snow depth calculation method gives a good approximation to the values measured at the station, which happened to be more accurate in comparison with other algorithms. Thus, RMSE of fresh snow depth in case of the proposed method is 1.1 cm and MAE is 2.9 cm, while relative error is equal to 8.3 %. Linear dependence on T700 could be used only for a limited temperature range. As a rule, use of constant value of 100 kg/m^3 and formula from TERRA lead to fresh snow depth underestimation.

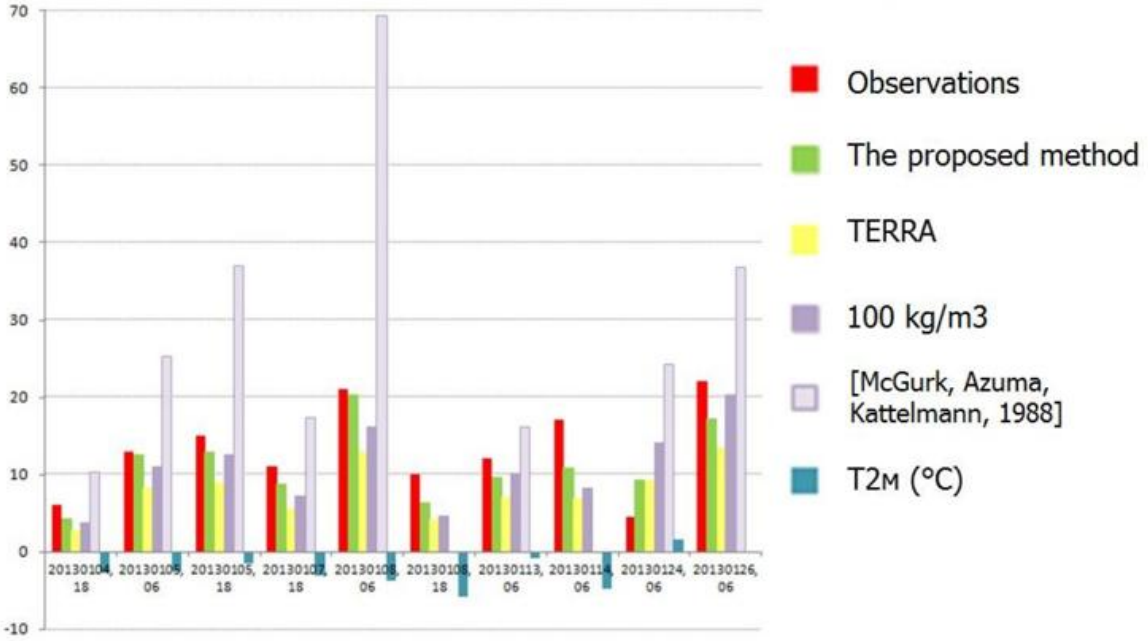

Figure 15: Fresh snow depth (cm) is coloured as: red observations at station Gornaya Karusel, light green results of proposed method using T2m (° C), yellow using formula from TERRA of the COSMO-model, violet under the assumption of the constant fresh snow density value of 100 kg/m^3, light violet according to linear dependency on T700. In blue T2m values (° C) are shown

From a network of observation stations and reports of road services in Moscow numerical experiments an assessment of the proposed method results in case of heavy snowfall in Central Russia at 3-4 February, 2013 was conducted. In particular, information of road services helped to take into account the increment of snow depth up to 25 cm, not recorded in the standard reports in SYNOP code. The latter indicated the snow depth growth only by 13 cm. Standard observations are done once a day, however, during this period snow had compacted. Calculated by COSMO-Ru7 prognostic values of accumulated snow were a little bit less than 12-hour observations (19.2 and 25.0 mm, respectively). According to the proposed method on the basis of observed 12-hour precipitation sums recalculation, fresh snow depth estimations of 25.2 cm were obtained (which corresponded the reports of road services). The research showed applicability of the method and its greater efficiency in case of using of accurate needed initial data of accumulated precipitation and air temperature when they were fallen.

5.3.2 COSMO-model fresh snow depth output

Prior to start of winter Olympic Games Sochi-2014, a prognostic maps of fresh snow depth were being produced since 3 February 2014 at Hydrometcenter of Russia on the basis of forecasts of accumulated precipitation provided by different versions of COSMO-Ru model with grid resolution of 7 km (COSMO-Ru7), 2.2 km (COSMO-Ru2) and 1.1 km (COSMO-Ru1). Maps were formed according to operational forecasts starting at 00, 06, 12 and 18 UTC.

Also values of fresh snow depth were recorded in meteograms for stations situated in North-Caucasian region. Prognostic values were calculated taking height-corrected air temperature into consideration.

The technological branch of fresh snow postprocessing and its output in the framework of COSMO-Ru system postprocessing are shown in Fig.16.

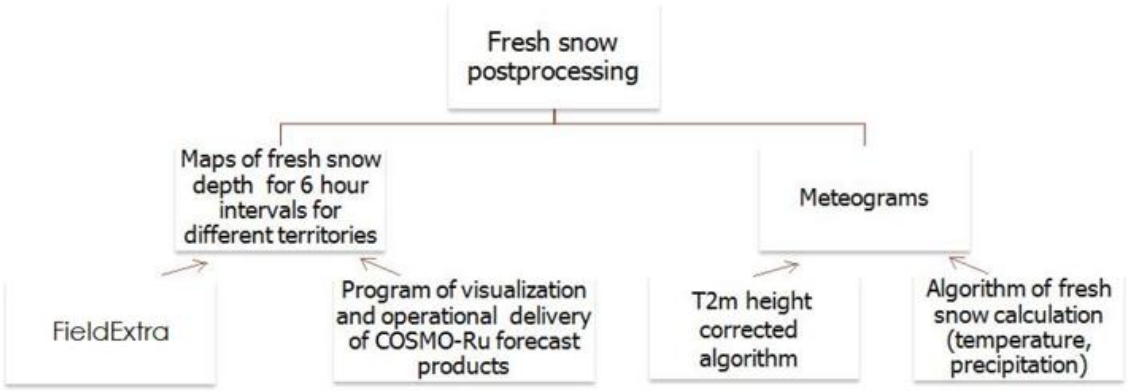

Figure 16: The scheme of fresh snow depth calculation at Hydrometcenter of Russia (based on mesoscale model COSMO-Ru)

Output in form of meteograms for stations and maps of fresh snow depth for 6-hour intervals prepared for versions COSMO-Ru7, COSMO-Ru2 and COSMO-Ru1 four times a day with the use of FieldExtra.

Fig.17 shows that there are significant differences in calculations using different COSMO-model versions.

The fact that relief detailing and its model heights for this region turned to be principle for precipitation phase prediction, large elevation and temperature extremes are observed. The relief is smoothed for coarser model resolution (COSMO-Ru7) and larger area with negative air temperatures occurred in comparison with more detailed modeling (COSMO-Ru2, COSMO-Ru1), where definition of relief led to more accurate description of extended valleys and relatively small highlands regions, for which snow falling was typical. In addition testing done in (Shatunova, Rivin, 2013) indicated to lower precipitation sums formed by COSMO-Ru1 in comparison with COSMO-Ru2.

5.3.3 Results of fresh snow depth calculation implemented into COSMO-Ru system postprocessing

Maps of fresh snow depth and meteograms were used for initial quality estimation of work of the proposed system as well as hourly measurements from AMS situated at different levels on

the mountain resort Roza Khutor and daily measurements from three HMS (Aibga, Kordon Laura, Gornaya Karusel-1500) located in the region of winter Olympic Games Sochi-2014.

Complexity of testing realization was determined by several factors: firstly, snowfalls were observed only several times during winter season 2013/2014; secondly, model data could be compared with measurements only at some stations.

During winter Olympic Games Sochi-2014 there were three cases with significant snowfalls: 17-19 February, 21 February and 26-28 February. The main peculiarities in fresh snow depth reproduced by COSMO-Ru in the region of winter Olympic Games Sochi-2014 are described below.

Preliminary results demonstrated significant variability of snowfall forecasts for the same period started at different time and the latest forecast was not always the best in comparison with forecasts started before. Based on quite detailed analysis of time-distribution intensities inside snowfall period its turned out to be impossible to conclude which forecast with what lead time is more successful, and which forecast is more accurate: obtained by model versions with resolution of 2.2 km or 1.1 km. Yet in general the best agreement with snowfall measurements was observed in case of all realizations averaging.

Comparison with similar calculations found at website www.snow-forecast.com (www.snow-forecast.com) showed systematic underestimation of represented fresh snow values and results are more close to reality calculated by COSMO-Ru1 and COSMO-Ru2 systems. Example of analysis of one snowfall case according to observations at Roza Khutor is shown in table 6.

Table 6: Fresh snow depth (cm) according to observations at AMS Roza Khutor 4, forecasts from COSMO-Ru2 and COSMO-Ru1 and data from publically available website, produced by WRF model, www.snow-forecast.com. 18 February 2014

	COSMO-Ru2						
28.2	27.6	30.0	39.5	22.1	25.4	21.3	12.0
	COSMO-Ru1						
28.2	23.8	17.0	24.9	40.8	19.9	16.8	12.0

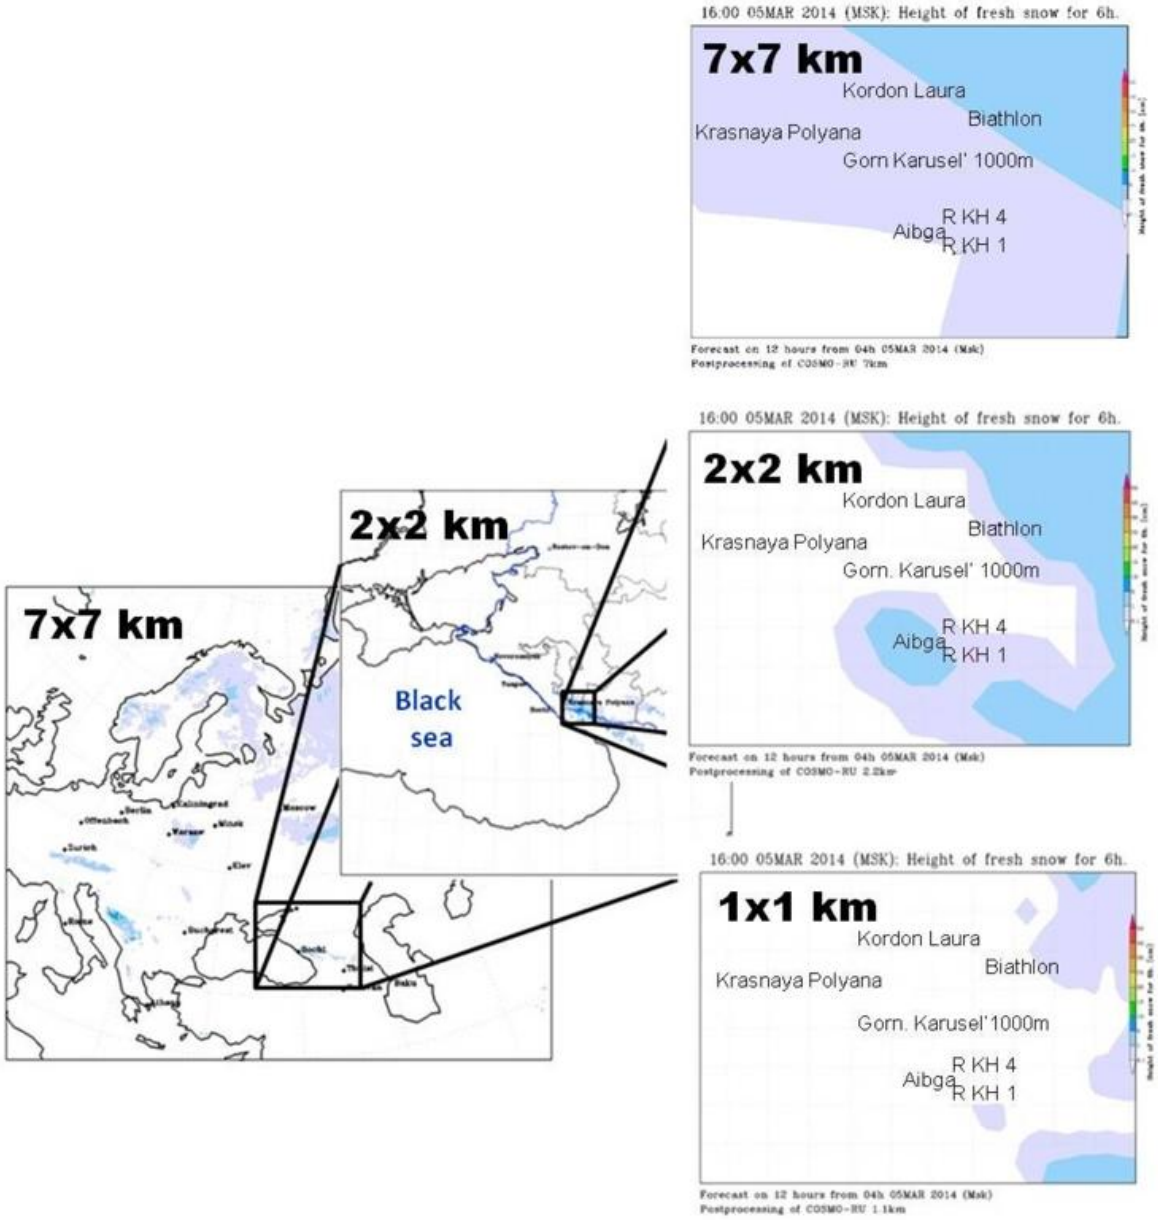

Figure 17: 12h-forecasts of fresh snow fallen for the last 6 hours according to COSMO-Ru7, COSMO-Ru2 and COSMO-Ru1. Start — 00 UTC 5 March 2014)

The proposed system gives more successful fresh snow depth forecast with account of height-corrected air temperature against the case of using air temperature received from standard version of COSMO-Ru model (the example is shown in Fig.11 (see Section 5.2.2 for station Aibga).

Maps of fresh snow depth can be created for any territory which coincides with the calculated grids of COSMO-Ru model versions (Fig.17). For example, it is true for the region, which include most part of the European territory of Russia. Meteograms containing fresh snow depth forecasts were prepared in January-March 2014 for North-Caucasian region for the purpose of specifying this meteorological element at points (stations). Analogous meteograms with fresh snow depth data can be obtained for stations located in other regions.

The testing showed that the developed system reproduces fresh snow depth quite realistically.

Note that COSMO-Ru provides the fact of precipitation falling in form of snow reliably, but quantitative estimations depend on forecast interval.

5.3.4 Conclusions

Thus, the system of prediction of fresh snow depth in the framework of COSMO-Ru post-processing is developed and realized at Hydrometcenter of Russia. The system includes preparation of fresh snow depth maps for 6-hour intervals four times a day according to model versions with the resolutions of 7, 2.2 and 1.1 km. Additionally, the fresh snow forecasts for stations are provided as meteodrams. Preliminary analysis of snowfalls occurred in North-Caucasian region in February 2014 showed that COSMO-Ru output connected with fresh snow characteristics could be used in weather forecasting. This output was used by weather forecasters in the framework of meteorological support of winter Olympic Games Sochi-2014, in particular for completion of daily bulletins and competitions planning.

5.4 Verification of COSMO forecasts for the Sochi-2014 region *(A. Bundel, A. Muravev, D. Blinov, A. Kirsanov)*

Verification of weather forecasts was one of the most important components of Sochi-2014 Winter Olympics and Paralympics meteorological support. The Sochi region has complex terrain with the Black Sea in close proximity. Information of high spatial and temporal resolution was required for competitions. These factors made more challenging both forecasting itself and verification and required development of new approaches.

5.4.1 Verification tools

Most of the scores were calculated in VERSUS (VERification System Unified Survey), an official COSMO verification tool. Several FROST online verification tools were used: FROST online monitoring of forecast quality only for stations, and FROST Point forecast and diagnostic data viewer. For some tasks, MET tool was used.

5.4.2 Verification problems

A dense observational network is needed for reliable verification. A number of automatic weather stations were installed in the regions of Games. However, their number was not sufficient for application of some verification methods. The stations are clustered. Even several 1-km grid points could be the nearest to certain station (Fig.18). For statistically reliable conclusions, long time series of data are necessary, while some models and verification tools became available just before the Games (for example, COSMO-Ru1 only at the end of January).

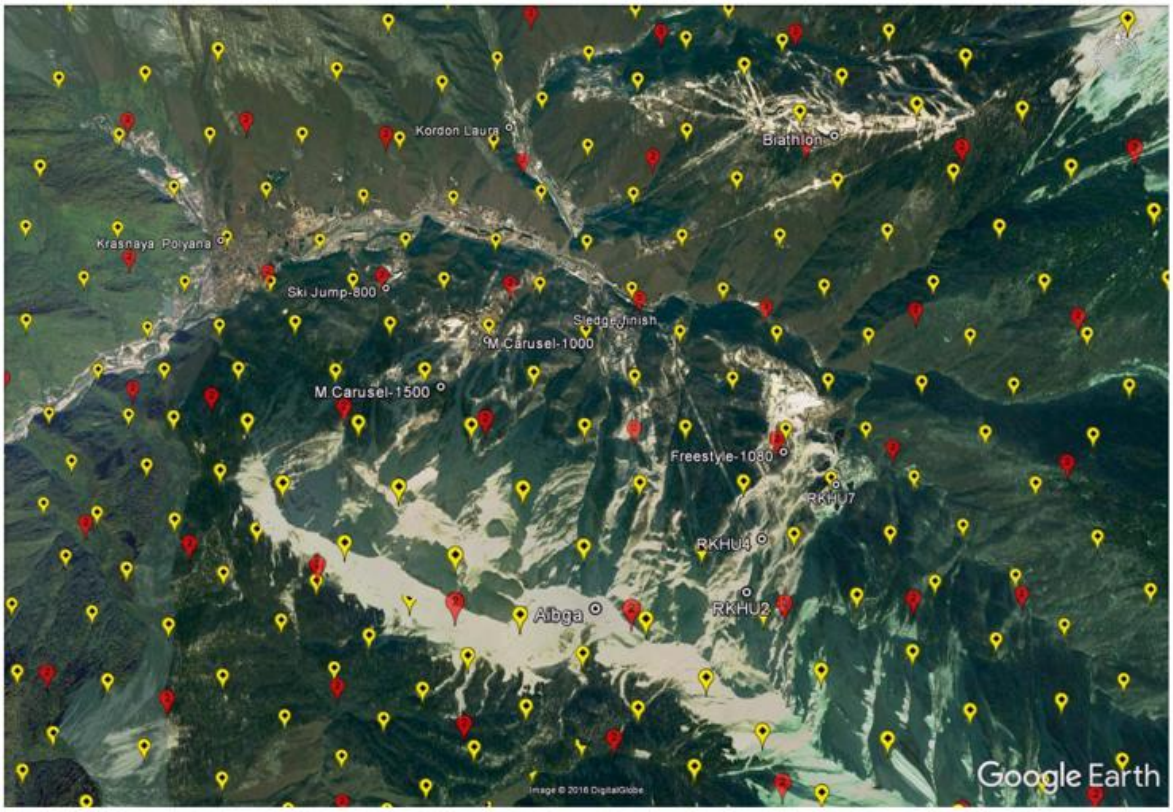

Figure 18: Nearest point approach: COSMO-RU2 (red lamps) and COSMO-Ru1 (yellow points) — models grid points and weather stations (superscripted)

5.4.3 Verification over the test periods and during the official evaluation period of the Games of 2014

Deterministic verification

Deterministic forecasts of COSMO-Ru7, COSMO-Ru2, COSMO-Ru1 systems were verified. The evaluation period was 15 January — 15 March, 2014. Various continuous and categorical metrics were applied to near-surface temperature, dew point temperature, relative humidity, wind speed, wind direction, wind gusts, and 3-hour accumulated precipitation.

Period of the Games was anomalously warm, the COSMO models, like most models providing forecasts for Sochi-2014, underestimated surface air temperature (in particular, during the daytime). The underestimation is more pronounced during the clear sky conditions compared to overcast ones. The likely cause of this behavior is insufficient soil warming in the sunny weather.

For the COSMO model family, the effect of resolution enhancement was especially notable for wind speed and gusts (Fig.19, Fig.20). COSMO-Ru7 is worse overall. T2m and dew point temperature were better in COSMO-RU2. Traditional scores aggregated over the Sochi region show overall prevalence of COSMO-Ru2 with relation to COSMO-Ru7 and COSMO-Ru1. However, some cases of intense precipitation and visibility were better predicted by COSMO-Ru1 during the period of Games. That coincides overall with subjective forecasters' opinion that among the five COSMO based models/ensembles, COSMO-Ru2 is perhaps the best.

The best precipitation forecasts were made during the late afternoon (16–19 h local time) according to the Pierce Skill score.

The spatial methods are needed to better analyze the effect of high resolution of precipitation (and some other variables, e.g., wind characteristics). These methods applied to the Sochi-2014 archive are explored within the relevant PP INSPECT tasks.

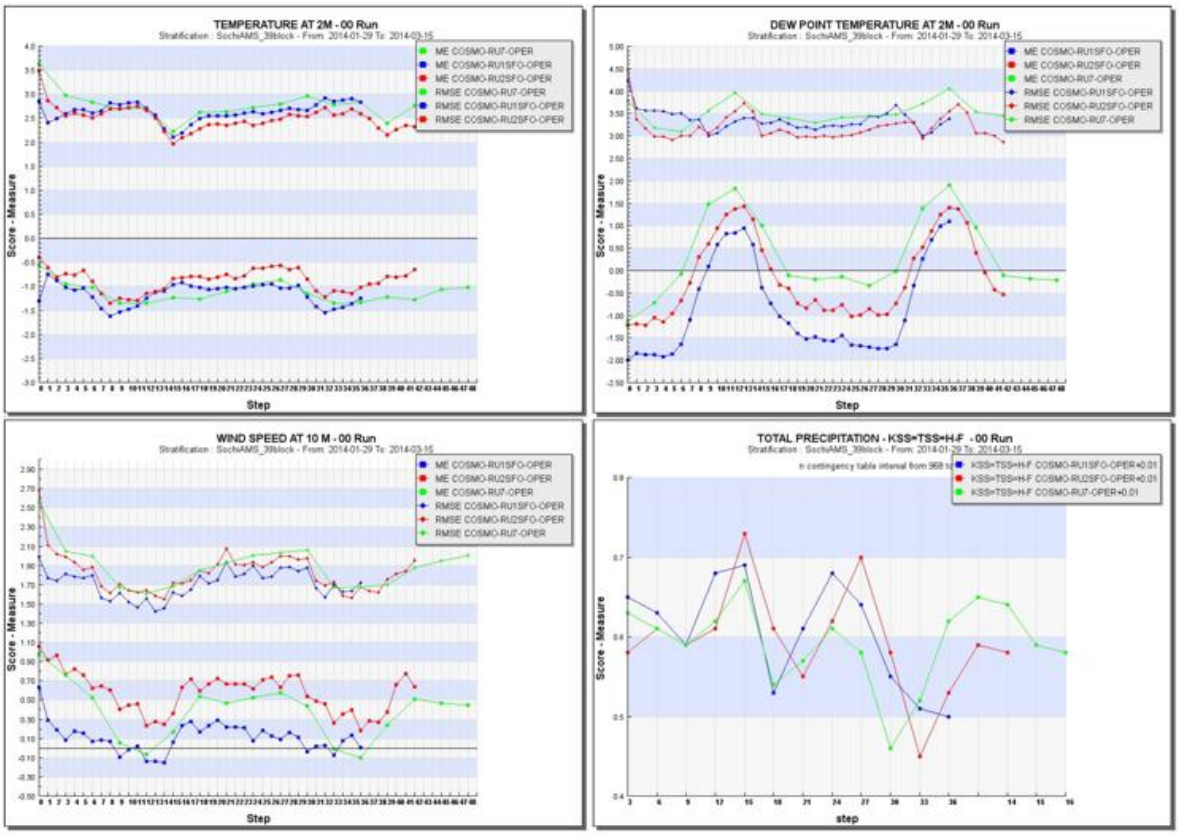

Figure 19: Scores for COSMO-Ru1, COSMO-Ru2, and COSMO-Ru7, 29 Jan–15 March 2014

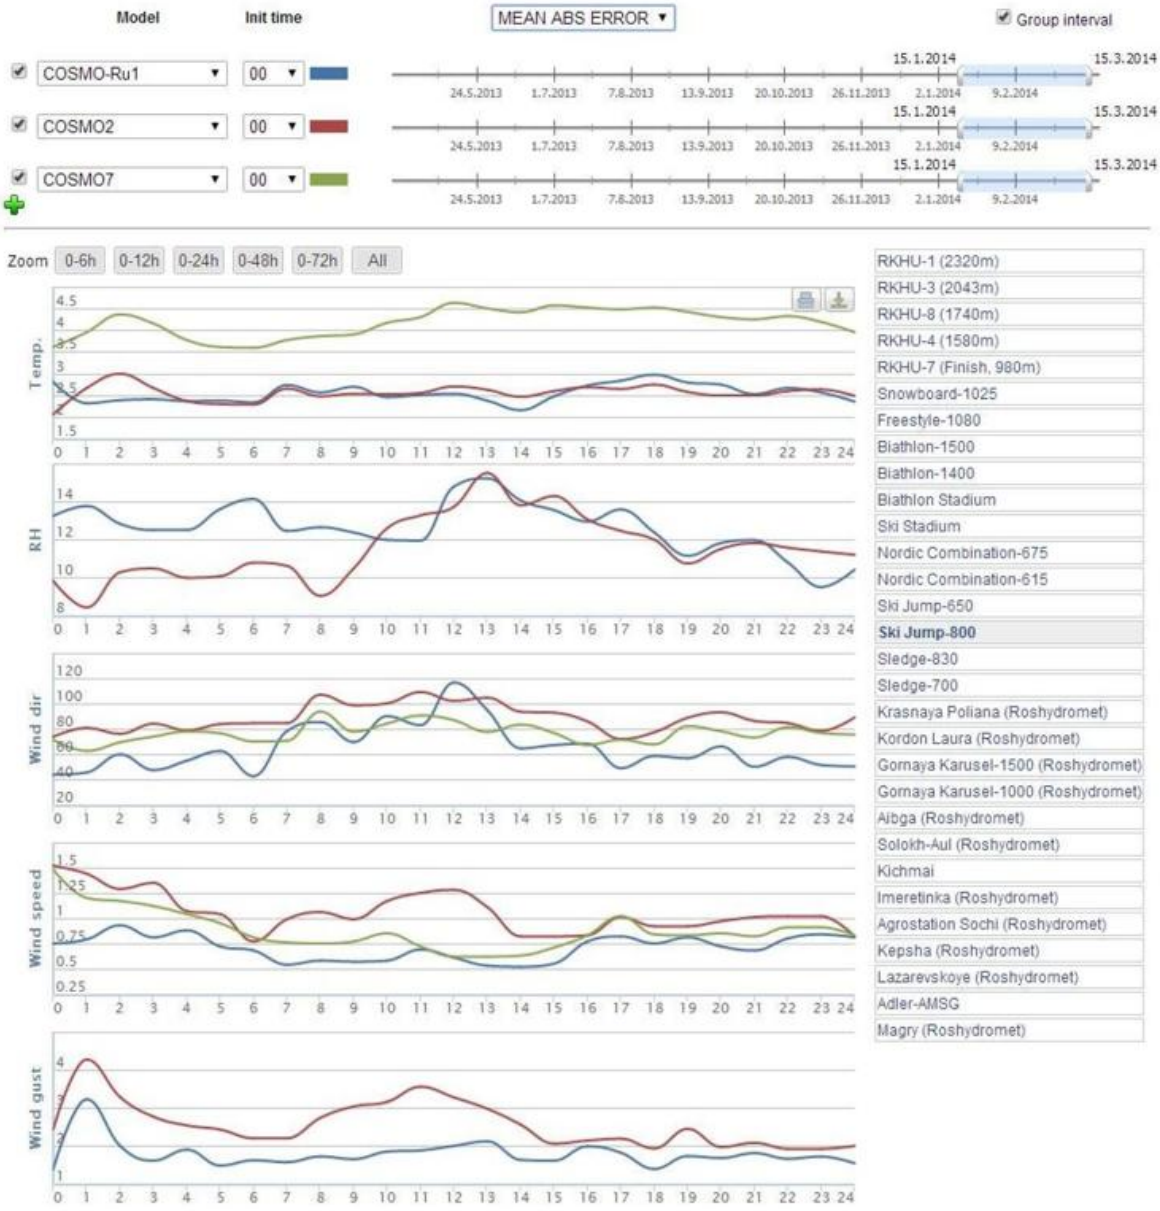

Figure 20: Effect of resolution, COSMO-Ru1, COSMO-Ru2, and COSMO-Ru7, 15 Jan–15 Mar 2014. Ski Jump-800 station

The dependence of COSMO forecast skill on the driving model (either ECMWF-IFS or DWD-GME) was found limited (study of Andrea Montani).

Analysis of test periods

Thorough verification of past seasons is important for the development of models and new methods. Analysis of COSMO-Ru performance during the previous test seasons revealed that the model bias could change its sign from one cold season to another depending on the prevailing weather regimes (Fig.21). It is still unclear, is it due to 2013 warm anomaly, or observation data distribution, amount, and quality? Therefore, it was found difficult to make model calibration.

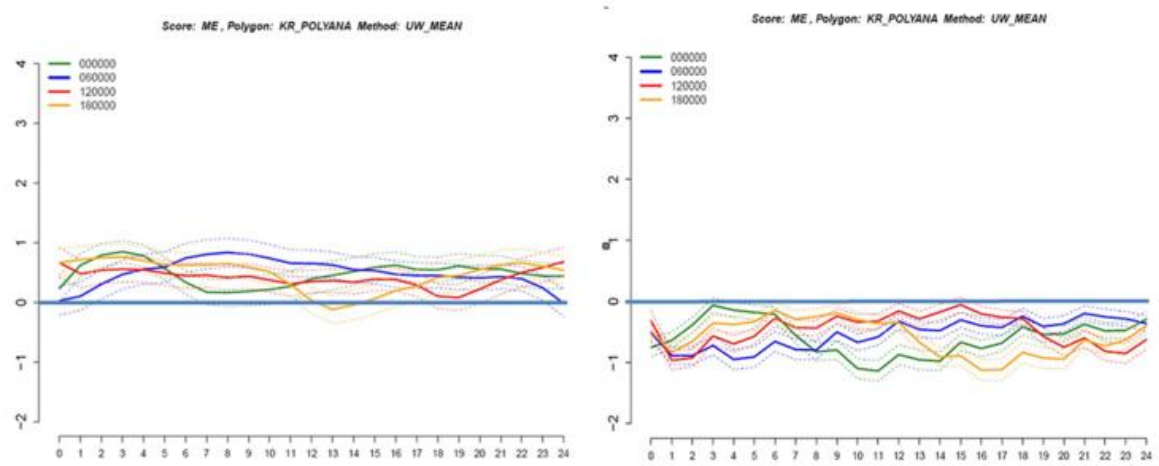

Figure 21: COSMO2Ru T2m mean error during the first test period (winter 2012–2013) (left panel) and the second test period (Jan–Feb 2014) (right panel) (all initial times) at Krasnaya Polyana station

Diagnostic verification

"It is advisable in verification projects to examine the data before computing the scores. This can be done by means of scatter plots and quantile-quantile plots, or, for categorical data, by histograms" (Recommendations of **"Suggested methods for the verification of precipitation forecasts against high resolution limited area observations"** by the JWGFVR for the WGNE (Laurie Wilson, Beth Ebert et al.)

A station-based diagnostic verification tool for thorough diagnostic analysis was created for the Sochi-2014 project. It is "diagnostic"in the sense that it focuses on the fundamental characteristics of the forecasts, the corresponding observations, and their relationships (A. Murphy, B. Brown, Y. Chen, 1989). Figure 22 shows an example of diagnostic verification plots. On the right-hand bottom plot, the red lines denote maximum, mean, and minimum observed value for each forecast bin. Green lines denote 75, 50, and 25 % quantiles for the bin sample volume of no less than 10 pairs (sample stability). Such plots were made for each variable, station, lead time, and method. They show the forecast errors in the whole variable range including the distribution tails, that is, extreme values important for decision making about the competitions; show the sample size in different categories and outliers. The interquantile range values are inversely related to forecast accuracy.

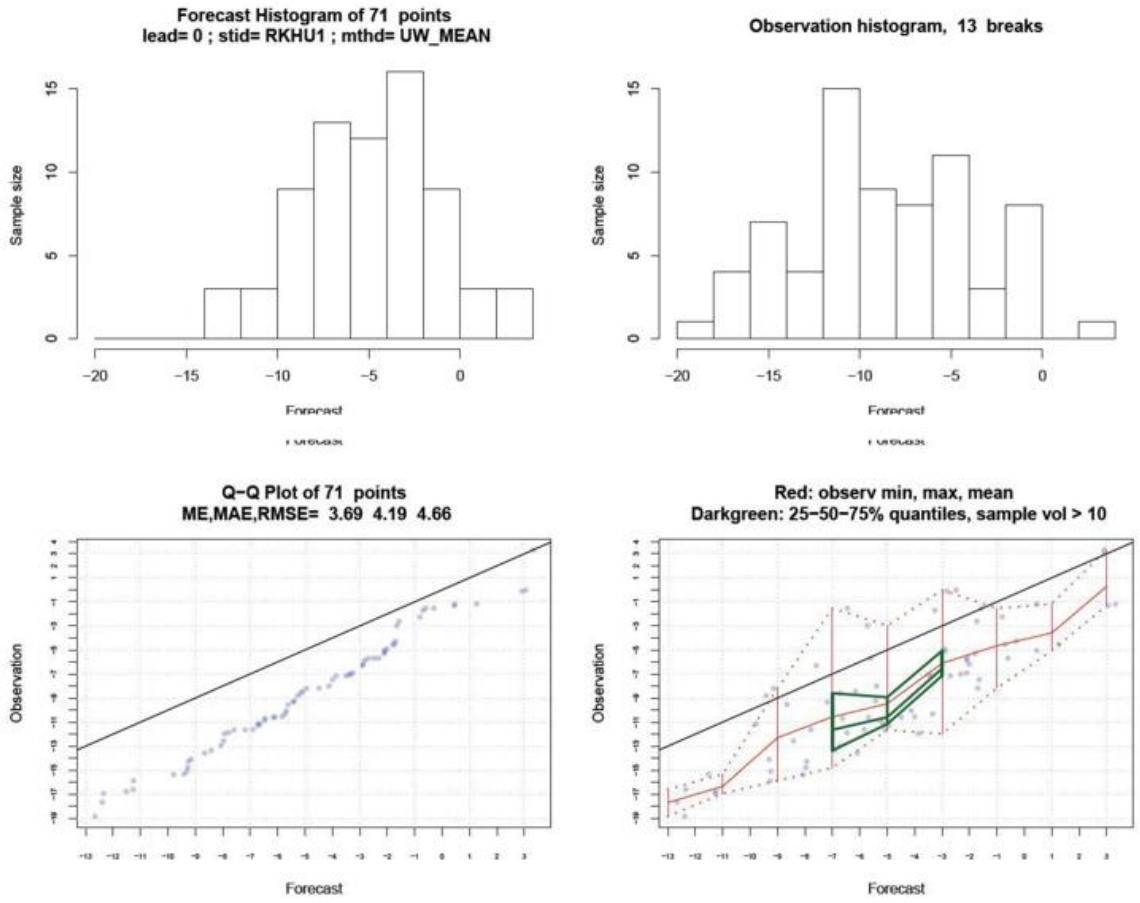

Figure 22: An example of diagnostic verification plots

High Impact Weather (HIW) verification

HIW definitions can be prescribed by value thresholds given by authorities or statistically determined by extreme values or distribution tail statistics.

Traditional scores become insensitive to changes in accuracy for low base rates (rare events) (base rate is the frequency of occurrence of the event in the verification sample). For example, the PSS becomes 0 with the base rate diminishing. There is increasing uncertainty about the quality (sample effect, jumping score values) *(J.Jolliffe, D.Stephenson)*. It was shown (Ferro and Stephenson 2011) that the extremal dependency index (EDI) and symmetric extremal dependency index (SEDI) are insensitive to base rate; they also are both formulated to use the hit rate (H) and false alarm rate (F) only, which links these scores to the Pierce Skill score (H-F) and the ROC curve frequently used in verification of probability forecasts.

$$EDI = (logF - logH)/(logF + logH)$$

The EDI is especially recommended for low base-rate thresholds, but it will give a good comparative estimate of accuracy for all thresholds. These scores were applied to the Sochi-2014 data. The dependence of EDI, PSS, and base rate on precipitation threshold is shown in Fig.23.

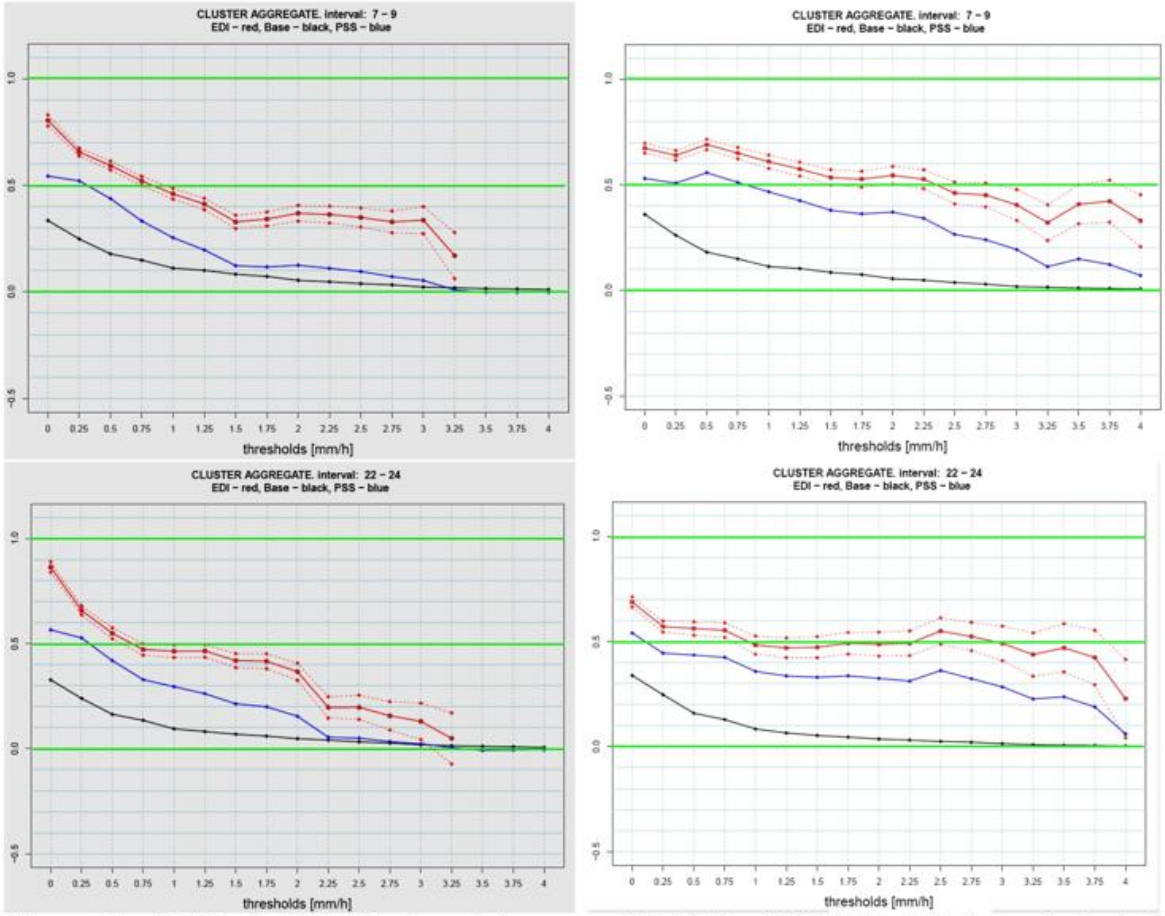

Figure 23: EDI (red), PSS (blue), and base rate (black) for COSMO-Ru2 (left panel, shaded) and NMMB (right panel) 3h precipitation, nearest point, Jan–March 2013, Mountain cluster

Figure 23 shows that:

- There are 10 % of events higher than 1 mm and 5 % , higher than 2 mm;
- $EDI > PSS$ (Pierce Skill Score);
- COSMO predicts better precipitation fact, NMMB predicts better more intense precipitation.

The similar graphs were made for temperature and wind speed.

The study on EDI application showed that:

- EDI is appropriate but not universally applicable (failure with wind speed);
- EDI does not always converge, often it reflects a combination of model, observation and sampling errors;
- EDI is generally not monotonic with relation to PSS (Fig.24);
- EDI is always greater than PSS for positive PSS (Fig.25).

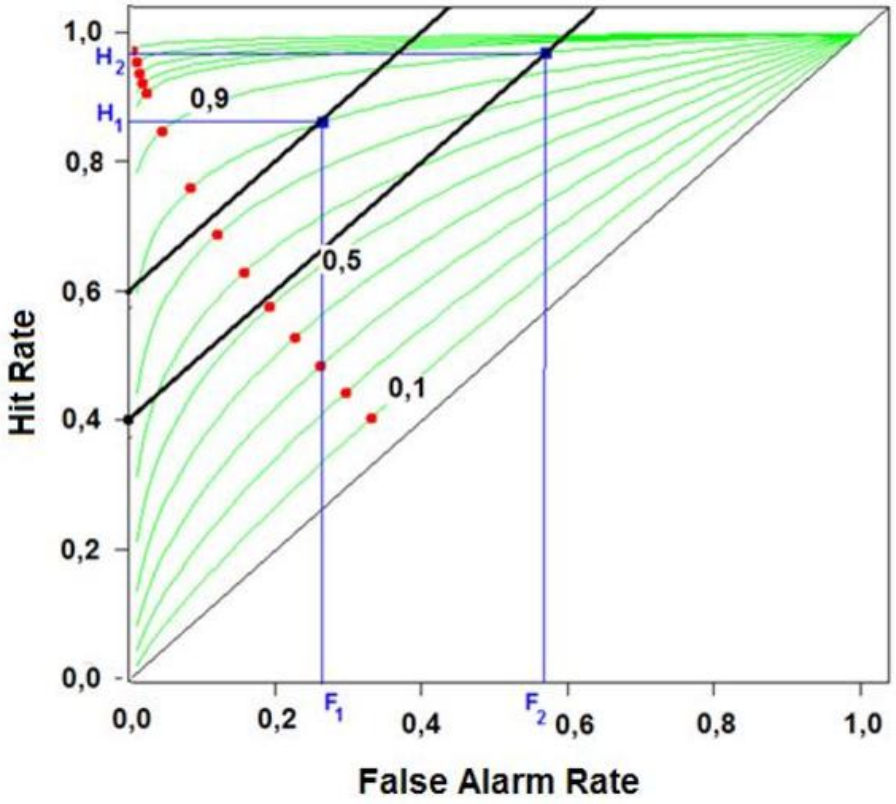

Figure 24: EDI (green) and PSS (black) isopleths; EDI for 0.1 – 0.9 and 0.95 – 0.99 with intervals 0.1 and 0.01; $PSS = H - F$ for 0.4 and 0.6 values; $H = F$ diagonal corresponds to $EDI = PSS = 0$.; Red points: EDI curves tangent to straight PSS lines (strict formulas). Blue squares at (F,H): the monotonic EDI and PSS relation breaks down: Nonlinear dependence — not STRICTLY monotonic: for $(F1, H1)$ and $(F2, H2)$ $PSS1 > PSS2$, but $EDI1 < EDI2$

Figure 25: Relation between EDI minimum value and PSS

5.4.4 Conclusions and prospect for the future

- Nearest point approach in the complex terrain
- Different seasons and model changes calibration difficulties
- Weather dependent verification much effort, but it turned out difficult to give exact instructions to forecasters because of insufficient data and calibration difficulties
- More Conditional verifications are needed

The spatial methods are needed to better analyze the effect of high resolution of precipitation (and some other variables, e.g., wind characteristics). These methods applied to the Sochi-2014 archive are explored within the relevant PP INSPECT tasks.

Overall, the findings of objective verification agree with subjective opinion of Sochi forecasters.

6 Development and adaptation of COSMO EPSs for the Sochi region *(D. Alferov, E. Astakhova, C. Marsigli, A. Montani, T. Paccagnella, G. Rivin, A. Shcherbakov)*

The Sochi region belongs to the moderately humid subtropical zone and is influenced by the non-freezing Black Sea and by the spurs of the Main Caucasus Range. The necessity of weather forecasting at Olympic venues located both in the coast and in the mountains, quite steep and intersected by multiple shallow canyons, made meteorological support of the Sochi-2014 Olympics rather complicated effort. A state-of-the-art approach to mountain weather forecasting implies the application of high-resolution modeling, nowcasting and ensemble technologies. Reasoning from this, the ensemble component was included to the CORSO project as task 3.

The goal of task 3 was to demonstrate the capabilities of ensemble systems in numerical weather prediction in a mountainous region with complex orography and to assess the effect of practical use of ensemble products during Sochi-2014 Olympic Games. To achieve this goal, two activities were planned:

- adaptation of COSMO-LEPS 7 km to the Sochi region and to specific requirements of winter Olympics; operational ensemble forecasts during the Olympics;
- development and verification of a convective-resolving EPS for the Sochi region (with ICs and BCs from the 7-km EPS).

As a result, the two ensemble prediction systems based on COSMO model were developed: COSMO-S14-EPS with a 7-km resolution (a relocation of COSMO-LEPS to the Sochi region) and COSMO-Ru2-EPS with a 2.2 km resolution (nested to COSMO-S14-EPS). Both systems ran in operational mode during the Olympics; the probabilistic products were regularly delivered to Sochi forecasters. Analysis of regular runs, their application, and case studies demonstrated that ensembles gave a valuable support to forecasters and the higher-resolution ensemble gave more detailed and precise forecasts.

The following sections give the description of the systems, survey their application during the Olympics and present the analysis of EPS performance.

6.1 Ensemble prediction system with a 7-km resolution

A system with a 7-km grid size named COSMO-S14-EPS (S14 stands for Sochi-2014) was created at ARPA-SIMC (Montani et al., 2013, 2014) and is a version of the COSMO-LEPS system displaced from the European area to the Sochi region. COSMO-LEPS has been operationally running for more than 10 years and demonstrated good results, in particular, for regions with complex orography (Marsigli et al, 2003; Montani et al., 2011).

Methods and approaches used in COSMO-LEPS and COSMO-S14-EPS are similar. The boundary and initial conditions came from the global ensemble system of the European Centre for Medium Range Forecasting (ECMWF-EPS, (Molteni et al, 1996)). The facts that the horizontal resolution should be higher in limited-area forecasts and the time for preparing operational forecasts should be minimal combined with usually limited computer resources lead to the necessity to reduce the ensemble size. It was done by selecting the most representative prognostic realizations of the global ECMWF-EPS via clustering (48-72 hour forecasts of geopotential, wind components, and humidity at 500, 700, and 850 hPa

were considered) (Molteni et al, 2001; Montani et al, 2013). The prognostic realizations of the global EPS chosen by this procedure were then interpolated to the grid of the mesoscale model COSMO (see http://www.cosmo-model.org) and served as initial and boundary conditions for limited-area forecasts. No additional regional perturbations were introduced. The most essential differences between the COSMO-S14-EPS and COSMO-LEPS systems were integration domains (the Sochi region or Europe) and ensemble sizes (10 or 16 members, respectively).

The lower boundary condition for all COSMO-S14-EPS members was taken from COSMO model runs in hindcast mode (short-range forecast nested on ECMWF analyses).

The model-related uncertainty was taken into account in COSMO-S14-EPS by using two different convection parameterization schemes (Tiedtke or Kain-Fritsch, random choice) in different members and also by varying tuning coefficients in parameterizations of sub-grid scale processes (in particular, turbulent).

The main characteristics of COSMO-S14-EPS are summarized in Table 7, which also reports some details relative to the global ensemble ECMWF-EPS.

Table 7: Main features of the present implementations of ECMWF-EPS, COSMO-S14-EPS, and COSMO-Ru2-EPS

	ECMWF-EPS	COSMO-S14-EPS	COSMO-Ru2-EPS
Hor. res. Vert. res.	$\sim 31\ km$ 62 ML	7 km 40 ML	2.2 km 50 ML
Forecast length	240h	72h	48h
Ensemble size	50+1	10	10
Initial time	00/12 UTC	00/12 UTC	00/12 UTC
Convection	Parameterized	Parameterized	Resolved
Running at	ECMWF	ECMWF	Roshydromet
ICs and BCs	SV ini pert + EDA	from selected ECMWF-EPS members	from COSMO-S14-EPS members
Model perturbations	Stochastic physical tendencies + backscatter	Physical parameterizations	

COSMO-S14-EPS was implemented on ECMWF supercomputers in November 2011 and ran on a regular basis from 19 December 2011 till mid-May 2014 thanks to the billing units provided by the ECMWF Special Project SPCOFROST.

6.2 Ensemble prediction system with a 2.2-km resolution

The experience of projects initiated by WWRP before the Olympic Games in Beijing in 2008 and Vancouver in 2010 (B08RDP and SNOW-V10) (Duan Y. et al, 2012; Isaac G. A., 2012), as well as of the MAP D-PHASE project (Rotach M. W. et al, 2009) demonstrated that good descriptions of meteorological processes and forecasts of severe events in the regions with complex mountainous relief can be achieved only with high-resolution models (with resolution not coarser than 2–3 km). This is because of more accurate orography data used in such models, fine resolution enabling to simulate local events, and switched off convective parameterization. It is worth to note that development of convection-permitting ensemble

prediction systems (with a grid size of 2–3 km) is in the mainstream now.

The ensemble prediction system COSMO-Ru2-EPS was created as a research tool and is based on the COSMO-Ru2 model version (Rivin et al, 2015) with a resolution of 2.2 km. The initial and boundary conditions were interpolated from COSMO-S14-EPS forecasts. The boundary conditions were refreshed every hour.

COSMO-Ru2-EPS and COSMO-S14-EPS had the same ensemble size. No additional model perturbations were introduced. Thus, COSMO-Ru2-EPS performed a dynamical downscaling of COSMO-S14-EPS increasing the forecast resolution both in horizontal (from 7 to 2.2 km) and in vertical (from 40 to 50 levels). The COSMO-Ru2-EPS system was implemented on a Roshydromet computer SGI Altix 4700.

The main features of COSMO-Ru2-EPS are summarized in Table 7 along with the features of ECMWF-EPS and COSMO-S14-EPS. The organization of COSMO-based ensemble forecasting for the Sochi region is sketched in Fig.26.

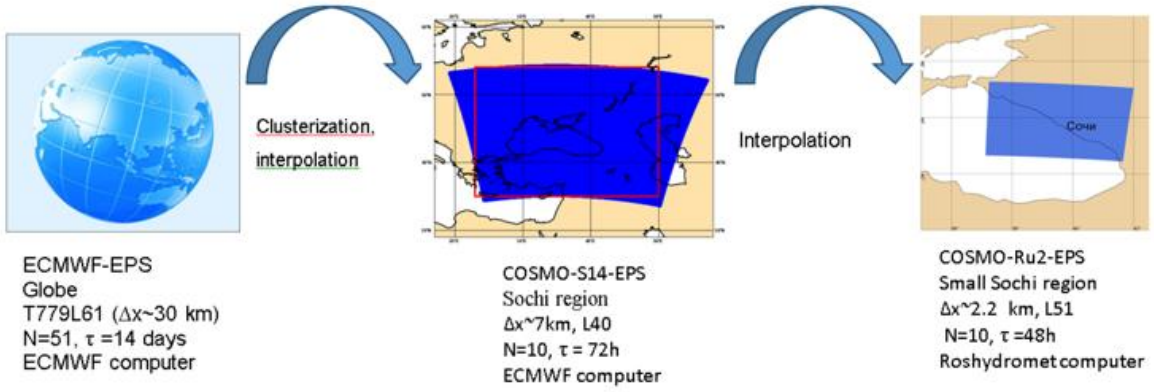

Figure 26: Organization of COSMO ensemble forecasting for the Sochi region. N is the ensemble size, τ is the forecast length, and L is the number of vertical levels

Figure 27 reports the orography for three systems of Table 7 and is meant to indicate the potential impact of increased horizontal resolution in the description of orographic and mesoscale-related processes.

The ECMWF-EPS orography (top-left panel) shows almost no evidence of the valley running for about 40 kilometres from Sochi-Adler, the coastal cluster of the winter Olympics 2014, where ice-sport competitions took place, towards Krasnaya Polyana, located in the mountain Olympic cluster where snow-sport competitions were held. COSMO-S14-EPS (top-right panel of Fig.27) already offers a better description of the complex topography of the area, although it has to be pointed out that only with the 2.2 km grid-size of COSMO-RU2-EPS (bottom panel) some important details of the geography (e.g. the eastward turn of the valley after Krasnaya Polyana) can emerge.

6.3 Providing ensemble forecasts for the Sochi Olympics and preceding trial competition

The COSMO-S14-EPS products were accessed by the Hydrometcenter of Russia since the end of 2011. These mesoscale ensemble forecasts for the Sochi region were the first for Russian forecasters. During the following three pre-Olympic years all technology problems were solved (in particular, the earlier time of forecast accessibility was achieved) and tools

for presenting the COSMO-S14-EPS probabilistic information were developed. The most important was that forecasters got a valuable experience of working with this information. Therefore, it is not surprising that COSMO-S14-EPS probabilistic forecasts were most widely applied among all ensemble forecasts prepared within the FROST-2014 project (the blended RDP/FDP project devoted to the Olympics 2014) and available to forecasters during the Olympic Games in Sochi.

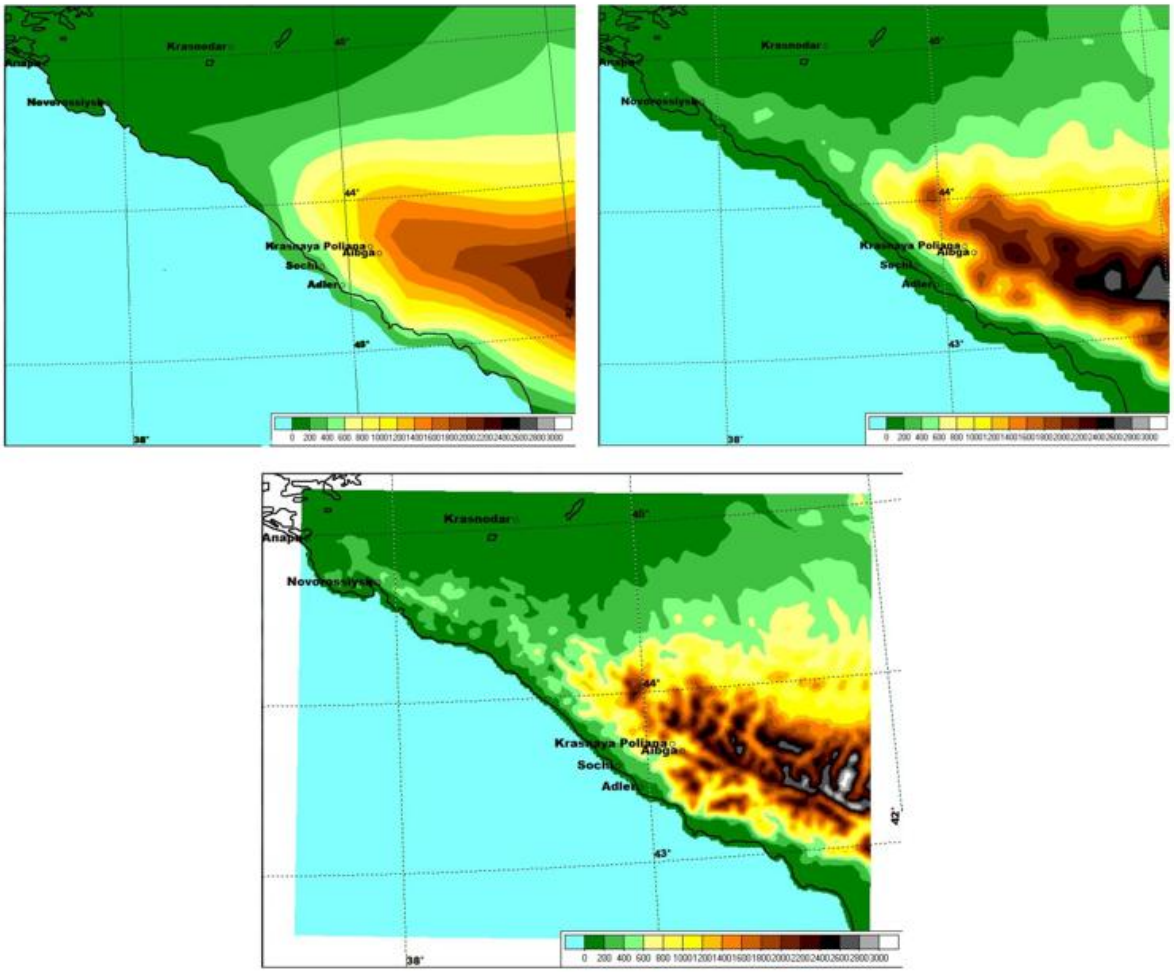

Figure 27: Model orography (in m) for ECMWF-EPS ($\Delta x = 31\ km$, top-left panel), COSMO-S14-EPS ($\Delta x = 7\ km$, top-right panel) and COSMO-RU2-EPS ($\Delta x = 2.2\ km$, bottom panel) in the Olympic region

COSMO-S14-EPS generated a set of standard probabilistic products, including probability of surpassing a threshold, ensemble mean and ensemble standard deviation for several surface and upper-air variables. These products were delivered in real time to the Hydrometcenter of Russia (Roshydromet), further disseminated to Sochi forecasters and presented at the FROST-2014 Web-site (http://frost2014.meteoinfo.ru, authorization required)). In addition to this, all forecast members for a specially defined area were transferred to Roshydromet where the epsgrams for predetermined points were prepared (see http://frost2014.meteoinfo.ru/forecast/arpa-new). Generation of different types of non-graphical products made use of Fieldextra, the official COSMO post-processing software (for information about Fieldextra, please refer to http://www.cosmo-model.org). The graphical products were prepared using the GRADS package.

In addition to the ensemble products, initial and hourly-boundary conditions (up to t+48h) were provided to Roshydromet for the experimentation with the convection-resolving ensem-

ble COSMO-Ru2-EPS (see below). Some examples of COSMO-S14-EPS products provided to Sochi forecasters during the Olympics are presented in figs.28 and 29. (Note that initially the system was named COSMO-FROST-EPS and this title was kept in the operational plots to avoid confusion).

In addition to the ensemble products, initial and hourly-boundary conditions (up to t+48h) were provided to Roshydromet for the experimentation with the convection-resolving ensemble COSMO-Ru2-EPS.

First it was not planned to use COSMO-Ru2-EPS for the meteorological support of the Olympics. However, the analysis of COSMO-Ru2-EPS skill during the winter of 2012/13 demonstrated the usefulness of the system and confirmed that the high resolution enables more detailed information (without loss of quality) to be achieved about the future state of the atmosphere. Thus it was decided to run COSMO-Ru2-EPS operationally in winter-spring 2014 and disseminate the prognostic results to the Olympic forecasters. COSMO-Ru2-EPS ensemble meteograms and plume diagrams were regularly posted at the FROST-2014 site and refreshed twice a day. A 2m temperature was corrected for the difference between the heights of model gridpoints and the real heights of the stations using the prognostic temperature lapse rate (see the description of CORSO task 2 for more details).

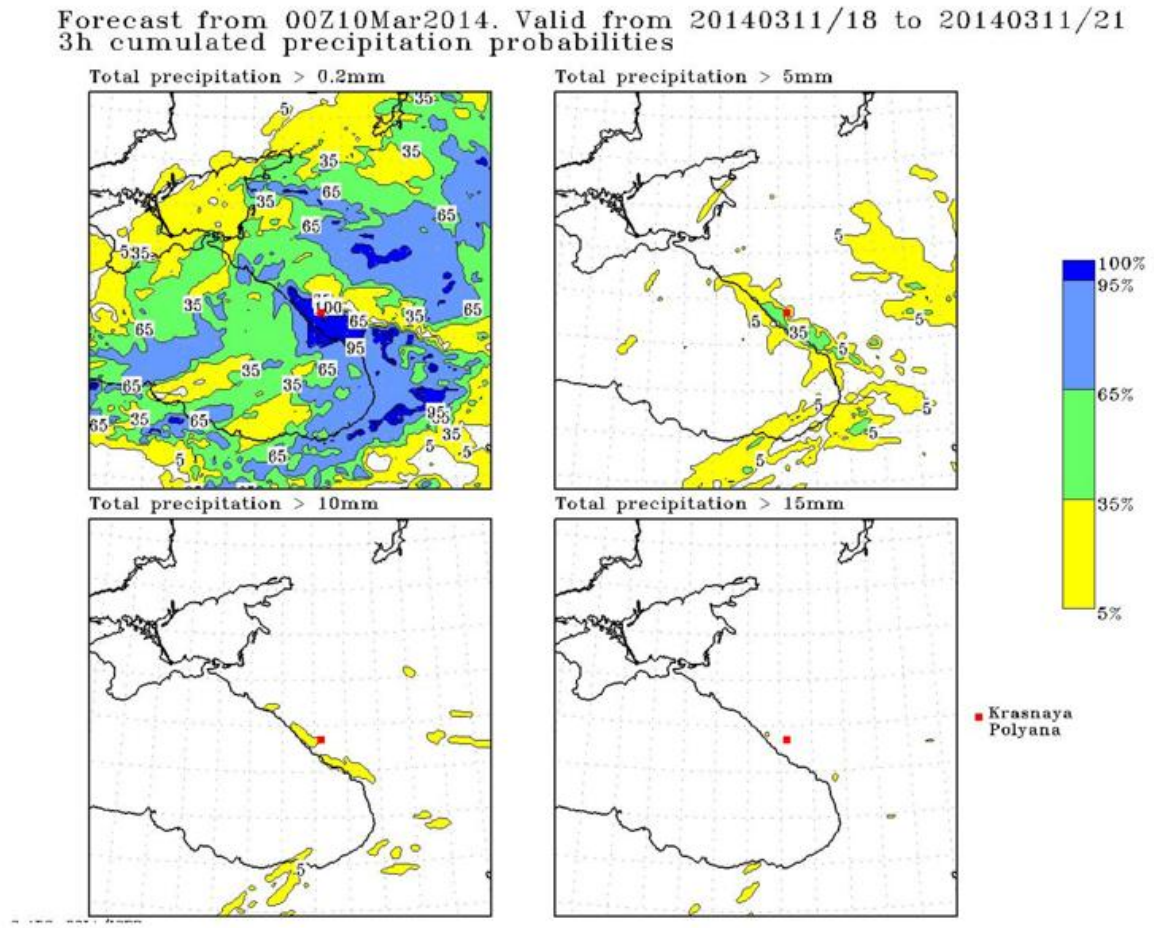

Figure 28: An example of COSMO-S14-EPS products operationally provided to the Olympic forecasters: probabilities of the events "3-h cumulated precipitation is more than 0.2 (upper left panel), 5 (upper right panel), 10 (lower left panel), and 15 mm (lower right panel)". COSMO-S14-EPS 45-h forecast starting from 10 March 2014, 00 UTC. A red square indicates the location of Krasnaya Polyana

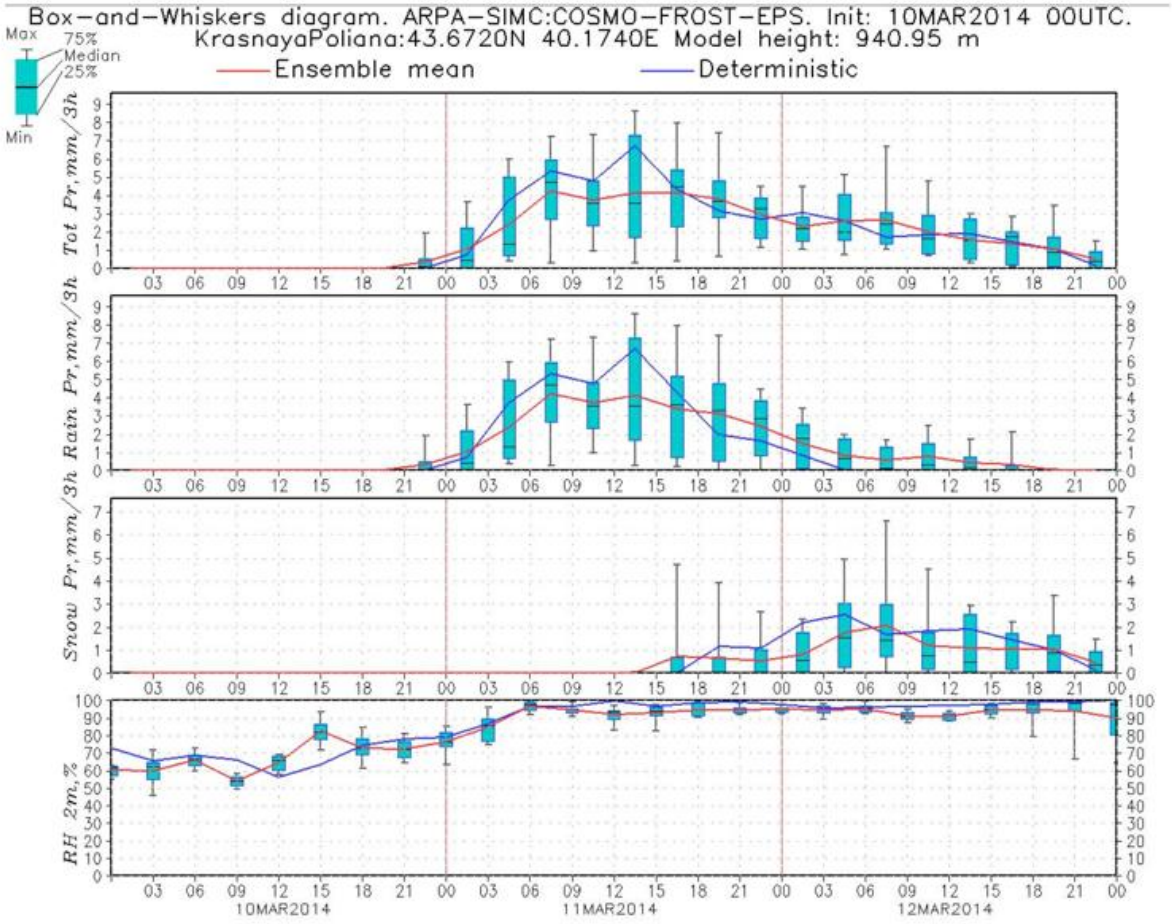

Figure 29: An example of COSMO-S14-EPS products operationally provided to the Olympic forecasters: the ensemble meteograms for total precipitation, rain, snow, and 2-m relative humidity for the Krasnaya Polyana station

6.4 Skill of ensemble forecasts *(E. Astakhova, A. Bundel, A. Muravev)*

The skill of the ensemble systems developed was analyzed step by step in several ways. First, the skill of COSMO-S14-EPS was compared to that of the driving ECMWF-EPS system and it was demonstrated that the mesoscale EPS outperforms the global system. Then several case studies with mesoscale EPSs of both resolutions were made showing the correct representation of near-surface temperature and precipitation patterns including the precipitation phase. Finally, probabilistic verification scores were calculated for month or longer periods. The details are given hereafter.

6.4.1 Verification of COSMO-S14-EPS compared to ECMWF-EPS

The skill of the mesoscale ensemble COSMO-S14-EPS was assessed over the period JanuaryMarch 2012 and compared to that of ECMWF EPS. For both systems, the probabilistic prediction of 12hour accumulated precipitation exceeding a number of thresholds for several forecast ranges was considered. Only forecasts starting at 12 UTC were examined.

As for observations, it was decided to use the data obtained from the SYNOP reports available on the Global Telecommunication System (GTS), since this was recognized to be a

homogeneous and stable dataset throughout the verification period. In order to quantify the skill of the system over complex topography, the verification was performed over the domain 40N50N, 35E45E. Within this domain, a xed list of 60 SYNOP stations was considered and the relative reports in terms of total precipitation were used to evaluate the COSMOS14EPS and ECMWF-EPS skill.

As for the comparison of model forecasts against SYNOP reports, the gridpoint closest to the observation was selected. Little sensitivity to the results was found when, instead of the nearest gridpoint, a bi-linear interpolation using the 4 nearest points to the station location, was used to generate the model forecasts. Therefore, the results shown hereafter will be relative only to the nearest gridpoint method. The performance of both systems was examined for 6 different thresholds: 1, 5, 10, 15, 25, and 50 mm/12 h.

The following probabilistic scores were computed over the verication period: the Brier Skill Score (BSS), the Ranked Probability Skill Score (RPSS), the Relative Operating Characteristic Curve (ROC) area and the Percentage of Outliers (OUTL). For a description of these scores, the reader is referred to Wilks (1995) and to Marsigli et al. (2008). The main features of the verification exercise are summarized in Table 8.

Table 8: Main features of the verification configuration

variable	12hour accumulated precipitation (18-06, 06-18 UTC)
period	from 1 January to 31 March 2012
region	40-50N, 35E-45E
method	nearest grid-point
observations	SYNOP reports
fcst ranges (h)	6-18, 18-30, 30-42, 42-54, 54-66
thresholds	1, 5, 10, 15, 25, 50 mm/12h
scores	ROC area, BSS, RPSS, OUTL

The skill of the two systems in terms of prediction of 12hour accumulated precipitation is summarized in Fig.30, where the Ranked Probability Skill Score (RPSS) is plotted against the forecast range for both COSMOS14EPS and ECMWF EPS. It can be noticed that COSMO-S14EPS has higher RPSS for all forecast ranges. The difference between the two systems is consistent throughout the full forecast range, with a larger gap for the first day of integration. This implies that, despite the larger ensemble size of ECMWF EPS, the higher resolution of COSMO-S14EPS contributes to provide more accurate probabilistic predictions of precipitation.

If the attention is now focused on the performance of both systems for a specic event, most of the above comments still hold. As an example, Fig.31 shows the scores of COSMO-S14-EPS and ECMWF EPS in terms of ROC area for the event "12hour accumulated precipitation exceeding 10 mm". COSMO-S14EPS outperforms ECMWF EPS for all forecast ranges, although both systems exhibit a semidiurnal cycle in the score and tend to provide better guidance for "night-time" precipitation, that is occurring between 18UTC and 6UTC (and corresponding to the ranges 6–18 h, 30–42 h and 54–66 h). As for COSMO, this is linked with a too rapid onset of convection, as pointed out by Oberto and Turco (2008) for runs of COSMO in "deterministic mode".

Finally, the attention is focused on the ability of COSMOS14EPS to reduce the number of outliers with respect to ECMWF EPS, thanks to the higher resolution and the better description of mesoscale and orographicrelated processes. Fig.32 shows that COSMOS14EPS has

fewer outliers than the global ensemble, with a clear added value of the mesoscale ensemble for short forecast ranges.

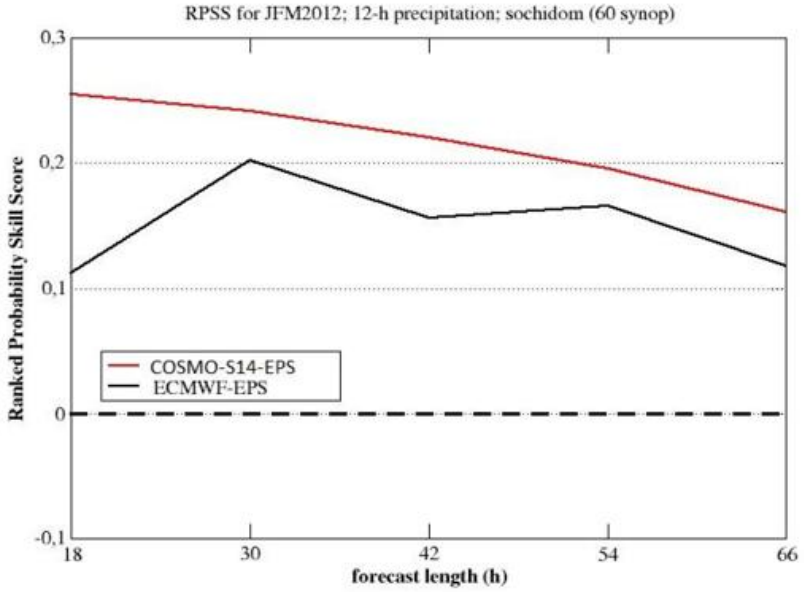

Figure 30: Ranked Probability Skill Score as a function of forecast length for COSMO-S14-EPS

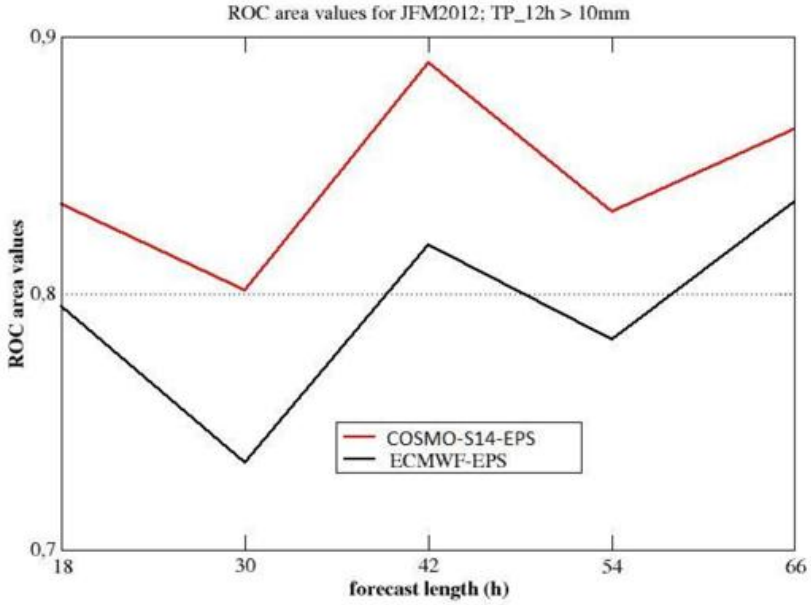

Figure 31: ROC area values for COSMO-S14-EPS (red) and ECMWF EPS (black) relative to the event "precipitation exceeding 10mm in 12 hours" for the forecast ranges of Table 8. Both scores are calculated over the 3-month period from January to March 2012

According to Talagrand et al. (1999), the value of outliers for a reliable ensemble of size N is given by $2/(N+1)$. These values should not be exceeded. The dashed lines of Fig.32 indicate these limits for both COSMO-S14-EPS (red, 18 %) and ECMWF EPS (black, 4 %). Therefore, it looks as if COSMO-S14-EPS approaches the theoretical value to larger extent than ECMWF EPS, which seems to have too many outliers in the short range.

Generally, it was concluded that the mesoscale COSMO-S14-EPS system, based on a relocation of COSMO-LEPS, provided added value with respect to the driving global ensemble

ECMWF EPS as for the probabilistic prediction of precipitation events.

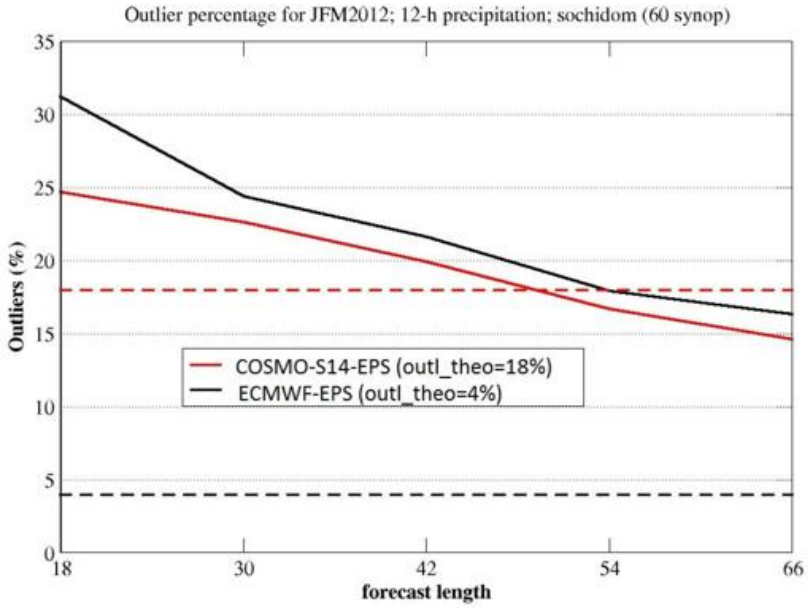

Figure 32: Percentage of Outliers for COSMO-S14-EPS (red) and ECMWF EPS (black), calculated over the 3-month period from January to March 2012. The red (black) dashed line indicates the theoretical limit of outliers for COSMO-S14-EPS (ECMWF EPS)

6.4.2 Case studies

The performance of COSMO-S14-EPS and COSMO-Ru2-EPS was analyzed in detail for several cases.

Hereafter, the attention is focused on two highimpact weather events:

- heavy precipitation event on 13 January 2013 with 21 mm of rain during the day on the coast (Sochi/Adler) and 33 mm of snow-water equivalent in the mountains (Krasnaya Polyana);
- Foehn event on 14-15 February 2013 with a sudden 14-degree warming.

Heavy precipitation event

Heavy precipitation was observed on the 13th of January 2013 in the Sochi region with mainly rain in the coastal cluster and snow in the mountain cluster. The corresponding SYNOP data are presented in Table 9.

Figure 33 reports the performance of COSMO-S14-EPS in terms of probabilistic prediction for two variables: probability of 12hourly accumulated rainfall exceeding 20 mm (left panel) and probability of 12hourly simulated snowfall exceeding 15 mm of equivalent water (right panel).

The ensemble runs start at 00 UTC of 11 January 2013 and the attention is focused on the 48-60 hour forecast range: it can be noticed that COSMO-S14-EPS provides quite accurate forecasts giving large probability of heavy precipitation. Despite the steepness of the orography and the length of the forecast range, the system is able to distinguish between the area more likely affected by rainfall (along the coast, left panel) and the region mainly affected

by snowfall (in the mountains, right panel). This is an interesting result, as the knowledge of the possibility of this weather event, with an advance of about 2 days, gives organizers the chance of taking counter measures and relieving the weather-related problems.

Table 9: 12-h accumulated precipitation observed in the Sochi region on January 11-14, 2013

Period (DDMM/HH UTC)	12-h prec, mm Sochi	12-h prec, mm Krasnaya Polyana
11.01/03 - 11.01/15	4	–
11.01/15 - 12.01/03	0	0
12.01/03 - 12.01/15	0	0.9
12.01/15 - 13.01/03	5	10
13.01/03 - 13.01/15	21	33
13.01/15 - 14.01/03	10	9
14.01/03 - 14.01/15	0	–

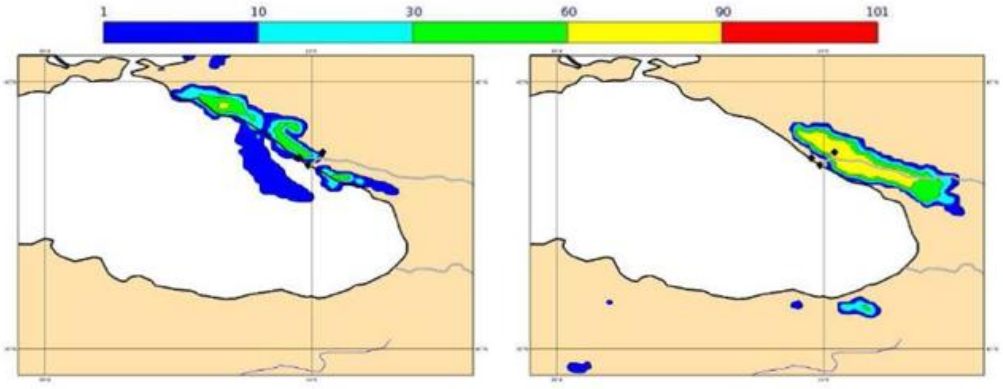

Figure 33: COSMO-S14-EPS run starting at 00UTC of 11 January 2013 (48-60 hour forecast range): probability of 12-hour rainfall exceeding 20 mm (left panel) and of 12-hour snowfall exceeding 15 mm of water equivalent (right panel). The black squares on the coast denote Sochi and Adler; the black square inland denotes Krasnaya Polyana

Let us compare the COSMO-S14-EPS forecasts to COSMO-Ru2-EPS ones. The attention is fixed on the ability of both systems to predict the possible occurrence of heavy snowfall inland. More precisely, we consider the predictability of the following event: "probability of 12h snowfall exceeding 15 mm of equivalent water". In Fig.34, the left column (right column) panels report the performance of COSMO-S14-EPS (COSMO-Ru2-EPS) for the forecast ranges 36-48 hour and 24-36 hour (top-row and bottom-row panels, respectively). It can be noticed that the signal by COSMO-S14-EPS forecasts (left column) is consistent for the different prediction ranges, with a probability of snowfall above 90 % in the area actually affected by the weather event. It is also worth pointing out that no snowfall is predicted along the coast at any forecast range (probabilities below 1 %), consistently with observations.

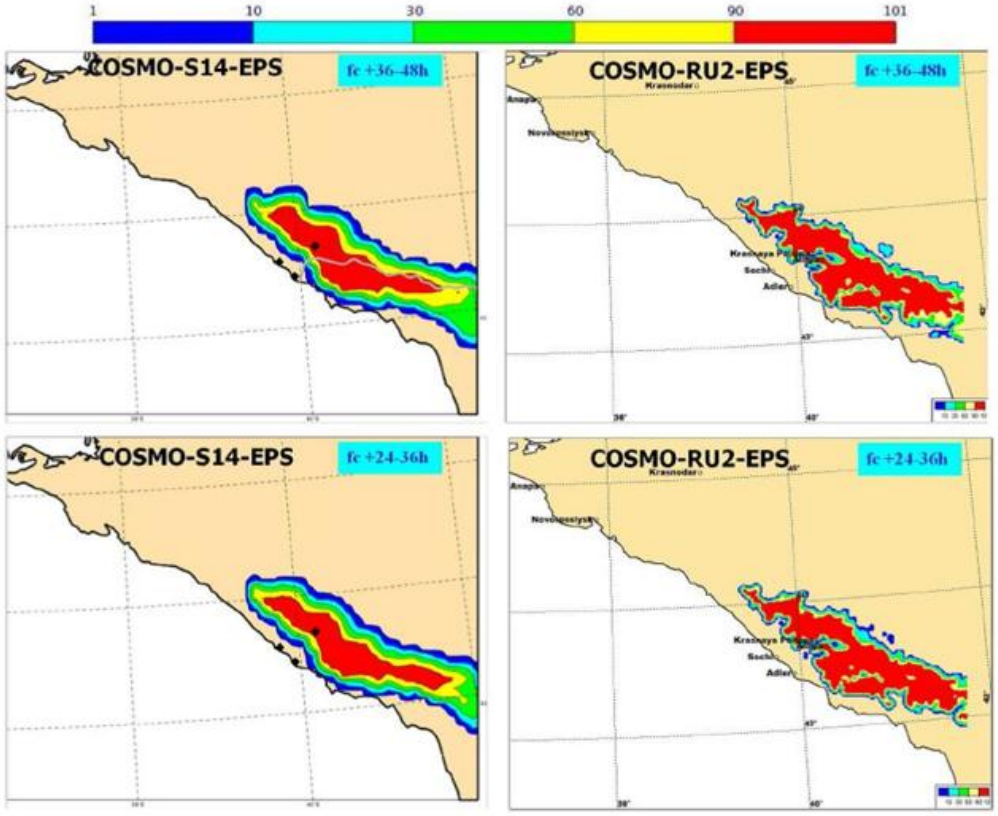

Figure 34: Probability of 12-hour snowfall exceeding 15 mm of equivalent water: COSMO-S14-EPS runs starting at 12 UTC of 11 January (top-left panel, t+36-48h) and at 00 UTC of 12 January (bottom-left panel, t+24-36h) and COSMO-Ru2-EPS runs starting at 12 UTC of 11 January (top-right panel, t+36-48h) and at 00 UTC of 12 January (bottom-right panel, t+24-36h). All forecasts verify at 12 UTC of 13 January 2013. As in Fig.33, the black squares in the left panels denote Sochi, Adler and Krasnaya Polyana.

A straight comparison of COSMO-S14-EPS against COSMO-Ru2-EPS forecasts indicates that the higher resolution ensemble (right column panels of Fig.34) provides more detailed information in terms of location of the regions affected or not by heavy snowfall. In the convective-resolving ensemble, the extent of the coastal region not interested by snowfall turns out to be more evident. At the same time, the higher-resolution ensemble is more confident in giving larger probabilities of snow in the mountainous region. Since more and more spatial and time details are usually required to the forecasts for shorter time ranges, COSMO-Ru2-EPS seems to have, on the basis of this case study, the potential to provide a larger amount of information to local forecasters and event organizers.

Foehn event

Sudden temperature changes in the Olympic areas are considered highimpact weather events possibly affecting outdoor competitions. Therefore, the prediction of this type of event is an important benchmark for the usefulness of ensemble prediction systems. Note that the event considered below was regarded as hardly predictable by local forecasters.

Table 10 shows the evolution of surface temperature in Krasnaya Polyana from 13 to 16 February 2013 (SYNOP data). Linked to the onset of Foehn winds, a marked increase took place between 13 and 15 February, affecting mainly daytime temperatures. On 14 and 15 February, the observed peaks amounted to 13 and 16.2° C, respectively. Ten-minute

observations of the automatic meteorological station located at the same point demonstrate even higher values (see Fig.35).

Table 10: Near-surface temperature (SYNOP T2m data) for Krasnaya Polyana during the Foehn event in February 2013

12.02/00	7.1
12.02/06	5.5
12.02/12	6.3
12.02/18	5.1
13.02/00	4.2
13.02/06	4.6
13.02/12	11.3
13.02/18	3.9
14.02/00	1
14.02/06	3.2
14.02/12	13
14.02/18	6.2
15.02/00	2.4
15.02/06	3.7
15.02/12	16.2
15.02/18	9.7
16.02/00	5.4

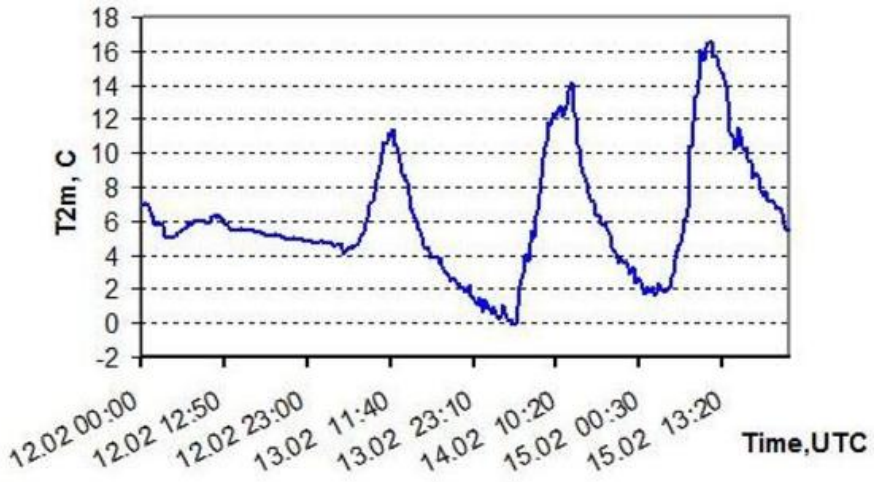

Figure 35: Behavior of 2-metre temperature in Krasnaya Polyana (10-min data of the automatic meteorological station)

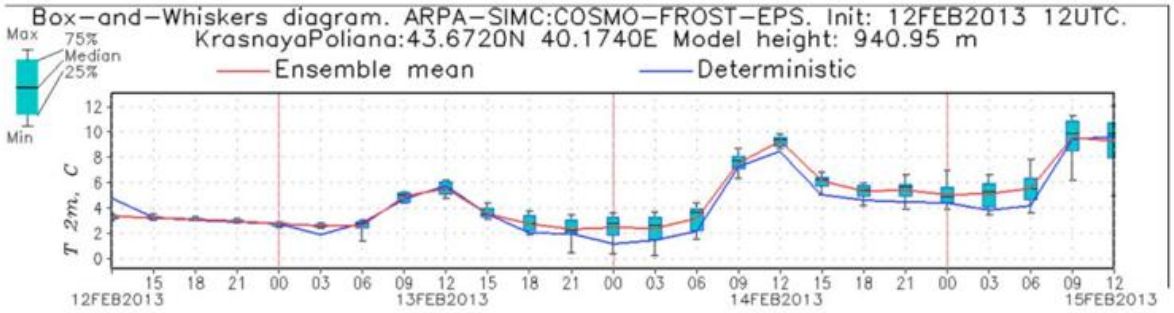
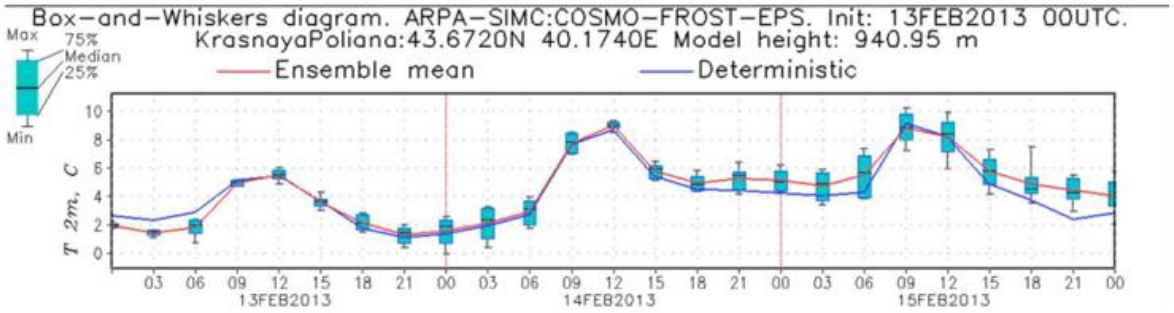
As for the ability of COSMO-S14-EPS to predict this temperature increase, Fig.36 reports the meteograms computed over the station point of Krasnaya Polyana, in terms of 2-metre temperature, for different starting times. The top panel of the figure indicates that, already at the 72-hour range (forecasts starting at 12UTC of 12 February), the COSMO-S14-EPS members predict the temperature increase of 14 and 15 February, with peaks close to, or above, 10° C. In this panel, as well as in the others, some discrepancies between observed and predicted temperature are evident, but the differences are partly related to the model

orography, which locate Krasnaya Polyana at about 941 m, instead of 564 m.



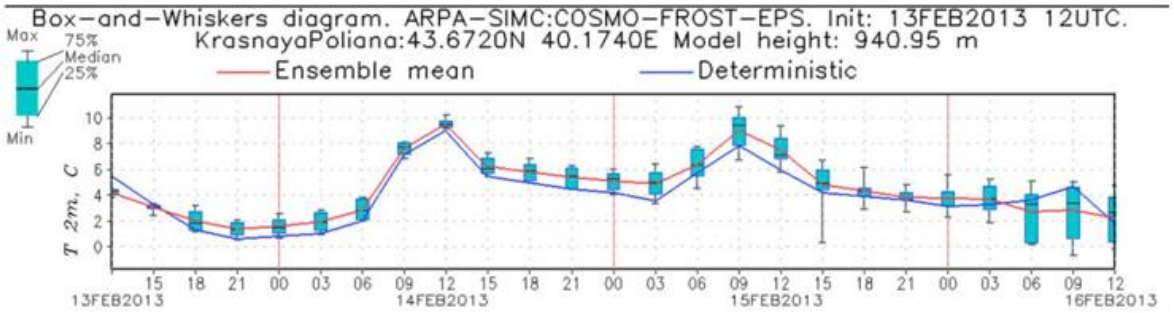
According to COSMO-Ru2-EPS orography, the model gridpoint nearest to Krasnaya Polyana lies at about 734 m above the sea level. This enables the higher-resolution system to describe the temperature peak on February 14 better giving about 12° C (see Fig.36e). However, similarly to COSMO-S14-EPS it fails to give strong enough increase in 2m temperature on February 15. Note that the ECMWF deterministic forecast presented in blue in the epsgrams shows even lower maximum on this date thus indicating that the mistake is possibly related to the weakness of the driving global system in this case.

Fig.37 demonstrates the ability of COSMO-Ru2-EPS to give reasonable probability fields. The probabilities of the event "3-h maximum of 2m temperature exceeds 5° C" are presented in the right panels and the temperature variations at two mountain stations, Aibga (upper curve) and Krasnaya Polyana (lower curve) are shown in the left panels. The vertical red bars in the left figures show two 3-h periods for which the probability fields are given on the right. The COSMO-Ru2-EPS forecast starts at 00 UTC on February 13, 2013 and the probability fields are valid for two 3-h intervals, 03-06 and 09-12 UTC on February 14. The figure obviously demonstrates the coincidence of the periods when 2m temperatures really exceeded 5° C in Krasnaya Polyana and the probability of this event was predicted as high. The temperature was less than 5° C during the entire period 12-16 February in Aibga. Note that the probabilities there are close to zero all the time considered.



The ensemble forecasts were analyzed in detail for many other cases, mainly characterized by heavy precipitation, sudden temperature changes, or strong wind gusts. As a result of such case studies it was concluded that both COSMO mesoscale ensemble prediction systems (COSMO-S14-EPS and COSMO-Ru2-EPS) were good in simulating 2m temperature and precipitation (precipitation phase was predicted correctly as well) and that much more details can be found in COSMO-Ru2-EPS prognostic charts.

6.4.3 Verification of COSMO-S14-EPS and COSMO-Ru2-EPS for the Olympic and pre-Olympic periods



In this section, some verification results are presented; the skills of COSMO-S14-EPS and COSMO-Ru2-EPS are assessed over the period January-February 2013. For both systems, we considered the probabilistic prediction of 2-metre temperature exceeding a number of thresholds for several forecast ranges. As for observations, it was decided to use the data obtained from the SYNOP reports available on the Global Telecommunication System (GTS) as well as from all non-GTS stations in the region.

Figure 36: Point meteograms in terms of 2-metre temperature over Krasnaya Polyana based on COSMO-S14-EPS and starting at: (a) 12 UTC of 12 February, (b) 00 UTC of 13 February, (c) 12 UTC of 13 February and (d) 00 UTC of 14 February; and based on COSMO-Ru2-EPS and starting at 12 UTC of 13 February (e)

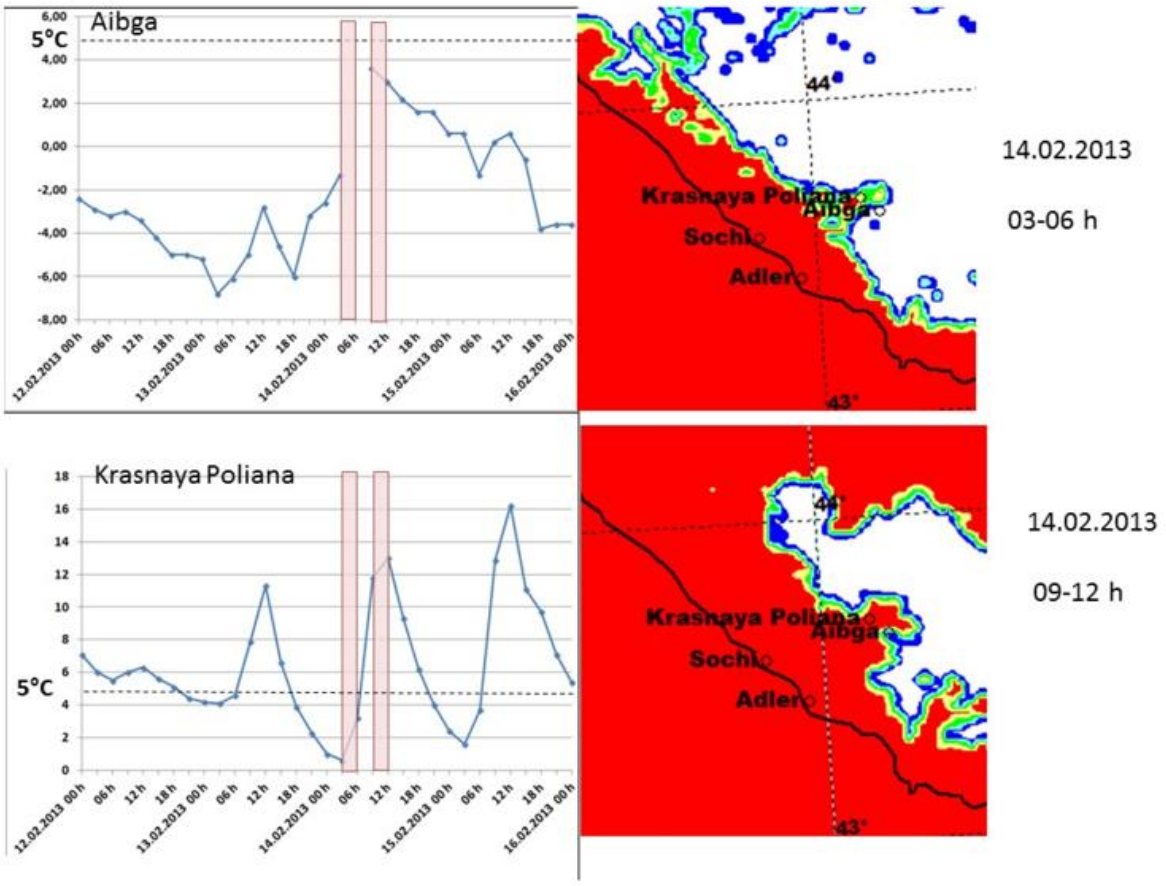

Figure 37: The probabilities of the event "3-h maximum of 2m temperature exceeds 50° C" (right panels) as predicted by COSMO-Ru2-EPS for two 3-h periods on February 14, 2013 and the observed temperature variations (left panels) at two mountain stations, Aibga (upper curve) and Krasnaya Polyana (lower curve). Red: 90-100 %, yellow: 60-90 %, green: 30-60 %, light blue: 10-30 %; blue: 0.1-10 %. See text for details

Table 11: Main features of the verification configuration

variable	2-metre temperature
starting time	12 UTC
period	from 1 January to 28 February 2013
region	42.5-45 N, 37.5-41.5 E
method	nearest 3D optimized grid-point; observations
observations	SYNOP reports + local stations (69 in total); fcst
fcst ranges (h)	from fc+3h to fc+72h every 3h
thresholds	-5, 0, +5, +10 ° C
scores	ROC area, BSS

This enabled the possibility to assess the performance of the systems over a relatively dense observation dataset (69 stations), since the verification domain was restricted to an area centered over the Olympic venue (42.5-45N, 37.5-41.5E). As for the comparison of model forecasts against observations, we selected the gridpoint closest (in 3D) to the observation. The performance of both systems was examined for 4 different thresholds: -5, 0, +5 and 10 ° C. Verification was performed using COSMO software VERSUS. The following probabilistic

scores were computed: the Brier Skill Score (BSS) and the Relative Operating Characteristic Curve (ROC) area. For a description of these scores, the reader is referred to Wilks (1995). The main features of the verification exercise are also summarized in Table 11.

The skill of two systems in terms of probabilistic prediction of 2-metre temperature is summarized in Fig.38, where the values of the ROC area are plotted against the forecast range for 4 different weather events: temperature below -5° C (top-left), above 0° C (top- right), above +5° C (bottom-left) and above +10° C (bottom-right). It can be noticed that the ROC area values are well above 0.8 for three out of the four thresholds, indicating that both COSMO-S14-EPS and COSMO-Ru2-EPS manage to discriminate these events. The performance of two systems is quite similar, with a slight predominance of COSMO-Ru2-EPS that has higher scores for most of the thresholds/forecast ranges. Worse scores are obtained by both systems for the highest threshold (bottom-right panel), where COSMO-S14-EPS outperforms COSMO-Ru2-EPS. It is worth pointing out that this is the rarest event with few observations; therefore, the statistical significance of this result needs to be confirmed by a more detailed investigation over a longer verification period.

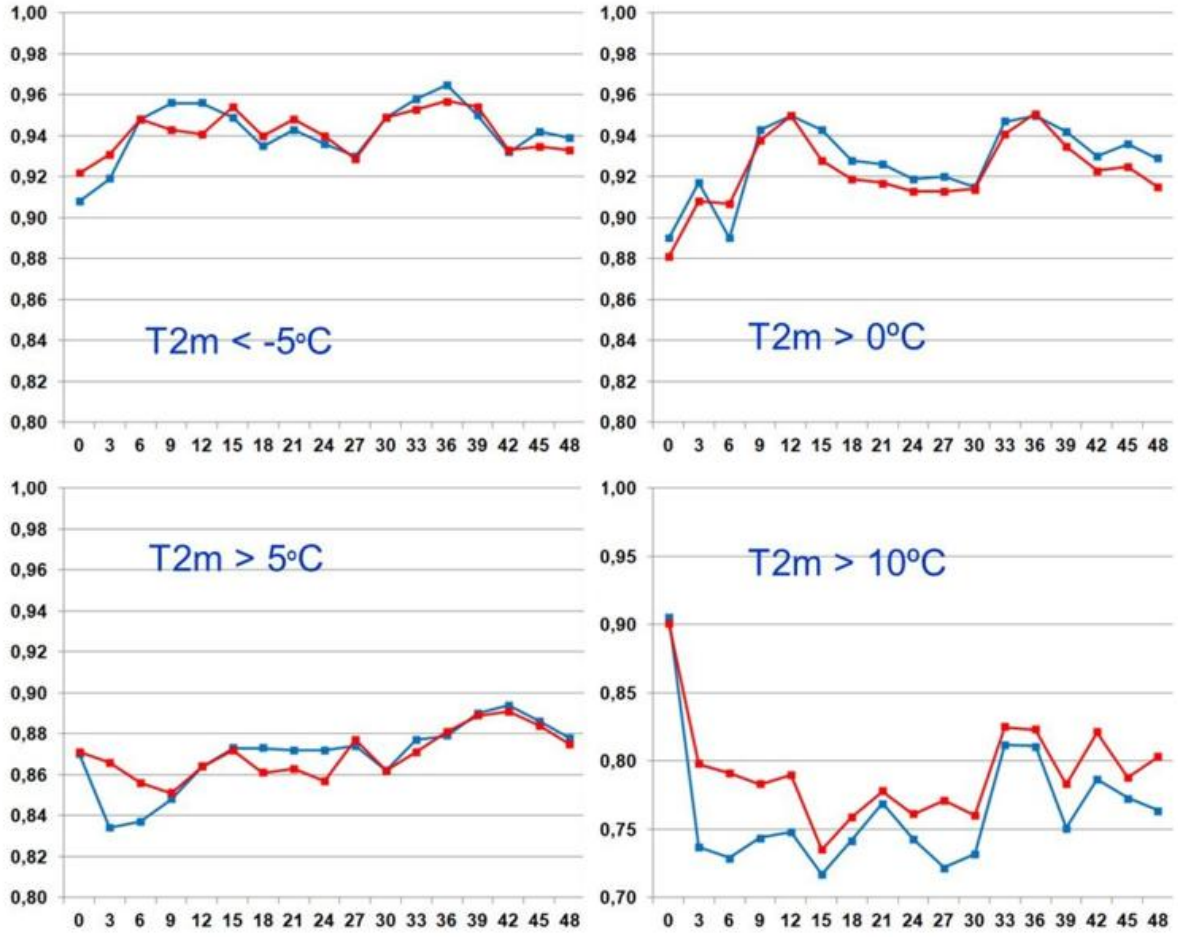

Figure 38: ROC area values as a function of forecast range for four different weather events: 2-metre temperature below -5° C (top-left panel), above 0° C (top right), above +5° C (bottom left) and above +10° C (bottom-right with different vertical scales). The scores are calculated over the period January-February 2013. Red (blue) lines refer to COSMO-S14-EPS (COSMO-Ru2-EPS)

Similar results are obtained when the attention is focused on the Brier Skill Score (BSS),

shown in Fig.39. Also with this score, the satisfactory performance of both systems is confirmed: the BSS is always positive for COSMO-S14-EPS and COSMO-Ru2-EPS, indicating a benefit of both systems with respect to climatology as regards the probabilistic prediction of 2-metre temperature for the thresholds of Table 11. Similarly to Fig.38, it can be noticed that COSMO-Ru2-EPS usually outperforms the lower-resolution ensemble, although the difference is not very marked. As for the +10° C threshold (bottom-left panel of Fig.38), the skill of the two ensembles is almost identical, with slightly higher scores for COSMO-S14-EPS.

Precipitation verification for January-February 2014 demonstrated rather high skill of both systems but only slight differences in ROCA and BSS (not shown).

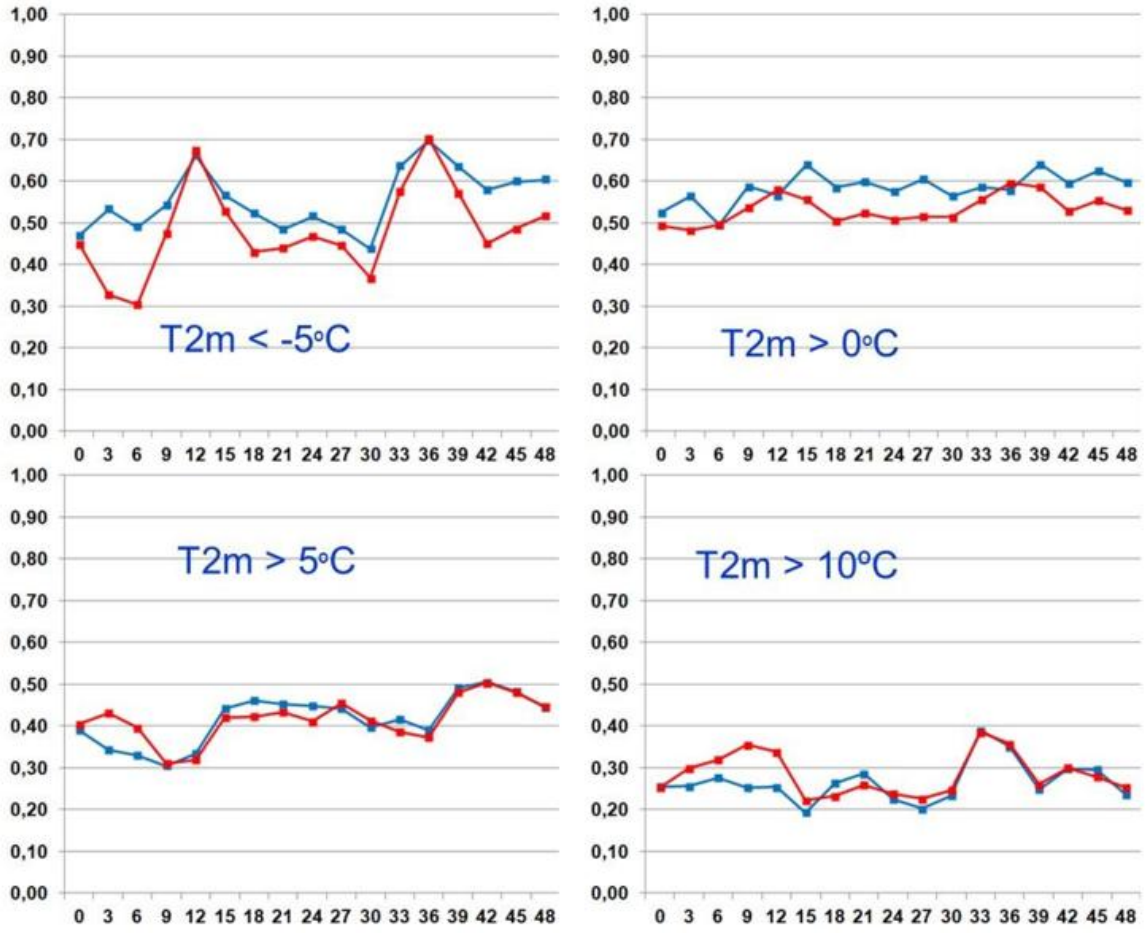

Figure 39: The same as Fig.38 but for the Brier Skill Score. The vertical scale is the same in all panels.

It is important to note that the scores strongly depend on the set of stations applied for verification. Unfortunately, the observation stations are very irregularly distributed over the Sochi region with their highest concentration in the Olympics mountain cluster. In this area, a model gridpoint is often matched (found to be the nearest) to several observation stations. The number of such gridpoints varies for different model resolutions. Additional difficulties are introduced by deviations of the model gridpoint heights from the real heights of meteorological stations. Figures 40a-f demonstrate the ensemble mean 2m temperature at 6 stations of the mountain cluster predicted by COSMO-S14-EPS and COSMO-Ru2-EPS starting from 00UTC February 18, 2014 analysis. The higher-resolution system obviously

outperforms. In Fig.40g-h the quantile-quantile plots are presented for 24-h forecasts of two systems from January 15 to March 15, 2014 and the corresponding observations at RKHU7 station. The COSMO-Ru2-EPS forecasts are clearly distributed more like observations for the entire two-month period (the blue line in Fig.40g almost coincides with the forecast-observation diagonal line). However, probably the advantage of high-resolution system mostly comes from a better gridpoint location: the RKHU7 station is 980 m above the sea level while the height of the nearest gridpoint of the COSMO model with resolutions of 7 and 2.2 km is 1460 and 941 m, respectively. This confirms the analysis of ROCA behavior in Fig.38. The scores presented there were calculated involving all stations in the Sochi region, located both in the coastal and mountain clusters. Though the COSMO-Ru2-EPS curves mainly lie higher thus indicating better forecast skill, the benefits from high-resolution are not great. Note that ROCA is not bias-sensitive.

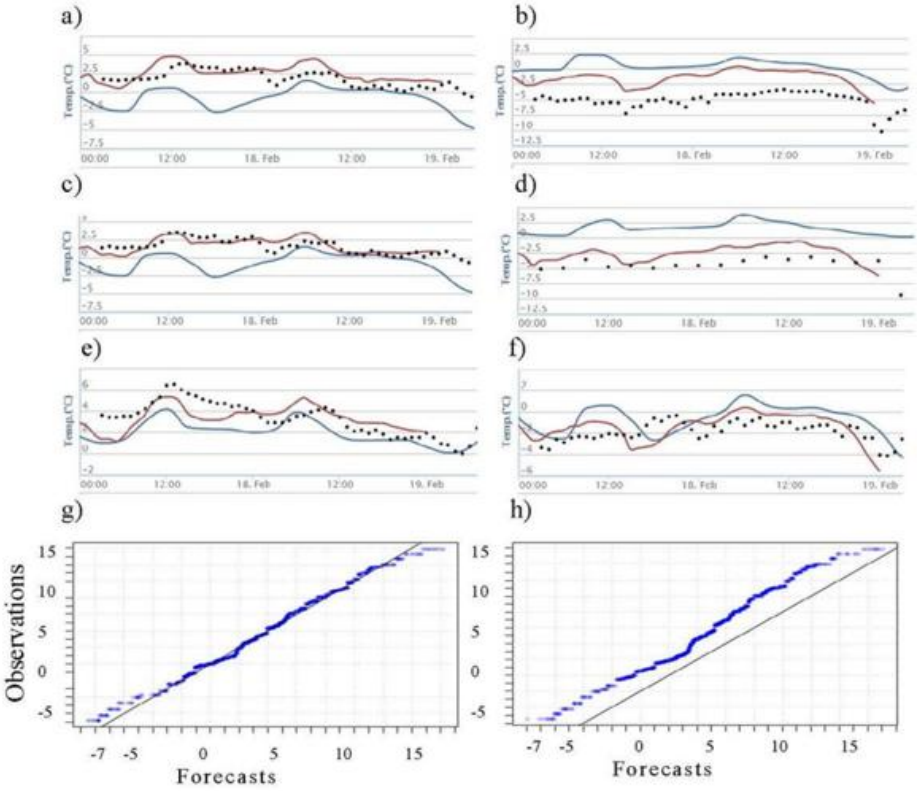

Figure 40: Ensemble mean 2-m temperature predicted by COSMO-Ru2-EPS (in red) and COSMO-S14-EPS (in blue) and observed (black dotted line) at mountain stations RKHU-7 (980 m) (a), RKHU-1 (2320 m) (b), Snowboard-1025 (1027 m) (c), Aibga (2225 m) (d), Sledge-700 (701 m) (e), Gornaya Karusel-1500 (1434 m) (f) using the analysis on 18 February 2014, 00 UTC; quantile-quantile plots for 24-h forecasts of COSMO-Ru2-EPS (g) and COSMO-S14-EPS (h) and observations at RKHU-7 station for the period from January 15 to March 15, 2014

On the whole, both EPS systems demonstrated good skill for 2m temperature, precipitation and wind. Higher-resolution system was slightly more skilful for temperature, but worse for wind. The verification exercises demonstrated the necessity of observations at high temporal and spatial resolution and application of spatial verification methods.

6.5 Conclusions

Two limited-area ensemble prediction systems, based on COSMO-model and referred to as COSMO-S14-EPS (convection-parameterized, 7-km resolution) and COSMO-Ru2-EPS (convection-permitting, 2.2 km resolution), were implemented and run on operational/quasi-operational basis during the pre-Olympic and Olympic seasons. The ensemble systems provided a good support to Sochi forecasters and their probabilistic products were highly appreciated.

The ensemble forecasts were verified by assessing the probabilistic skill of both systems in terms of 2-metre temperature and precipitation during the Olympic and pre-Olympic season (January- February 2013, 2014) over a region centered around Sochi.

Both COSMO-S14-EPS and COSMO-Ru2-EPS turned out to have an overall good performance with ability to discriminate different weather events. The added value of the higher resolution in COSMO-Ru2-EPS was confirmed for 2m temperature by the better probabilistic scores obtained by this system. Verification activity should be continued, including application of new approaches and observations, comparison with other FROST-2014 ensembles.

The forecasts and meteograms prepared during the Olympics were saved in a special archive along with the results of other ensemble systems that participated in FROST-2014 project. The archived information on forecasts, initial and boundary conditions for the higher-resolution system, and observations are valuable and new experiments can be performed within the Sochi testbed.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction

The PP CORSO (Consolidation of Operation and Research results for the Sochi Olympics) dedicated to development of high-resolution NWP meteosupport of Sochi2014 Olympics held in 2011-2014. PP CORSO was adopted with a goal to enhance and demonstrate the capabilities of COSMO-based systems of NWP in winter conditions for mountainous terrain and to assess the effect of practical use of this information during Sochi-2014 Olympic Games. There were 3 directions of activities concerning the development and implementation of:

a) high-resolution forecasting system (Task1),

b) the means of practical forecasting and down-scaling post-processing (Task2),

c) mesoscale EPS (Task3).

PP CORSO obtained the successful results. The main result of FDP part of PP CORSO was the implementation of high quality NWP system, which the forecasters of Organizing Committee and of sport venues have used as a basic. The COSMO experience and its possibilities were concentrated for obtain the renovated NWP system for SOCHI-2014 region with complex geographical terrain. Due to the cooperation of FDP and RDP activities of PP CORSO, the new level of modeling and of interpretation of results were obtained (The new COSMO-version with step 1.1km, the some down-scaling postprocessing algorithms, knowledge of feed-back from forecasters, the implementation of High-resolution EPS-system 2.2. km for mountain area). Some aspects obtained results could be further researched and could be useful for implementation and investigations in whole COSMO community. The obtained experience, accumulated data of measurements and of forecasts and new numeric experiments permit to adapt & develop and test of the proposed algorithms and technical solutions. The new PT CORSO-After (CORSO-A) should meet these developed challenges for implementation in COSMO technologies and investigations.

1.1 The goal of PT

To prepare the new COSMO tools and practical instructions for be available for COSMO-community related to:

- the implementation of versions COSMO-1km (SubTask1 The guidance of the optimal domain's size selection for 1.1 km resolution of nested COSMO models for the regions with complex mountain relief, TL G.Rivin),
- the realization of down-scaling postprocessing tools for mountain area, (SubTask2, Development of algorithm of subgrid h-correction of T2m (due to the differences between models and real heights) based on COSMO- forecasts of vertical T-gradient , STL I.Rozinkina),
- the development of archive for development of convective-resolution EPS (SubTask3 Preparing of archives of 7 km and 2.2 km EPS forecasts for the Sochi- 2014 modeling area applicable for research aimed at improving COSMO EPS systems and available for community. Their compliance with FROST2014 archives, STL E.Astakhova, A.Montani),

- the preparing of instructions for forecasters for use the results of meso-scale deterministic and EPS results (SubTask4 Preparing of recommendations for forecasters The features of using and interpretation of the results of limited- area meso-scale modeling STL I.Rozinkina).

2 SubTasks, brief description

2.1 SubTask 1 The guidance of the optimal domain's size selection for 1.1 km resolution of nested COSMO models for the regions with complex mountain relief (STL G. Rivin)

2.1.1 Motivation

The development and implementation of COSMO1 were obtained as result of RDP part of PP CORSO. As addition the participants managed to organize the operational runs of COSMO1 for Sochi2014 area during the Olympics 2014, and the positive experience of use of COSMO 1 for Sochi area was gained. The modeling with grid step about 1 km is significantly more realistic for mountain area and as sequence permit to provide for forecasters the additional important products as, e.g. flows of wind in bottom level, that determines the weather in hills and valleys. During the CORSO PP were obtained results shown the strong dependence of the predicted precipitation amount and spatial distribution on the models domain size. This problem need the more attentive examination, because the runs of COSMO1 as part of nested technologies are very expensive in point of view of computing time. The computing resources and the technological requirements of providing forecast by a certain time determine the model run timing. On the other hand it exists the requirements for the quality of the forecasts.

2.1.2 Goal

To formulate and to prove the selection of models domain size for COSMO1 model runs for disseminate this experience for create the similar technologies for detailed calculations on mountain domains in condition of limited computing resources.

2.2 SubTask 2 Development of algorithm of subgrid h-correction of T2m (due to the differences between models and real heights) based on COSMO- forecasts of vertical T-gradient (STL I. Rozinkina)

2.2.1 Motivation

In framework of PP CORSO were realized some approaches for subgrid correction of T2m, as the direct forecasts from COSMO-model of T2m for mountain region were not convenient. There are some causes because it. One of principal causes of this fact for mountain area is the simple discrepancy of local real and averaged of grid cells height. As traditional, T2m can be corrected by use standard adiabatic gradient, but in Sochi2014 region the real temperature profiles can be significantly different including inversions. Because of the variability of the vertical temperature profile depending on a large-scale weather forecasts the implementation of KF or MOS in lot of cases is inefficiently because there are non systematic errors. The CORSO participants proposed the algorithm of correction of local

values of T2m for mountains based the COSMO- models forecasts of T-profile of bottoms levels (H-corection). The implementation of this algorithm in meteogram tables permit to obtain the more realistic T2m forecasts for points before the possible subsequent correction tools (KF or MOS), due to improve the limitations of parameterization schemes. This proposed algorithm can be disseminate in two direction of implementation: a) by modified technology of forming of meteograms by including into FieldExtra for calculate the fields of subgrid variations of T2m (for min and max real height of cells).

2.2.2 Goal

To realize the updated software of Fieldextra with including of calculations of subgrid values of T2m based the forecasts of vertical T gradient. To provide the software of 1-D correction of T2m forecasts based the forecasts of vertical T gradient (h-correction).

2.3 SubTask 3 Preparing of archives of 7 km and 2.2 km EPSs forecasts for the Sochi-2014 modelling area applicable for research aimed at improving COSMO EPS systems and available for community (TL E. Astakhova, A. Montani)

2.3.1 Motivation

The two ensemble prediction systems were developed within the PP CORSO: COSMO-S14-EPS with a 7-km resolution and COSMO-Ru2-EPS with a 2.2 km resolution. The results of both ensembles were provided to Sochi forecasters during the Olympics and proved to give a valuable support to them. COSMO-S14-EPS (S14 stands for Sochi-2014) is a relocation of COSMO-LEPS to the area of Olympic Games and was generated rather similarly to COSMO-LEPS but with some changes introduced because of computer-time constraints and the interest towards the short-range. Initial and boundary conditions for COSMO-S14-EPS were taken from ECMWF EPS. The initial ensemble size was reduced to 10 members selected by a clustering procedure (Montani et al., 2011). The lower boundary condition for all COSMO-S14-EPS members was taken from COSMO model run in hindcast mode (short-range forecast nested on ECMWF analyses). COSMO-S14-EPS ran on a regular basis since 19 December 2011 on ECMWF supercomputers. COSMO-S14-EPS generated a set of standard probabilistic products (including probability of surpassing a threshold, ensemble mean, ensemble standard deviation, and ensemble meteograms for several surface and upper-air variables) which were delivered to Sochi forecasters in operational mode. COSMO-Ru2-EPS is a convective-permitting ensemble, based on initial and boundary conditions provided by COSMO-S14-EPS. The system ran on Roshydromet computers. The first winter of its regular runs (2012-2013) and case studies (2011-2013) showed that COSMO-Ru2-EPS gave rather precise and detailed forecasts and therefore could be useful for Sochi forecasters. Following this conclusion, COSMO-Ru2-EPS operationally ran twice a day (00 and 12 UTC) since November 2013 and during the Olympics. In course of CORSO project, the output results of the two EPSs were archived on Roshydromet computers. In total, the results of nearly six months of runs of the COSMO EPSs (both 7 and 2.2 km) are available (November 2013-April 2014). These are forecasts for a very specific area, where mountains with very steep slopes are in close vicinity to the sea and where high-resolution forecasting of high-impact events is a real challenge. The available COSMO-EPS forecasts can be also considered as a part of the FROST2014 archive. Roshydromet suggested that the FROST2014 archive be freely accessible to the entire meteorological community. In addition to the forecasts, available in the FROST2014 archive, the initial and boundary conditions generated by COSMO-S14-EPS

were stored at Roshydromet as well. The entire dataset available (COSMO EPSs forecasts + initial and boundary conditions for COSMO high-resolution EPS + FROST forecasts and observations) can be very useful for the international community and especially for COSMO community. Re-forecasts using a modified high-resolution EPS can be done to estimate the influence of different aspects of ensemble generation (e.g. model-related perturbations, soil perturbations, etc.) However, at present there are still some obstacles for using the COSMO-related data:

- there are some gaps in the data;
- the COSMO-Ru2-EPS forecasts are stored on different computers to which there is no external access;
- the entire outputs of COSMO models are stored for COSMO-Ru2-EPS while only a pre-specified set of variables should be archived according to the FROST rules;
- there is no manual;
- the data should be completed by a list of severe events and periods that are worth to examine.

2.3.2 Goal

To prepare an archive of COSMO ensemble forecasts (with 7 and 2.2 km resolutions) for the Sochi area accompanied by initial and boundary conditions for high-resolution ensembles and by a list of important weather events during the period considered. The archive must be provided according to TIGGE-LAM archiving standards, easily accessible and have a clear manual to provide COSMO-community a possibility of experiments over an area where steep mountains are in close vicinity to the sea and high-resolution forecasts of severe events are a challenge.

2.4 SubTask 4. Preparing of recommendations for forecasters The features of using and interpretation of the results of limited- area mesoscale modeling (TL I. Rozinkina)

2.4.1 Motivation

Due to the COSMO PP CORSO and the WMO DP Frost2014 the forecasters of Sochi 2014 region obtained the cascade of model outputs form deterministic and ensemble modern mesoscale NWP technologies at large window of spatial resolutions. The some synoptical trainings for understanding of possible limitations of models are realized d at 2011-2014. Sometime there are not evident forecasting rules for correct interpretation of it output. The study of experience of feedback form forecasters permitted to obtain the experience, useful for disseminate among the forecasters. This practical rules must be based the knowledge of technology and limitations of algorithms for more effective interpretation the main correction.

2.4.2 Goal

To prepare the recommendations for forecasters to formulate and disseminate the experience of feedback and trainings of period before and during the Sochi-2014 concerning the features of interpretation of limited- area mesoscale NWP Systems (based COSMO-Ru technologies).

3 The guidance of the optimal domain's size selection for 1.1 km resolution of nested COSMO models for the regions with complex mountain relief (G. Rivin, M. Shatunova, J. Helmert)

3.1 Introduction

The development and implementation of COSMO model with 1.1 km resolution for the Sochi region was a part of RDP works within the Priority Project CORSO (Consolidation of Operation and Research results for the Sochi Olympics). The RDP results shown the strong dependence of the predicted precipitation amount and its spatial distribution on the models domain size. This problem need the more attentive examination, because the run of COSMO-Ru1 as part of nested technologies is rather expensive in point of view of computational time. The computing resources and the technological requirements of providing forecast by a certain time determine the model run timing. On the other hand, there are requirements for the quality of the forecasts. Factors determining the weather in the region, e.g., predominant direction of air mass transfer, and regional orography define possible location and size of the simulation domain. Forecasts assessment for the area on interest, area of the Sochi Olympics 2014 in our case, allow designate preferable domain. We used data from the observation sites located for the most part near the sports venues in two clusters coastal and mountainous, for verification. Sites of the first cluster are located on the coastline of 95 km and at distance up to 12 km, at an altitude from 2 to 660 m. Mountainous sites are located within the Mzymta river valley and adjoined highlands at an altitude from 560 to 2225 m. Forecast verification was made for the whole region and for mountain valley separately considering distribution of the observation sites.

3.2 Simulation domains

Selection of the simulation domains size and location was made using the results of Subtask 2.2 of PP CORSO Compilation of significant weather climatology for the Sochi region, based on automated weather classification and taking into consideration influence of regional orography. Area of Sochi Olympics and surroundings presented on Fig. 1, where red rectangle indicates location of the Sochi2014 sport venues. Air masses coming from WSW and EN determined weather conditions in the area of Sochi2014 during the winter. Local cyclone formed over the eastern Black Sea basin affects weather also. While western (NW or SW) direction prevails in a large-scale air transport, warm and moisture air mass moves along the local cyclone periphery and along the coast in NE direction, shifts over land and inflows into the mountain valleys. Two mountain ridges Main Caucasian Ridge and East Pontic Mountains are a kind of natural border, preventing the penetration of air masses in the Sochi2014 area from the northeast and southeast. It seems reasonable that simulation domain covered the eastern Black Sea basin and be limited by mentioned mountain ridges. The following three variants were suggested: domain 1 (D1) has 300x300 grid points, domain 2 (D2) has 450x450 and domain 3 (D3) has 450x650, and grid points (see Fig. 2). The results obtained for these three domains were verified by VERSUS. An effect of the simulation domain size and location on precipitation forecast was investigated also for several cases of heavy precipitation. Additional simulations were performed for the one more domain D4 (750x750 grid points) for case studies. COSMO-Ru7 model (7 km grid spacing) provided initial and boundary conditions for COSMO-Ru1.

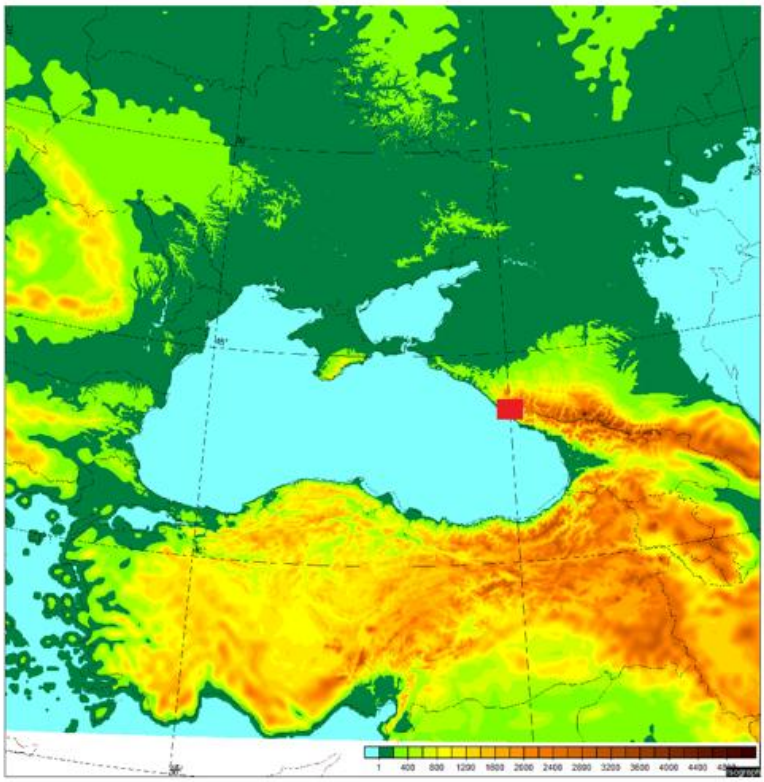

Figure 1: Geographical location of Sochi2014 region (red rectangle).

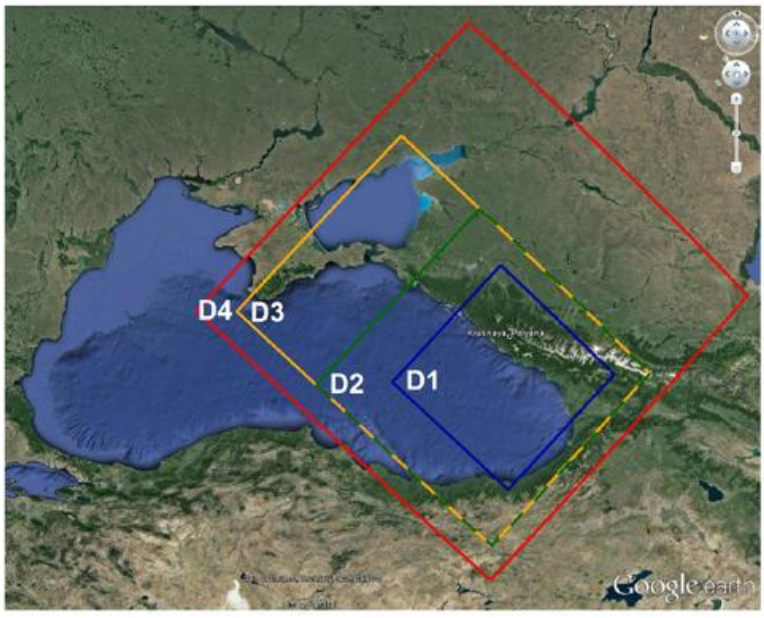

Figure 2: Simulation domains: D1 (blue rectangle) 300 x 300 grid points, D2 (green rectangle) 450 x 450 grid points, D3 (yellow rectangle) 450 x 650 grid points, D4 (red rectangle) 750 x 750 grid points.

3.3 VERSUS verification results

By means of VERSUS, 24 h forecasts for air temperature at 2 m, dew point temperature at 2 m, wind speed at 10 m and 3 h precipitation sum were verified. Two kind of VERSUS stratification were used. The first, Sochi39, includes 56 stations of which half is in the coastal zone and half is in the mountains. The second stratification, Sochi_Mount, includes 25 stations located in the mountain cluster of Sochi2014 within the upper and middle part of the Mzymta river valley. Nearest point 3D optimized method was chosen for verification. During February and March, 2014 local time was equivalent to UTC + 04 h. Verification results mean error (ME) and root mean square error (RMSE) of the 24 h forecast for the different domains are presented on Fig. 3. The results for all domains and two variant of stratification look rather similar but have some features:

- RMSE is less for the D1 for the daytime (04 14 UTC) for air temperature and wind speed forecasts. RMSE difference reaches 0.8 for T2m forecast and 0.3 for wind speed forecast;
- dew point temperature was predicted better for D1 for the most, difference between results for D1 and D2 and D3 became greater after 18 h and at 24 h lead time amounts 0.7-0.9 for mean error.

The difference between results for D2 and D3 is negligible. Thus, the expansion of the simulation domain in the NW direction has not given effect. Average difference between results for D1, D2 and D3 for air temperature is less 0.1 (for ME) and 0.1-0.2 (for RMSE), for dew point temperature is less 0.4 (for ME) and 0.4-0.6 (for RMSE), for wind speed is less 0.1 (for ME) and about 0.1 (for RMSE). Analysis of the results for two stratifications shows that wind speed is slightly better predicted for the mountain cluster, whereas air temperature and dew point temperature forecasts for mountain cluster have lesser score than for the whole assessment area. To assess accumulated precipitation several verification scores described below were calculated using 2x2 contingency table (Table 8) for different thresholds. These scores were calculated for 3h precipitation forecast and for all lead-time (Tables 9-13).

Bias is used to detect whether model overestimated precipitation event or underestimated it (Schirmer, Jamieson, 2015), $bias = (A + B)/(A + C)$.

Critical success index (CSI), also called the threat score (TS), $CSI = A/(A + B + C)$. This score indicates the relative worth of different forecasting techniques (Schaefer, 1990).

True skill statistic (TSS), $TSS = (A \cdot D - B \cdot C)/[(A + C)(B + D)]$; also known as Hanssen-Kuiper skill score is a verification measure of categorical forecast.

Heidke skill score (HSS), $HSS = (A + D - E)/(A + B + C + D - E)$, where E is the correct random forecasts. HSS score used for evaluating rare event forecast is suitable for heavy precipitation forecast assessment.

Equitable Threat Score (ETS), also called Gilbert skill score (GS), $ETS = (A - CH)/(A + B + C - CH)$, where $CH = (A + B)(A + C)/(A + B + C + D)$ is hit due to chance. ETS is commonly used for precipitation verification, in particular because correct no-event forecasts are not considered in this score.

Extremal Dependency Index (EDI), $EDI = (\log F - \log H)/(\log F + \log H)$, where $F = B/(B + D)$ is false alarm rate and $H = A/(A + C)$ is hit rate. EDI is an innovative

categorical measured, being independent from base rate $(A+C)/(A+B+C+D)$, used for rare dichotomic events verification.

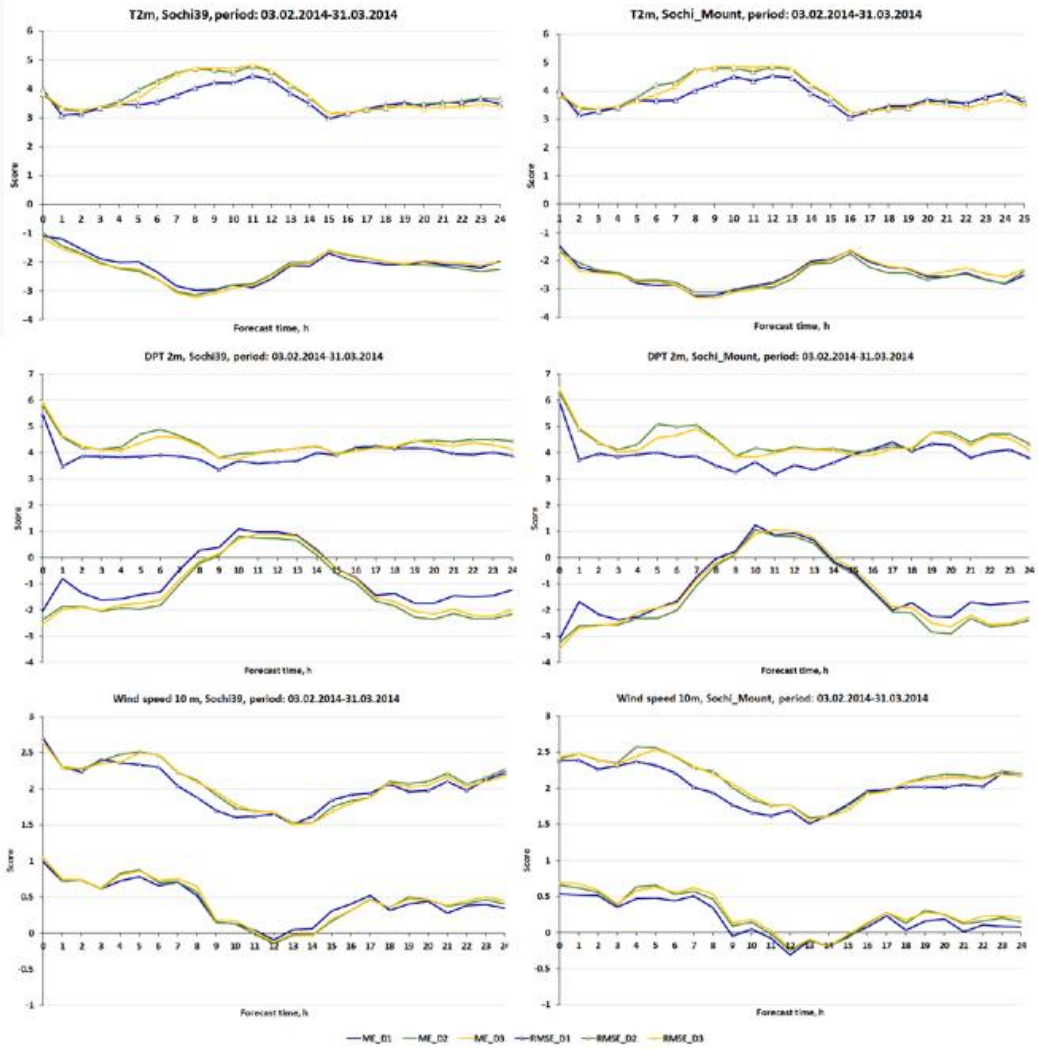

Figure 3: Mean error and RMSE of the air temperature at 2 m, dew point temperature at 2 m and wind speed at 10 m forecasts obtained for three domains.

Precipitation on February and March 2014 in Sochi2014 region usually occurred during daytime, 7-15 h local time (total number of cases indicated at the bottom of the column on Fig. 4). The most cases of heavy precipitation were observed within the 10-16 h local time. Secondary maximum of heavy precipitation (>5 mm/3h) was registered at 22-01 h local time. Bias values for precipitation threshold 0.1 mm/3h for different lead-time (Fig. 5a) show that model overestimates precipitation event for all lead-time regardless of the domain size. For moderate and heavy precipitation (1-5 mm/3h) there is a temporal shift shown on Fig. 5b: while precipitation for the period 9-12 UTC is overestimated, there is underestimation of the event for the previous 3 hours (6-9 UTC). Evaluation of the precipitation with the threshold 3, 5 and 10 mm/3h was made using sample large enough to obtain statistically significant scores.

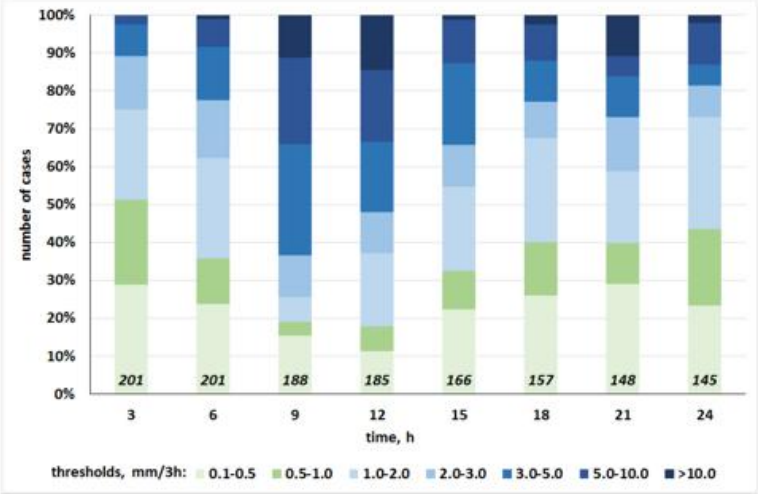

Figure 4: Number of observed precipitation cases for different threshold for 3-hour periods during the day.

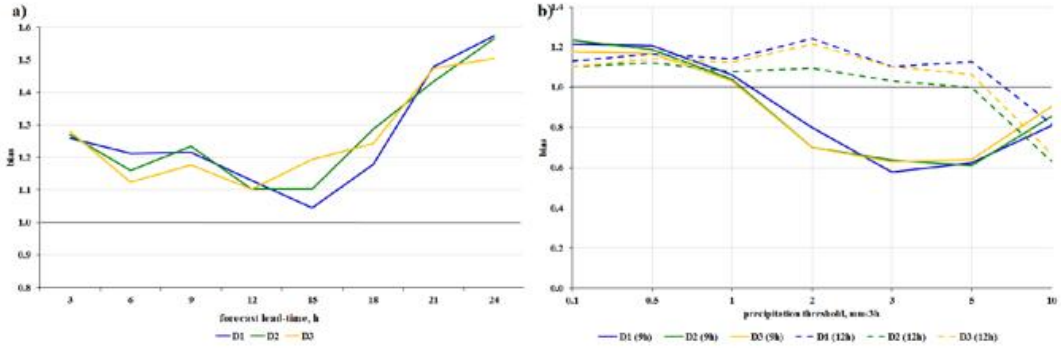

Figure 5: Bias for precipitation threshold 0.1 mm/3h for different lead-time (a) and for different thresholds for lead-time 9 and 12 h (b) for different simulation domains.

Analysis of the scores presented in Tables 9-12 shows that for the first 3 hours period for all domains forecast may be considered no more than satisfactory. Assessment increases for the next periods and for the 9-12 h period forecast has the highest scores for all domains and precipitation thresholds from 0.1 to 5 mm/3h. It is noted that model has rather high scores for forecast precipitation more 10 mm/3h with lead-time 21 h, when secondary maximum of heavy precipitation observed. Comparison of the results for different domains shows that scores for precipitation event forecast (0.1 mm/3h threshold) for D1 are slightly worse than that for D2 and D3. Based on ETS and HSS values that are most suitable for rare event assessment it can be conclude that D1 and D3 have some advantages in heavy precipitation forecasting. It is interesting to note that precipitation forecast for 10 mm/3h threshold is better for D1 for 12 h lead-time, while D3 has some advantages for longer lead-time 21 h. This is also confirmed by the EDI values. Verification by VERSUS shows that small domain can be used for precipitation simulation for the lead-time until 18 h, for greater lead-time it is better to make simulation for larger domain.

3.4 Verification of heavy precipitation event forecast (case studies)

Analysis of the several cases of heavy precipitation was performed to assess the effect of the domain size on the forecast of precipitation amount, its spatial and temporal distribution. The analysis was performed for 12 sites located in the central part of the Sochi2014 area (Fig. 6). Solokh-Aul, Lazarevskoe and Imeretinka are in the coastal cluster, but only the last two are on the seashore. Solokh-Aul is located in the hills at a distance of 12 km from the sea.

Figure 6: Location of the observation sites used in case studies.

Predicted precipitation daily amount for all domains in comparison with the observations are presented in Tables 1-5. The maximum difference between forecasts was nearly 10 mm/24h. Comparison of the results detects various situations, e.g.:

- results for all domains could be very close to each other and to observation (see Table 3 for G.Karusel-1500);
- difference between forecast and observation could be much greater than difference between forecasts for various domains (see Table 2 for Solokh-Aul);
- for the one domain predicted amount could have good agreement with observations while the difference between forecasts for various domains could be significant (see Table 1 for Kepsha).

Site	Obs.	Forecast			
		750x750	450x650	450x450	300x300
Coastal cluster					
Solokh-Aul	23.0	27.5	28.9	30.5	31.7
Lazarevskoe	19.7	10.8	14.5	7.8	14.2

G. Karusel-1500	26.0	22.3	21.0	22.3	19.1

Table 1: Observed and forecasted accumulated precipitation for 24 h on February 18, 2014.

Precipitation temporal distribution presented on Fig. 7 for several sites allows detect domain size influence on the forecast. Variation of the hourly precipitation amount depending on domain could be estimated also. The precipitation on March 17 was caused by convection developed on the cold front and occurred in the morning with peak at 6-7 UTC on coastal sites and at 8-10 UTC on mountainous sites. Maximum hourly amount equal to 12.7 mm was observed at Kepsha. On March 18 precipitation was accompanied by the passage of the rather weak warm front and continued throughout the day. On coastal sites two peaks were observed at 7 and 12 UTC, while within the mountain valley precipitation was more evenly distributed in time. The same forecasted temporal distribution of the precipitation was obtained for all simulation domains. There is shift of the event start time that is about 1-2 hours, predicted precipitation starts earlier than observed. The difference between forecasts for D1-D4 is small for the first 3-5 hours of the forecast. Later it could reach 2-3 mm for hourly-accumulated amount and this was noted both for coastal and mountains sites.

Site	Obs.	Forecast

Table 5: Observed and forecasted accumulated precipitation for 24 h on March 18, 2014

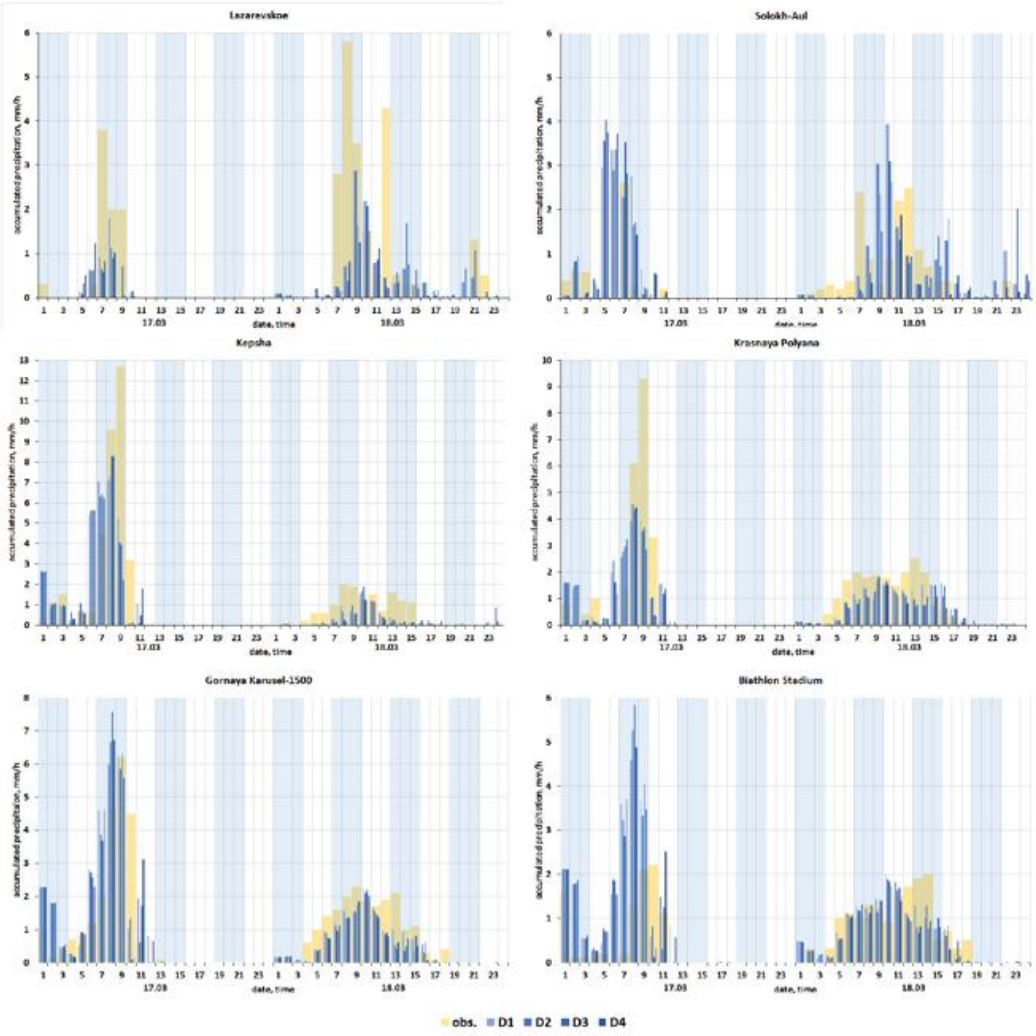

Figure 7: Hourly accumulated precipitation forecasts simulated for various domains in comparison with observation.

The most evident effect of the domain size in precipitation spatial distribution reveals near the domains boundary (Fig. 8 and 10). The difference between forecasts for two domains can reach 10 mm/day. Looking closer on the results for D1-D4 (Fig. 9 and 11), it is noted that the main structure of the precipitation spatial distribution is the same, but there are some variations. In particular, on March 17 precipitation amount increases within the Mzymta river valley (where the Olympic competition took place) with increasing domain size (Fig. 11). Comparison the results for different events shows that changes of the precipitation maximum location and amount could occurred in different direction. The interrelation of the direction of the air mass movement and local orography plays its role here.

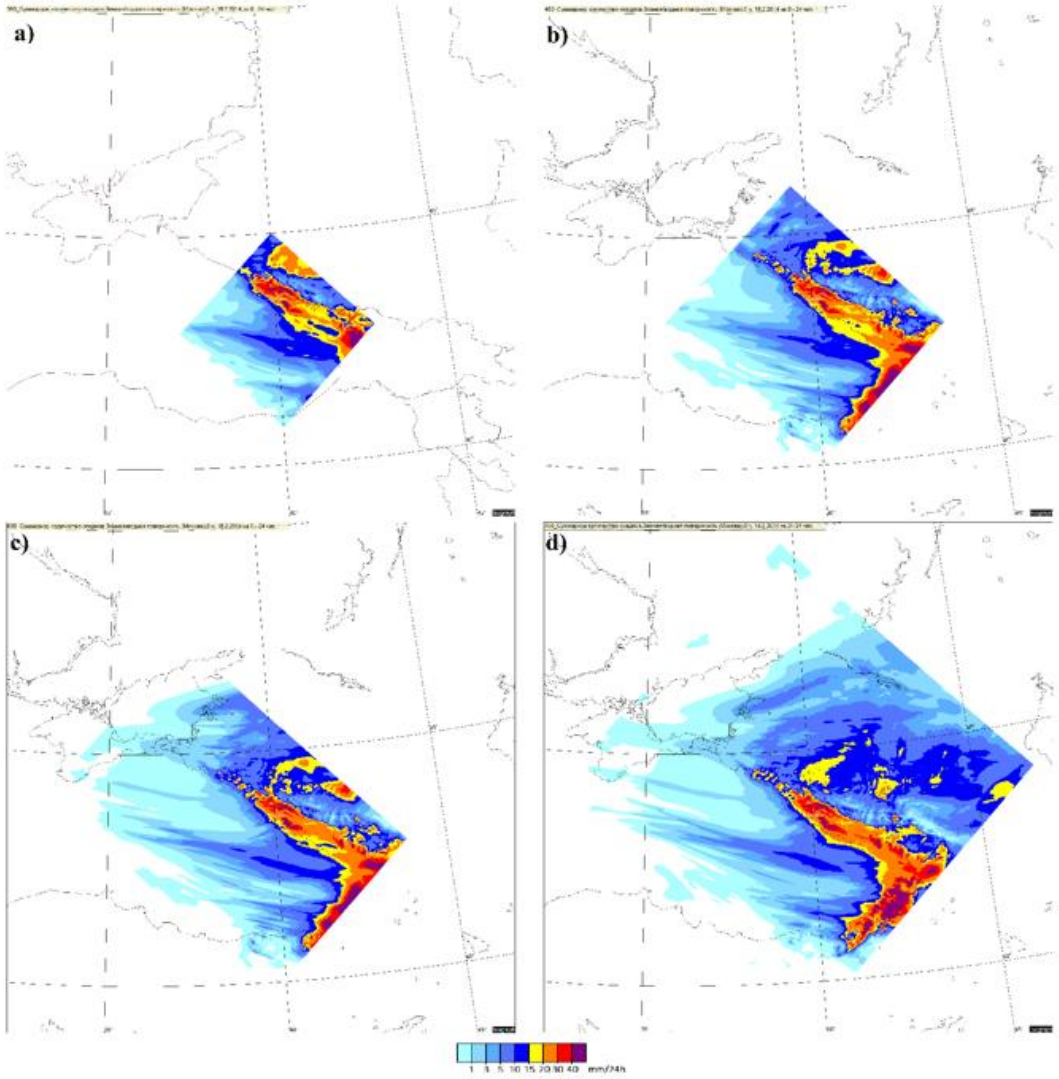

Figure 8: 24 hours accumulated precipitation predicted for various domains: D1 (a), D2 (b), D3 (c), D4 (d). Forecast start 18.02.2014, 00 UTC.

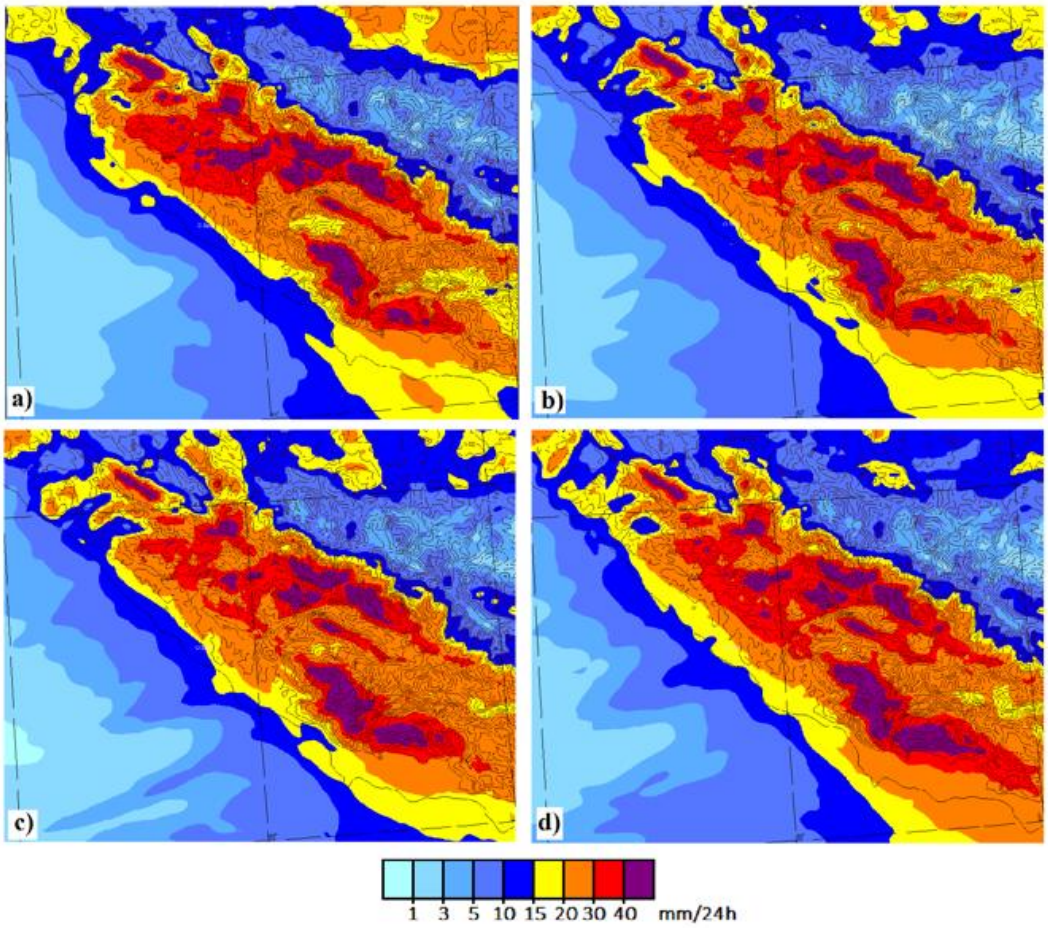

Figure 9: The same as Fig. 8 but for the Sochi region with model orography (isolines).

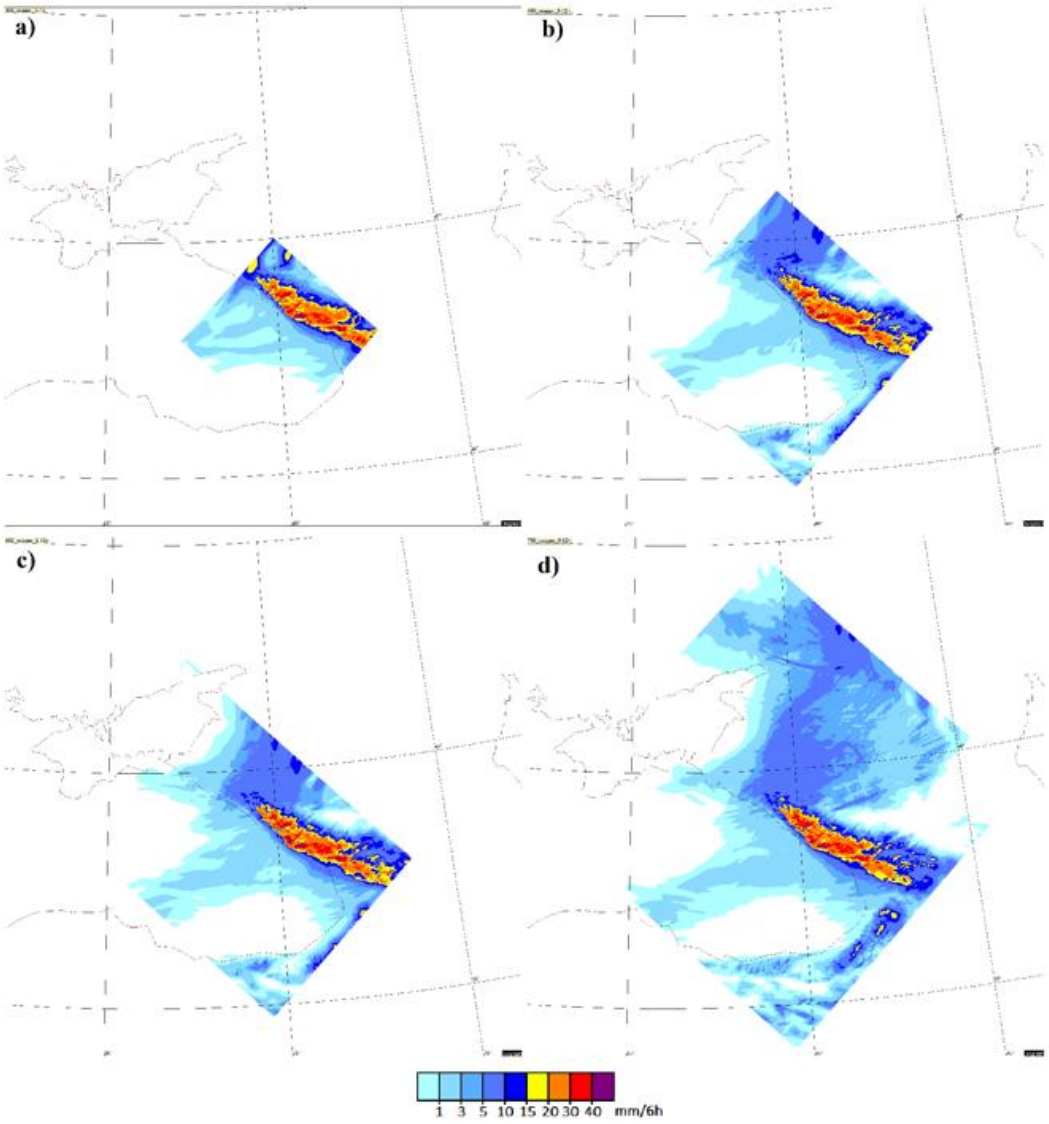

Figure 10: Accumulated precipitation for the period 06-12 UTC predicted for various domains: D1 (a), D2 (b), D3 (c), D4 (d). Forecast start from 17.03.2014, 00 UTC.

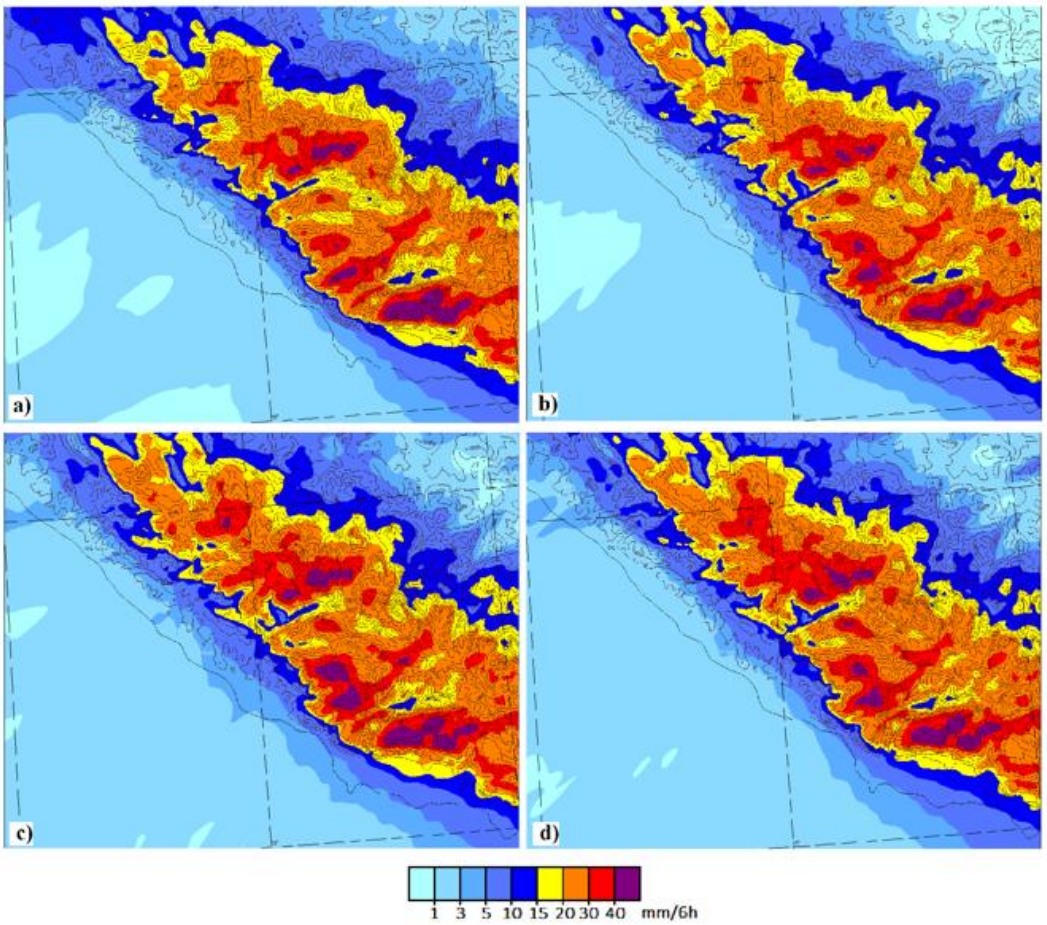

Figure 11: The same as Fig. 10 but for the Sochi region with model orography (isolines).

3.5 Conclusions

COSMO-Ru1 model simulations performed for different domains allow evaluate influence of domain size on the weather elements forecast. A large number of observations provided an assessment period from February 3 to March 31, 2014 for Sochi2014 region. Verification by VERSUS of the forecasts for air temperature at 2 m, dew point temperature at 2 m, wind speed at 10 m shown insignificant variations of the results for chosen domains. Verification shown that model overestimates precipitation event for all lead-time regardless of the domain size and indicated the presence of temporal shift in the forecast of the moderate and heavy precipitation. The difference between forecasts of heavy precipitation amount for various domains can reach 10 mm for daily amount and 2-3 mm for hourly-accumulated precipitation. Verification scores used traditionally for precipitation assessment demonstrate possibility to use rather small simulation domain (300x300 grid points) for the forecasts with lead-time until 18 h without loss of forecast quality.

4 Development of algorithm of subgrid h-correction of T2m for mountains based on COSMO forecasts of local lapse rate (h-correction) (I. Rozinkina, J-M. Bettems, D. Blinov, A. Euripides)

The mail idea of proposed technique is to forecast the lapse-rate of T and Td for the points and make the T2m and TD2m correction based these values. This could be useful in inversia-situations via hight- resolution modeling. In the framework of CORSO-A the proposed algorithm should to be included into FieldExtra.

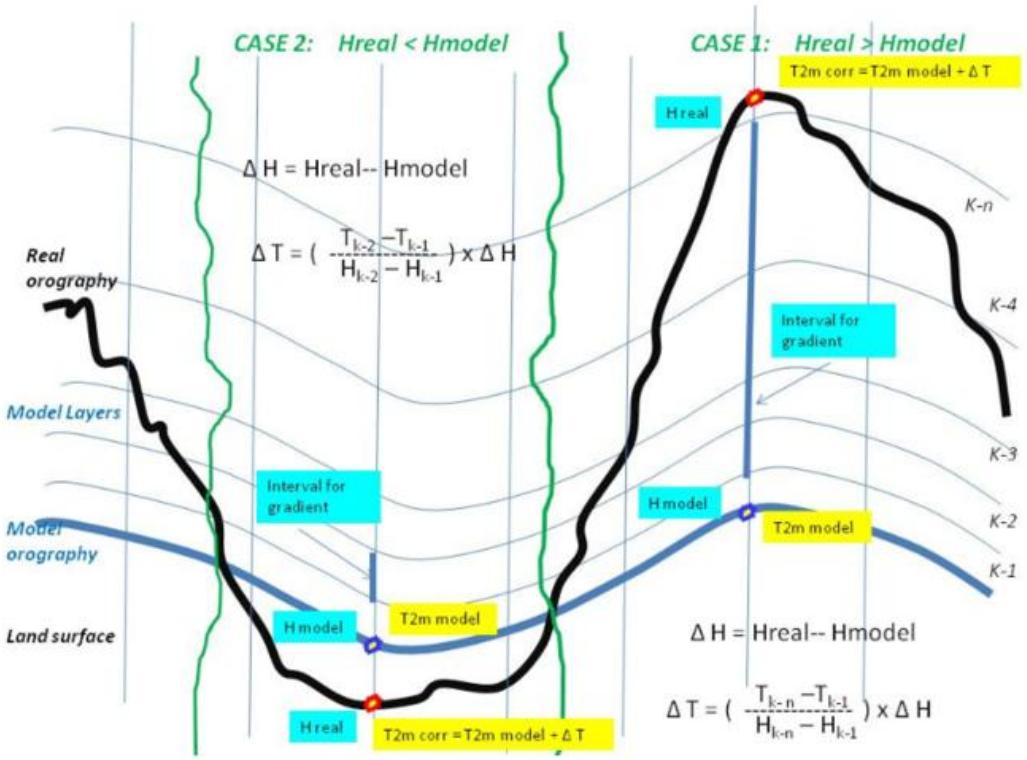

Figure 12: The description of tests and results is given in PP CORSO report.

The description of algorithm and proposals for FieldExtra extension are obtained. The realization of algorithm of FieldEextra (calculation of orography differences for points in FieldExtra and extension of software) + additional testing of 1-D version have been included The algorithm was formulated and included into FieldExtra Software (since 2016, FieldExtra 12.2.0, J-M Bettems).

5 COSMO-BASED ENSEMBLE FORECASTING FOR SOCHI-2014 OLYMPICS: ARCHIVING THE RESULTS (E. Astakhova, A. Montani, D. Kiktev, D. Alferov, A. Smirnov)

5.1 Introduction

The last winter Olympic/Paralympic Games were held in February-March 2014 in Sochi, Russia. The Russian Meteorological Service (Roshydromet) initiated a special international project FROST-2014 (FROST - Forecast and Research in the Olympic Sochi Testbed) related to these Games; it got a status of WMO World Weather Research Programme (WWRP) blended Forecast Demonstration and Research and Development Project (Kiktev et al., 2015a; Kiktev et al., 2015b) . The COSMO activity in FROST-2014 was integrated within a consortium priority project Consolidation of Operation and Research results for the Sochi Olympic Games (PP CORSO) (Rivin and Rozinkina, 2013). PP CORSO finished in 2014. Its results included a successful experience of high-resolution modeling in mountainous areas, improved downscaling/postprocessing procedures for the Sochi region, regular provision of probabilistic forecasts during the Games as well as research in ensemble modeling with different resolutions. It was realized in 2014 that some additional work was necessary to implement CORSO achievements to COSMO practice and to enable their better usage. That is why the priority task CORSO-A followed PP CORSO. Here only the ensemble component of CORSO and CORSO-A activity will be considered. We shall briefly remind CORSO results, overview the goal of CORSO-A, and summarize its results.

5.2 Ensemble prediction systems developed in CORSO

Two ensemble prediction systems (EPS) were developed within PP CORSO: COSMO-S14-EPS with a 7-km resolution and COSMO-Ru2-EPS with a 2.2 km resolution (Montani et al, 2013, 2014, 2015). COSMO-S14-EPS (S14 stands for Sochi2014) was created at ARPA-SIMC (Montani et al, 2013) and was a version of COSMO-LEPS system (Montani et al, 2011) displaced from the European area to the Sochi region. The system was driven by the ECMWF EPS, namely, by its most representative prognostic realizations which were selected by a clustering procedure. The lower boundary condition was a result of COSMO model run in hindcast mode (a short-range forecast nested on ECMWF analyses). The model-related uncertainties were taken into account in COSMO-S14-EPS by using two different convection parameterization schemes (Tiedtke or Kain-Fritsch, random choice) in different members and also by varying tuning coefficients in parameterizations of sub-grid scale processes (in particular, turbulent). The most essential differences between COSMO-S14-EPS and COSMO-LEPS systems were integration domains (Sochi region or Europe) and ensemble sizes (10 or 16 members, respectively). The system with a 2.2-km grid size named COSMO-Ru2-EPS ran at Roshydromet and performed a dynamical downscaling of COSMO-S14-EPS increasing the forecast resolution both in horizontal (from 7 to 2.2 km) and in vertical (from 40 to 50 levels). No additional perturbations were introduced neither to initial and boundary conditions nor to the model. The ensemble has the same size as in COSMO-S14-EPS and was composed of 10 perturbed members with no control. Both EPSs ran operationally during the Olympics/Paralympics, their results were provided to Sochi forecasters and proved to give a valuable support to them. In fact, the entire length of parallel runs of COSMO-S14-EPS and COSMO-Ru2-EPS was longer than the period of the Games and covered December 2013-April 2014. The forecast results were archived on Roshydromet servers along with initial and boundary conditions generated by COSMO-S14-EPS and later used by COSMO-Ru2-EPS.

5.3 CORSO-A necessity and goal

It is worth to note here that COSMO ensemble forecasts can be considered a part of a more extensive FROST-2014 archive that included the results of four more ensemble prediction systems (Kiktev et al, 2015; Astakhova et al, 2015). The two systems, GLAMEPS and HarmonEPS, were presented to FROST-2014 by the Norwegian Meteorological Institute, while ALADIN-LAEF and NMMB-EPS came from the Central Institution for Meteorology and Geodynamics (ZAMG), Austria, and the National Centers for Environmental Prediction (NCEP), USA, respectively. The EPS resolution was 7 to 11 km except for the convection permitting HarmonEPS with its 2.5 km horizontal step; the ensemble size varied from 7 to 54. Additionally, deterministic forecasts by 9 different systems, nowcasts from 6 systems, and a variety of observational data of different types, including station, radar, profiler data, operational meteorological bulletins, camera snapshots, etc., were aggregated at the FROST-2014 server and available via the project web-site http://frost2014.meteoinfo.ru. By no doubt, this huge amount of forecast and observation data could be very useful for research in the field of short-range limited-area deterministic and ensemble prediction. Remember that the Sochi area is a very complex region with steep mountains lying near the warm Black Sea and forecasting in mountainous regions is still a challenge for numerical weather prediction models. However, it became clear after the Olympic Games, that in research tasks it would be quite difficult and problematic to use the forecast data in the form presented on the FROST-2014 server because of different coding and organization of data files transferred to Roshydromet by various data providers. The application of the archive would be much easier if the forecast data were organized following some standard rules. A good idea is to follow TIGGE-LAM project and to prepare a Sochi unified archive using the coding standards and user interfaces adopted in TIGGE-LAM (Paccagnella et al., 2012). TIGGE and TIGGE-LAM data portals are well known and very popular in scientific community and a lot of research has been done using the data presented there. That is why one of CORSO-A goals was to implement a unified archive of COSMO ensemble forecasts (with 7 and 2.2 km resolutions) for the Sochi area. The archive was expected to be accompanied by the data on initial and boundary conditions for high-resolution ensembles and by a list of important weather events during Olympics and Paralympics.

5.4 A Unified Sochi archive

The Sochi unified archive covers the period from January 15, 2014 to March 16, 2014. This time interval coincides with the period adopted for verification in FROST-2014 (January 15 - March 15, 2014). The archive contains the ensemble forecasts by COSMO-S14-EPS and COSMO-Ru2-EPS starting at 00 UTC and 12 UTC on the dates within the above-mentioned two-month interval. The prognostic fields for all members are presented with a 3h time frequency on the original COSMO-model rotated latitude-longitude grid with resolutions 7 and 2.2 km for COSMO-S14-EPS and COSMO-Ru2-EPS, respectively. The accumulated parameters (precipitation and wind gusts at 10 m) are not archived at zero time step. The data are in WMO-GRIB2 format. The archived parameters and the corresponding coding information are listed in Table 6. The parameter set is slightly different from the TIGGE-LAM high-priority parameters. The Sochi archive does not contain large-scale precipitation, convective inhibition, and convective available potential energy. As static fields (land-sea mask and orography) did not change during the period, they were written to the archive only once.

Parameter	Abbreviation	Level	Units	GRIB2 specifics
10 meter U-velocity	10u	10m (103,10)	m/s	Instantaneous Product Discipline 0 Parameter Category 2 Parameter number 3 paramId 165

Table 6: Specification of Sochi archive.

Case	Meteorological process/ phenomenon	Models behavior	Impact on competitions
07.02	Foehn	Poor temperature forecast (underestimated by 1.4 ... 3.7 °C) by most models at Biathlon Stadium	
10-11.02	Dissipated precipitation	Precipitation in the Mountain Cluster predicted by the majority of systems, but not observed actually	
15.02		Poor forecast of maximum wind speed by most models at Krasnaya Polyana (underestimated by 3.5 ... 7 m/s)	
16.02	Low visibility		Postponed competitions at Laura and Extreme Park
18.02	Cold front	Good precipitation forecast by most models	
22.02	Foehn	Poor temperature forecast by most models (negative forecast errors: -2.4 ... -4.4 °C, mostly at 1500 m)	
11.03	Cold front. Low visibility	Bad description of the behavior of maximum temperature (Tmax) by most models (Tmax forecasted at noon, whereas in reality it was observed in the morning)	Postponed skiing competitions at Roza Khutor
13.03		Poor precipitation forecast by most models above 1500 m	
17.03	Cold front	Underestimation of maximum wind speed by most models above 1500 m	

Table 7: The most interesting cases during the Olympics/Paralympics.

The following ensemble meta-data information is included to the GRIB files:

- the ensemble size (GRIB key numberOfForecastsInEnsemble);
- the number of ensemble member (GRIB key perturbationNumber);
- the forecast type (GRIB key dataType = pf/cf, i.e. perturbed/control).

No data for mean sea level pressure is available for COSMO-S14-EPS. Initial and boundary conditions for high-resolution COSMO EPS are available on demand. All other FROST-2014 forecast data (both deterministic and ensemble) in the Sochi unified archive are coded

in the same way. The archive is available at http://frost2014.meteoinfo.ru (authorization required). To download the forecasts, you must switch to Forecasts (upper panel) -Export of gridded ensemble forecasts (right panel), and then select the necessary data using the interface similar to that of TIGGE-LAM data portal (Fig. 13). The necessary data will be prepared in compressed form, the corresponding reference will be sent by e-mail, and then the data can be downloaded. In addition to the prognostic fields, point forecasts (mean for ensembles) can be exported in csv format for more than 30 stations in the Sochi region. During the Olympics these forecasts were regularly presented at the multi-system page of the FROST-2014 site along with observation data and were considered very useful both by forecasters and researchers. To prepare these forecasts, the nearest grid-point approach was applied. A Web-tool to export observation data was also developed. For more details, please visit http:/frost2014.meteoinfo.ru, where you will also find a short description of all FROST-2014 numerical weather prediction systems. When research deals with the investigation of the skill of different weather prediction systems and of new ways to improve the forecast, it is important to have information about the synoptic situation in the analyzed domain and to select really essential events for case studies. To facilitate research in the field of short-range forecasting, Sochi forecasters prepared a list of cases recommended for detailed consideration. This list supplements the unified archive and is given in Table 7.

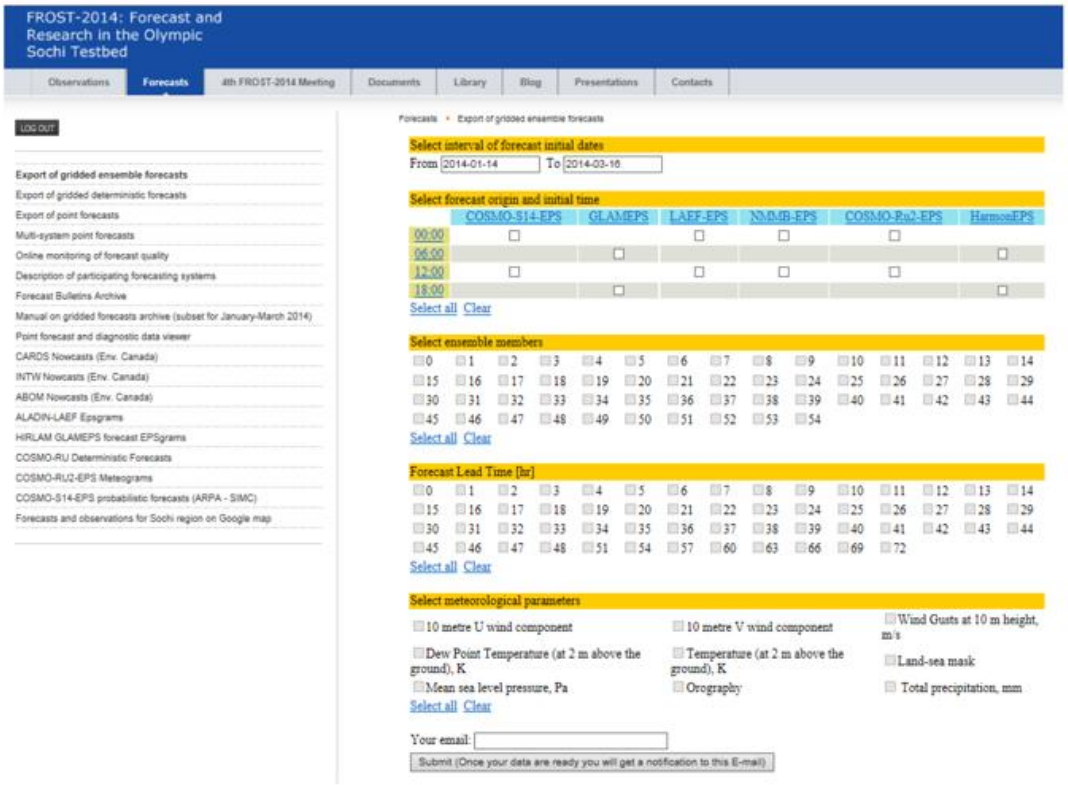

Figure 13: The FROST-2014 Web-interface used to download forecasts from the unified Sochi archive.

5.5 Conclusions

The unified Sochi archive containing forecasts for the area of Olympic Games 2014 for the period from January 15, 2014 to March 16, 2014 was prepared. The forecasts of two COSMO-based ensemble prediction systems, COSMO-S14-EPS and COSMO-Ru2-EPS with

resolutions 7 and 2.2 km respectively, are stored in the archive. The Web-tool to download the forecasts and observations as well as the list of interesting cases for research supplement the archive. The archive is organized in TIGGE-LAM style and is available at http://frost2014.meteoinfo.ru.

6 PREPARING OF RECOMMENDATIONS FOR FORECASTERS ABOUT FEATURES OF INTERPRETATION OF THE RESULTS OF MESO- SCALE MODELING (How to use the LAM mesoscale NWP results for mountain terrain) (I. Rozinkina, P. Eckert, G. S. Rivin)

The feed-back from forecasters of Sochi-team in domain of experience of use of numeric mesoscale products was studied. The Some recommendations for improving the further trainings were obtained.

6.1 Introduction

This document summarizes the lessons from experience of meteorological support of Sochi Trials 2011, 2012, 2014), Olympics and Paraolympics (2014), matters of trainings for forecasters team for Sochi2014 meteosupport (2011-2014) in part of use of High resolution NWP products based on COSMO-Ru output, the discussions of experts of the COSMO WG4 sessions during and after period of Sochi-2014 meteosupport and learning exercise. Some examples of NWP output of named learning period were upgraded. The complexity of the Sochi region (steep mountains located in close proximity to the wide warm Black Sea area) justifies the application of the high resolution for short-term numerical weather forecasting. Weather forecast for the "Sochi-2014" is yet a big challenge. This document is focused on the features of using Mesoscale NWP products for mountain terrain on example of COSMO-Ru model with resolution 2.2 km with 1.2 km nested domains. This document is prepared in framework of COSMO PT "CORSO-A" which had the goal to summarize the experience of using results obtained during the realization of Sochi meteosupport for dissemination among the COSMO participating countries. As part, it consists of fixation of certain experience obtained using the products of High-resolution mesoscale model.

6.2 Key definitions

- **Mesoscale atmospheric circulations** - in context of this document it is determined as the atmospheric processes of the spatial scale from several (first tens kilometers) to 100 - 500 km (as distinct from synoptic scale processes - from 100 - 500 to 5000 km). It should be considered that no defined distinction between these scales could be stated as absolute truth. All scales are cross-related and could be determined only specifically in context of specific synoptic situation. In terms of time scale the mesoscale processes could last from minutes to several hours. However these phenomena can generate the synoptic scale events, which could be viable for several days. The cyclones, including tropical cyclones are defined as synoptic objects. The earlier classifications (1970-th) limit the synoptic processes with much more rough scale 2000 km, latter (1980-th) - several hundred km, which partially was related to possibility identifying the circulation objects according the density of observation data.

- **Model grid step** - horizontal distance between the centers of adjacent grids. Size of atmospheric model grid step limits the lower edge of the synoptic objects, which could be identified by the certain model.

- **Resolution of modelled processes** - determines the dimension of reliably circumscribed by the model circulation objects. Normally these objects are of the size of 7 - 10 model grid sells. Accuracy of forecast of atmospheric phenomena related to these objects is of the same scale. For meteorological parameters near the surface, especially at the mountains, the accuracy of the detailed model results could be significantly closer to the size of grid sell due to local limited land surface forcing.

- **Mesoscale atmospheric models** - global or limited area models (LAM) with the grids allowing describe the different atmospheric processes of defined spatial and time intervals (1, 3).

- **Non-hydrostatic atmospheric models** are the models with such spatial resolution when the hydro-static approximation is non-correct, and is required the explicit consideration of vertical motion acceleration (based on vertical component of wind speed), where the hydrostatic approximation can not be used. Non-hydrostatic effects should be taken into account for the grids with the step lesser than 9 - 10 km. This is the typical characteristic of the contemporary models for the limited areas. At the same time, the non-hydrostatic approach is evolved in global modeling aspect.

- **Convective-resolving atmospheric models** - models of the atmosphere allowing (not using parameterizations) describe the large convective systems. Such models have the horizontal grid step of less than 3 km. However, a certain part of convective processes (depending on grid step) will remain in the under-grid scale and should be parameterized. The algorithms of remaining share of convective processes should adequately describe their scale.

6.3 Main statements of use of products of global / Limited area NWP Products for short-range and very-short range forecasting

For short-range weather prediction a forecaster should analyze the output of both kinds of NWP technologies: global and systems of the limited area modeling. The advance of LAMs against the global models is determined by combination of two factors: higher resolution / considering non-hydrostatic effects and the list of available output for forecasters of National meteorological centers, which develop LAM technology. The following statements explain the above.

Purposes for the use of the output of:

a) **Global modeling**

To determine the large-scale weather patterns of atmospheric processes, analyzing and forecasting of generation, evolution and trajectories of the cyclones and anticyclones in short- and medium-range forecasting (in medium-range forecasting the forecasts are based usually on global ensemble modeling). Grid resolution of advances operational global models allows reasonably accurately reproduce the baroclinic zones, jet streams in upper troposphere and stratosphere, processes of cyclones generation, forming and degradation of atmospheric fronts. The grid resolution of global models has a tendency to more and more increasing, and the new generation of Global NWP are usually use non-hydrostatic approach. However, frequently some limitations exist for providing the

full sets of products of Global NWP to local users - this is one of serious reasons why the LAM technologies become more and more popular in the National Meteorological Services.

b) **Limited-area modeling**

For forecasting of large variety of phenomena from synoptic to local (depending of dimension of calculation area and dimension/resolution of grid cells. Operational non-hydrostatic LAM might have a large range of grid dimensions - from hundreds meters to several or even first tens of kilometers. They can reasonably adequately reproduce the wide range of meteorological processes in different LAM, often, by "nested" technologies: from large-scale processes (generation, evolution and trajectories of the cyclones) to events of convective nature and/or hazard of appearance of local phenomena (wind gusts, heavy showers, blizzards), fogs, circulation in the mountains and in the coastal areas, influence of the urbanized territories on meteorological characteristics, genesis and development of small-scale, but extremely dangerous polar-lows, etc. Possibility of description of the processes of certain scales is limited to the dimension of LAM grid resolution and form one side and from another - to the dimension of calculation area. Products of LAM operating in the spacious areas of calculation could be used by forecasters along with the products of global systems in analysis of synoptic objects dynamics.

Centers operating the models:

a) **Global NWP models**

Global NWP systems are developed on their own in relatively small number of centers. These global centers have sufficient computational, technological and communicational resources, as well as a proper personnel skills. An important component of the global NWP producing is the development of comprehensive technologies of data assimilation and processing.

b) **Limited-area NWP systems**

The LAM systems are developing in more than 70 National meteorological centers of WMO. LAM systems are developing as a role, both in the centers of global modelling, and in the National meteorological centers, and in some local forecasting centers. LAM "cascade" technologies produce more and more detailed products from initial global model, using the more rough version to LAM versions with each step increasing resolution 3-4 times to hundreds meters comparing with the models, which are used for producing the initial and boundary conditions for LAMs normally having more rough resolution. These systems could be developed for weather forecasting in relatively small areas within the region of responsibility of National (district) meteorological services. Many NGMSs are using LAM models developed in other countries, which relates especially to international consortiums. The LAM systems are based on the operational access to the sets of initial data and boundary conditions for calculation area provided by centers of global NWP via Internet.

Features of Dissemination of NWP products for NHMS WMO weather forecasters

a) **Global NWP products:**

1 Information is provided via WMO WIS in standard code formats on the net - grids in correspondence with WMO regulations (if other is not envisaged by agreement of the country with producers of global forecasts). WMO WIS regulations are oriented on φ/λ grids and standard vertical levels. In the Global models grids of disseminated products are naturally more rough than computational grids. Therefore a part of information of the surface weather produced by global models are often additionally smoothed in the process of transmission of digital information.

2 Via specialized meteorological Internet sites as graphical products. At the same time, lists of the placed products are limited and it is practically impossible to satisfy all requirements connected with detailed visualization and maps design for zone of responsibility of each NHMS.

b) **LAM NWP products:**

Each NHMS can use maximally the LAM output with required details both in computational aspect and visualization for certain region via Internet-technologies.

6.4 Stages of analysis of NWP products for local short- range forecasting

6.4.1 Common recommends

The forecaster analysis of NWP products should have certain stages.

The main idea: To understand the genesis of meteorological processes (following, their properties and potential conditions for severe weather) for identified areas based on combination of synoptic analysis with more detailed data.

The daily operational forecaster discussions (briefing):

The discussion (synoptic briefing) have to be organized to coordinate forecasts for all venues of area of responsibility creating unified concept of understanding of different forecasters and forecasters groups of current and future weather processes. These briefings should be organized firstly in the each forecasters group (e.g. concrete venue or region) and after that via video-conference arranging participation of representatives of all groups at least once a day, but preferably - twice a day, before the issue of morning official forecast and in the evening. The main responsibility takes the main forecaster group, which issues the daily bulletin and controls the Web-site information The discussion have to contain the following items:

1 Analysis of processes from large to local space - scales

2 Proposals for 4-5 Day weather trends based on NWP of large-scale processes for about half/third of Hemisphere

3 Analysis of weather of previous day/night

4 Knowledge of current NWP forecast quality (typical errors for the last several days)

5 Proposals for short-range (from 12 until 72h: tomorrow, after-tomorrow) and very short-range (from 2 until 12 hours: today/tonight)

6 Threat assessment of severe weather events for each forecasting interval.

6.4.2 Experience of large-scale weather types before the analyze of HR products

Each forecasting center or leading forecasting group in specialized meteosupport should have a previous knowledge of relationship between large-scale circulation types and probable local weather phenomena. In framework of development of meteosupport Sochi2014 forecasters from Sochi Black and Azov-seas Branch of North Caucasian Department of Roshydromet prepared the description of typical for rainy/snowy weather situations for mountain cluster of Sochi-2014 area. The typical large-scale processes which lead to the mesoscale circulations with heavy precipitation in Sochi area were described with applicate pictures, examples. The most dangerous hazards for this region are the heavy precipitation events, which can lead to the avalanches, mudslides, floods, traffic jams, damages to electric networks and roads. The previous investigations of weather types were concentrated firstly on the forecasting of probable heavy precipitation and on its phase. Some typical large-scale patterns of processes were identified. In Fig. 14 one of these is shown. This situation can provide a forming of the local cyclones on the South-Eeast of the Black Sea. The cold advection from the North to the western parts of Mediterranean cyclones and cold advection to the central part of Black Sea can amplify the local cyclone forming. These cyclones often could not be well detected in the pressure fields, and sometimes the hazards arrive suddenly for forecasters.

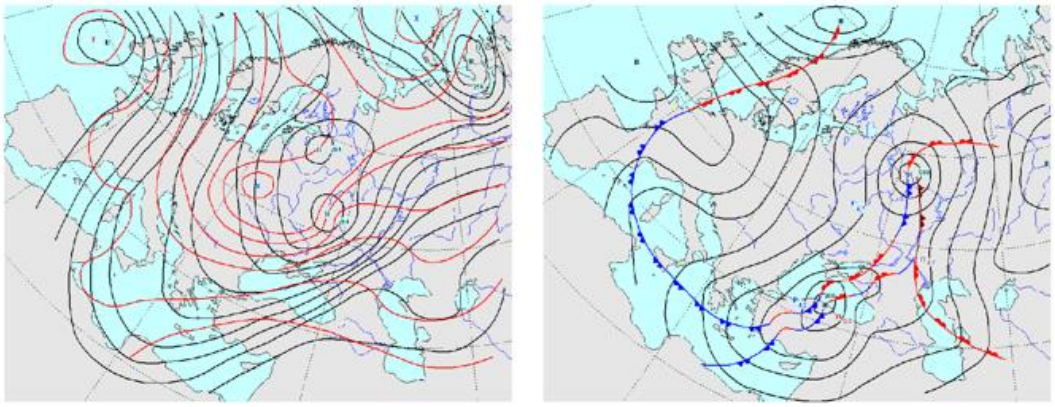

Figure 14: Example of one of typical large-scale situation providing the local cyclogenesis over Southeast of Black sea: H700 and H_{1000}^{500} are on the left, sea level pressure with frontal analysis is on the right.

This forming of little cyclone over the South-eastern coast of Black Sea, providing the transport of wet air to the Sochi mountain valleys in correspondence with orientation of mountain chains. These little cyclonic circulation is well presented on the maps of stream-lines for near-surface level, since the pressure minimums often are not sufficient for draw them. The high resolution information (stream-lines over Black Sea in COSMO realization) helped to detect these situations. The other approach had attempted to be realized for Sochi. Based on COST 733 facilities, the set of synoptic pictures for entire winter period of 2013 was analyzed. Forecasters had a lot of difficulties for join the concrete processes to certain circulation types in provided in COST 733 classifications. It appeared to be easier to do it for the types determined in classification GWT_27 (mainly attachment of every day real synoptic picture to the one of proposed types from GWT_27). It was surprising that the heavy precipitation were probable for a most part of provided large-scale types. It happened to identify only few situations with low probability of precipitation (NN8 and 20, picture 4) and corresponding to heavy rain events in mountain cluster 4 first (Fig. 15, the heavy rains in most cases) as well, 15, 16, 26 (heavy rain are probable in few cases). The formal use of typical patterns

from GWT_27, type 4 showed a good correspondence with process shown in Fig. 14, selected in independent mode via only forecasters experience.

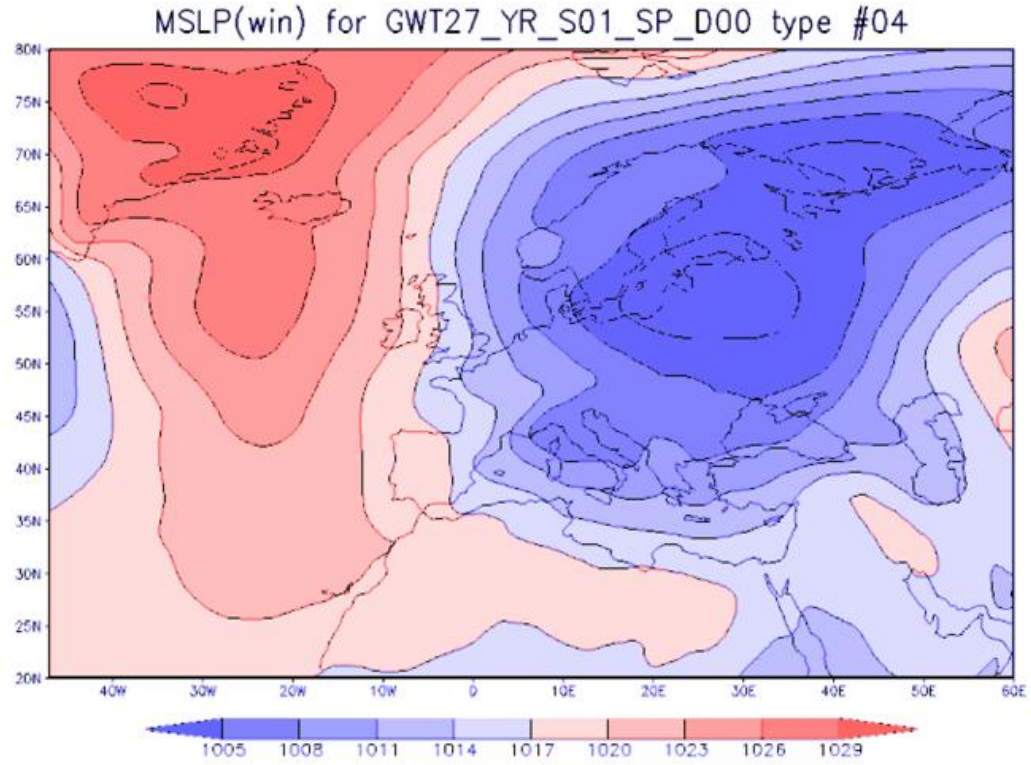

Figure 15: The Pattern N4 from GWT-27. ("wet" with lot of cases of heavy precipitations).

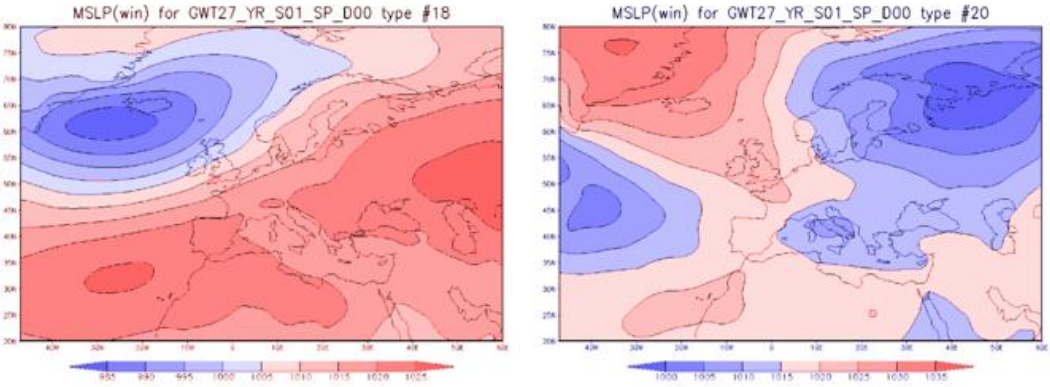

Figure 16: The Pattern N4 (left) and 20 (right) from GWT-27. ("dry" without precipitation).

Note, these "dry" cases are not depended form Ps values, but in both cases the advection of cold air to the middle Black sea is blocked. This below illustrates following conclusions:

- **A large scale synoptic analysis for this region has to establish the factors (cold advection from North or North-East, high humidity flows) to front**

forming near and over the area of forecasters responsibility. For certain days cold advection to the Black Sea has to be detected.

- **The combination with HR results is necessary for notify the forming of the regional circulation or to notify the large-scale synoptic circulation with passing of active fronts with additional advection from North-West.**

6.4.3 Recommended sequence of analysis, design and content of forecasters maps

A view of some - days forecast row of H500 pictures in parallel with P for further 3-4 days

A goal to detect the main atmospheric flow forming advection on area of responsibility, the velocity of processes moving and development, the lapse rates and resemblance to the typical large-scale patterns. The combining of H500 with T2m (or T850) and of P with Middle level clouds and 3-h precipitation amounts is recommended. The printing of these rows of maps is recommended for forecasters for compare the next day old and new forecast rows to discover tendencies of model errors in movement of synoptic objects and front development. The initial part of such forecast row (until 48 hours) by COSMO-Ru7 (step 7 km) is shown at Fig. 17). Figs 18 and 19 present more detailed an example of H500+T2m forecast map design.

Some remarks:

- *The time step for quick large- scale analysis can be 12 hours.*
- *The grid- step of modelling of 15 km is sufficient (If global products with similar grid-step are available, they can be used in similar visualization).*

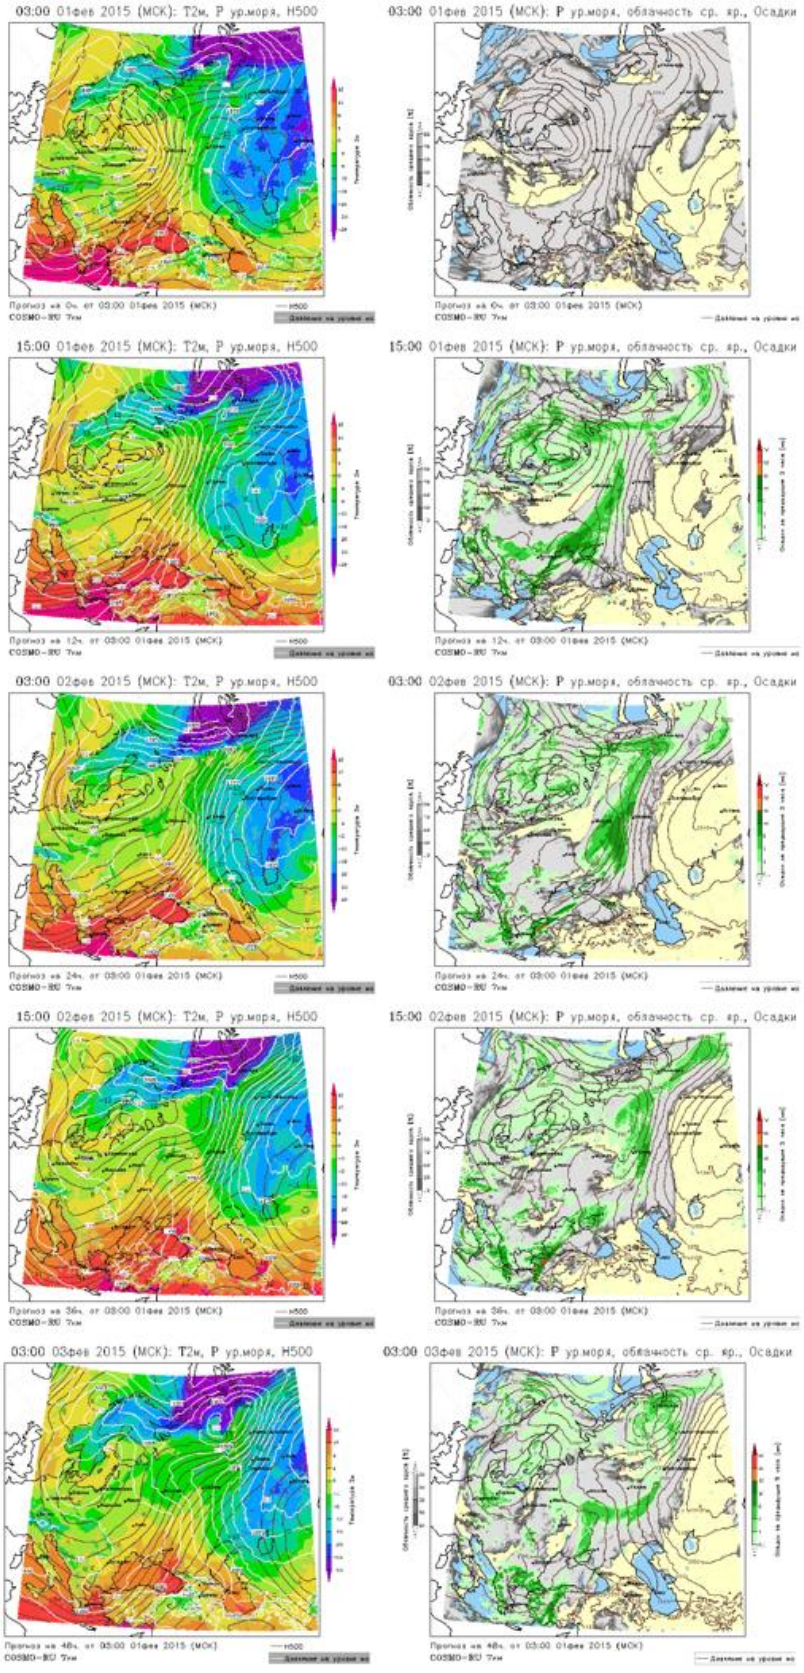

Figure 17: A row of forecasts: H500 and T2m on the left, PMSL, 3h accumulated precipitation and midlevel cloud on the right.

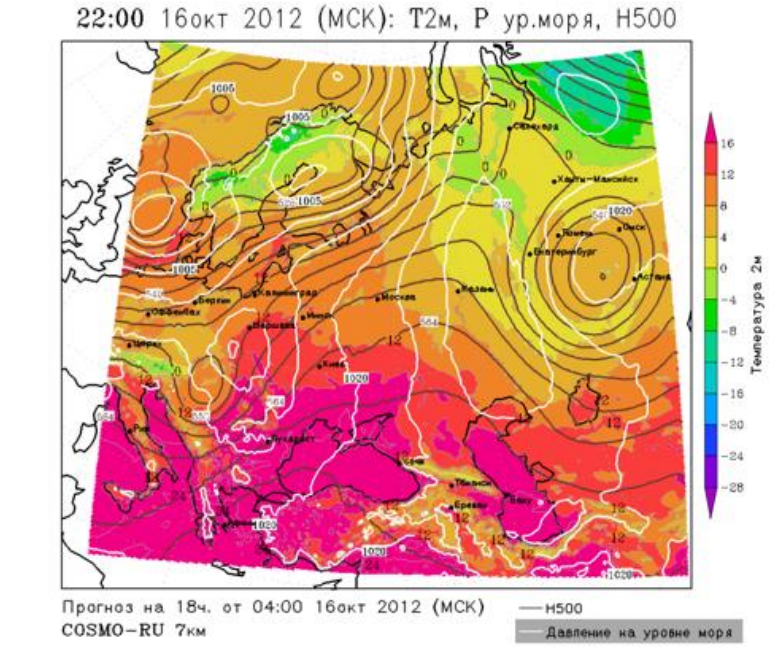

Figure 18: An example map design with H500 and T2m forecast. (Inscription in Russian: (Top) Forecast time and date, forecasted parameters; (Bottom) lead time and forecast start time, model and grid spacing; map legend: color scale for temperature, lines: black- , white: PMSL).

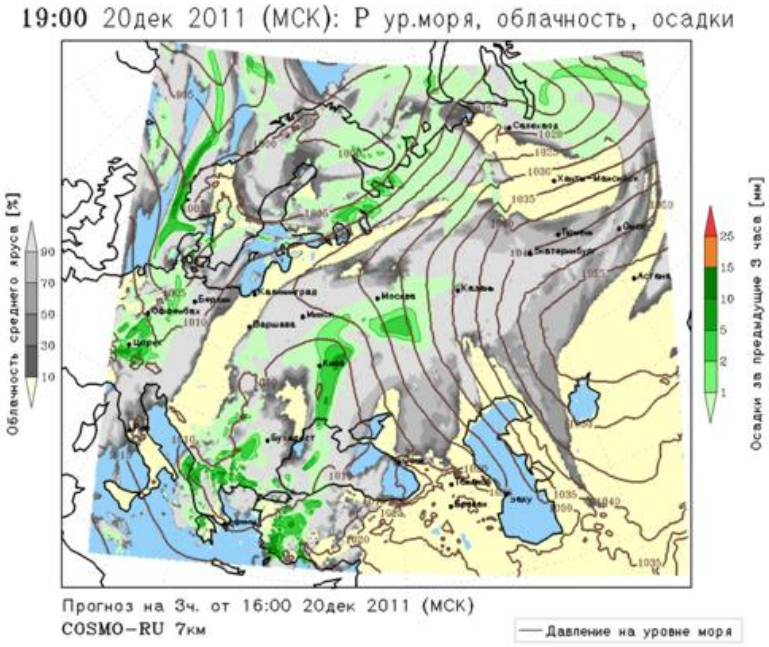

Figure 19: An example map design with PMSL, 3h accumulated precipitation and mid-level cloudiness forecast. (Inscription in Russian: (Top) Forecast time and date, forecasted parameters; (Bottom) lead time and forecast start time, model and grid spacing; map legend: color scale of 3h Precipitation, color scale of Clouds, lines: black: PMSL).

Analysis of maps series of PMSL, Cloudiness, Precipitation with 3h-temporal resolution until 78-84 hours lead time is recommended additionally. This permits to understand the genesis of cyclones and related precipitation. The Mid-level clouds correlate with the frontal area.

Analysis of map series of high- resolution output: COSMO-Ru2 (2.2.km)

Temporal resolution 1 hour, until 48 hours lead time, for entire Caucasian and Eastern Black Sea area:

- Low clouds
- PMSL+ Mid-level Clouds + 3h Precipitation /1h Precipitation (recommended time step of view maps is 3 hours)
- V10m and wing gusts
- T2m + T850
- Fresh snow accumulated for 3 hours and for 24 hours
- Stream lines + Relative humidity at the 900, 800, 750 hPa
- Stream lines + Relative humidity at the 900, 800, 750 hPa

Some design examples are shown in Figs. 20-22.

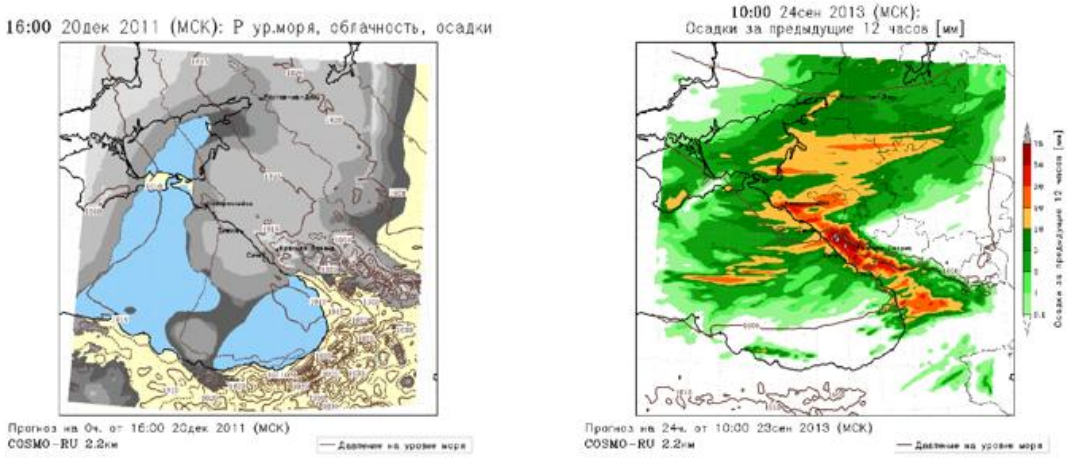

Figure 20: Design of COSMO-Ru2 forecast maps: PMSL, mid-level clouds, 1h precipitation (left) and 12 h accumulated precipitation (right).

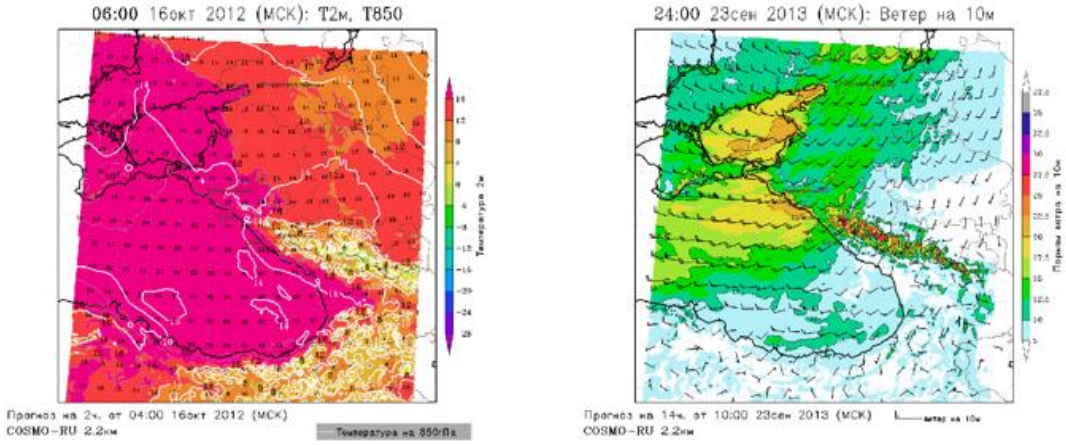

Figure 21: Design of COSMO-Ru2 forecast maps: T2m and T850 (left), wind speed and direction at 10m and wind gusts (right).

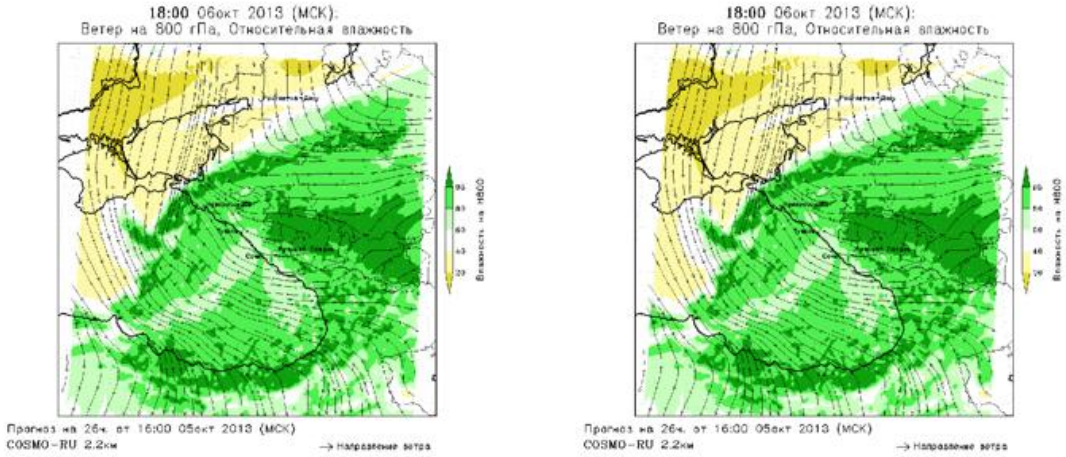

Figure 22: Design of COSMO-Ru2 forecast maps: Streamlines and relative humidity at 800 hPa (left) and at 700 hPa (right).

The Streamlines forecasting maps of HR NWP permits to determine the direction of air movement, the presence of convergence-divergence zones, mesovortices, to specify the time of passage of fronts. The combining with relative humidity helps to determine the change of different air masses (wet-dry), because the relative humidity is the good conservative characteristic of air mass. Sometimes the relative humidity pictures can more clearly indicate the front position (sometimes poorly detected in clouds or wind fields in mountain conditions).

Analysis of rows of maps of high- resolution output: COSMO-Ru1 (1.1.km)

Temporal resolution 1 hour, until 24-36 hours lead time, for Sochi, mountain cluster (minimal area size 200x200 km):

- Low clouds
- Mid-level clouds + 1 h Precipitation
- 12h Precipitation (recommended time step of view maps is 3 hours)

- V10m and wing gusts
- T2m + T850
- Fresh snow accumulated for 3 hours and for 24 hours
- Stream lines + Relative air humidity at the 900, 800, 750 hPa

The products of NWP technology with 1km grid step are the most important kind of NWP information for weather forecasting in the mountains. The most important forecast elements via NWP-1 km are wind and fresh snow fields. The forecasts reflect mountain chains and valleys most accurately (see Fig. 23).

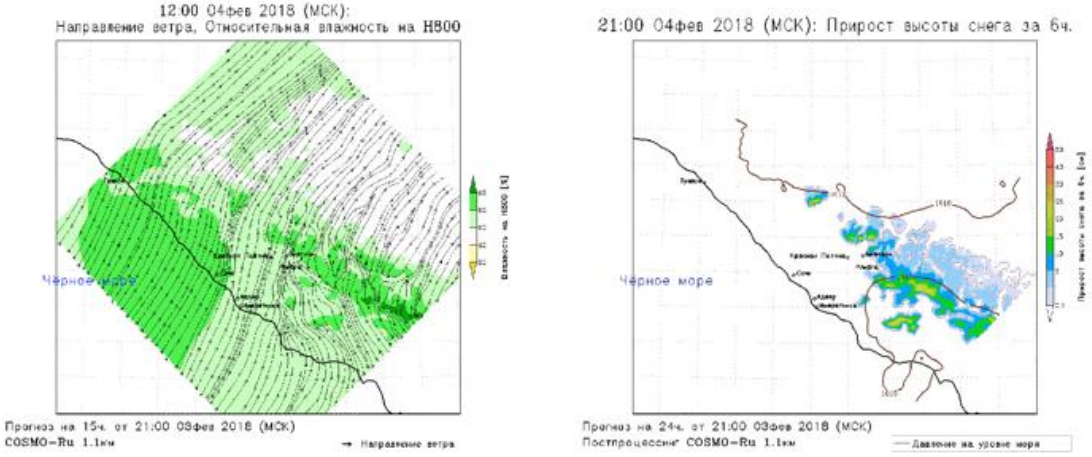

Figure 23: Design of COSMO-Ru1 forecast maps: Streamlines and relative humidity at 800 hPa (left) and fresh snow (right).

6.5 Analysis of Meteograms of deterministic LAM HR NWP

6.5.1 Definitions and goals

Definitions. Meteograms are the graphs, which combine model output (deterministic or ensemble) with form of **time evaluation graphics** of selected meteorological parameters. In case of ensemble forecasting ones are named Ensemble Prediction System meteograms (EPS-grammes). The information of this section relates to **the deterministic high-resolution (HR) model output. Goals and applications.** Meteograms permit to observe time evaluation of key meteorological parameters for selected vertical levels for concrete points. The 1-h (or less) time steps of presenting information (as a rule lesser than for forecasting charts) permits to notify a time of fronts passing, of star-end of weather phenomena, as well of daily temperature extrem time. Another application of meteograms (Fig. 24) is a very quick forecasters complication of meteorological data for big number of points for not large region to receive an information about spatial differences and uncertainties of some parameters. The analysis of NWP matters by forecasters can start by watching of meteograms, as well, it is useful to look at them after analysis of all forecasting maps, after understanding of forecasted synoptic and mesoscale processes. Fig. 24 shows the Meteograms design, which was realized as a result of feed-back from forecasters of Sochi / Hydrometcenter of Russia based on adaptation of DWD variant of COSMO software. The color and placing of picture for forecasts of different parameters are important.

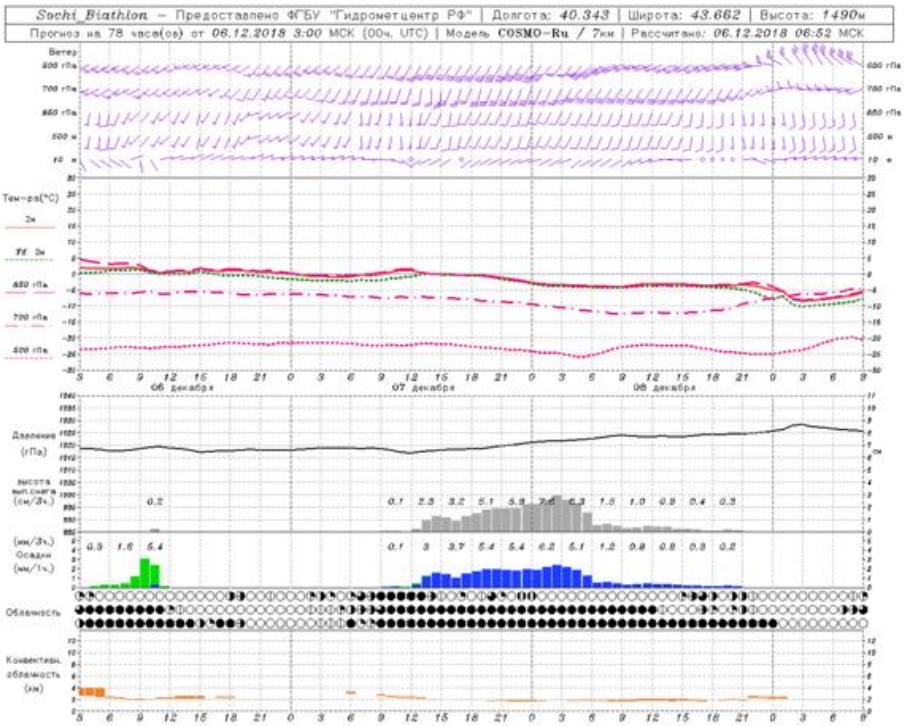

Figure 24: Example of deterministic meteogram for points of Sochi mountain.

6.5.2 Key principles for technology of meteogram forming

- **Meteograms are presented** in some sections of graphics for one point with unified time axe of selected elements adapted to the forecasters expert analysis, e.g. wind, temperature, clouds on several levels, precipitation, etc. The levels for pictures for different elements can be different. A feedback from forecasters for realizing the most efficient pictures design (icluding fast loading of pictures for big number of points on the monitor) is strongly recommended.

- **Meteograms technology has** to provide for quick forecasting analysis the pictures of few-days changes for nominated points of maximal number of important parameters with timestep no more than 1 hour.

- **A severe meteograms around nominated point or inside an area** (a city, a cluster of competitions, etc.) is recommended for more reliable forecasting of random precipitation and of probably hazards.

- **The volume of pictures should be minimal.** This requirement was set up: firstly, to necessity of quick forecasters analysis and comparison of large number of meteograms for different points for one region, secondly, by possible limitations of Internet channels available to forecasters outside on large forecaster centers.

- **Lists of points for meteogram visualization** should be prepared by forecasters/users with indication of Lat/Lon (as rules, there are points of meteostations, towns/cities, important objects, venues of competitions) in stage of forming of meteogram-technology. Systems of forming of meteograms of high resolution modeling such COSMO do not interpolate from the gridded model results to nominated points, and as rules,

a nearest model grid-point is automatically selected. In cases of high spatial variability of geographical properties grid- points have to be manually selected based an expert analysis of geographical properties. As an example, Fig. 25 shows grid-points of COSMO-Ru7 (blue) and COSMO-Ru2 (yellow). In the red are shown the points of venues / observing stations. COSMO-Ru2 grid- nodes nearest to the venues have a good concordance with the 2 nominated points (chance coincidence), but a most representative grid-point for the point Krasnaya Polyana should be chosen manually (which has a close high is preferable from 4 nearest grid-nodes).

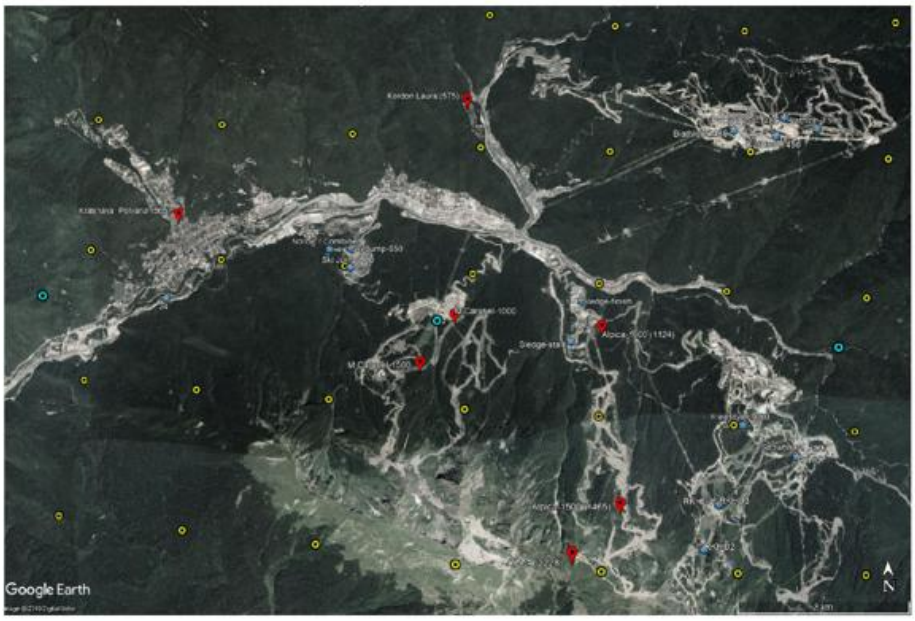

Figure 25: Grid-nodes of COSMO-Ru7 (blue circles) and COSMO-Ru2 (yellow circles) over Earth map for mountain cluster of Sochi region. Red balloons and blue snowflakes indicate the venues locations.

6.5.3 Forecasters analysis based on meteograms

Forecasters should take account that:

- Coordinates of nominated by forecasters points are not same as ones of meteograms (nearest corresponding model grid- points) (see above the previous section) Coordinate values of model meteograms points have be indicated at the top of the picture pages. Forecasters have to compare indicated values with coordinates of real nominated point. In cases of complicate geographical conditions it can lead to the completely wrong forecasts for selected points of local weather conditions (e.g. a land point can be automatically corresponded to a maritime nearest grid point, a point in the valley - to the point at the top of mountain, etc.). In the Fig. 26 grid-point coordinates longitude 40.2E, latitude=43.7N are indicated by red oval. The coordinates of nominated point are 40.1E, 43.6N).
- The real high of nominated point is not same as high of corresponding model grid point (important especially for the mountain cases) High of model grid points is indicated at the top of the picture pages (Fig. 26 at the green oval - 1544m). Forecasters have to

compare these values with ones of real nominated points and to analyze a difference. Some postprocessing technologies calculate the corrected values of T2m and of Td2m based on assumptions of temperature lapse rate. In our example, the real high is only 576m. The results of correction of T2m is shown on the meteogram by violet line, parallel to the red line, corresponding a T2m forecasts from direct model output.

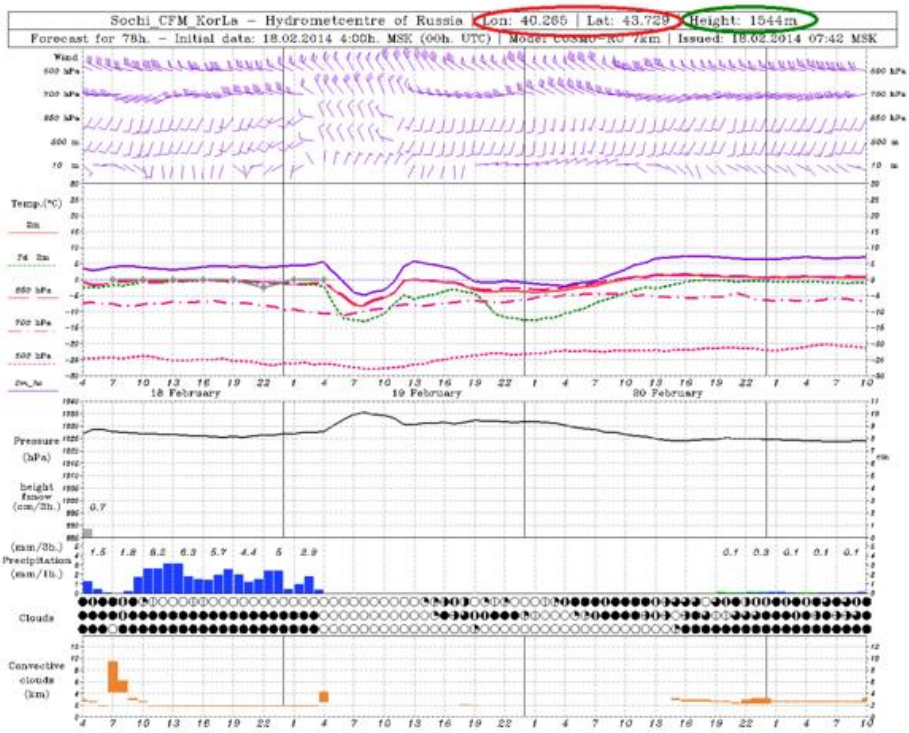

Figure 26: Example of meteogram for Cordon Laura. The coordinates and high of grid- box are circled in ovals (red and green).

There are some features of analysis, important for forecasters:

- *Pressure section:* pressure values and its tendencies, the time interval of minimum due to the rapid cyclone passage
- *Temperature section:*
  - Temperature values and their tendencies at 2, 850 hPa, 700 hPa and 500 hPa can be important for mountain area. Note the inversion state (e.g. if T2m less than T850, in mountains T850 less than T700). (Following special requests, the levels can be other).
  - T850 In mountains regions can be close to the T2m (or underground)
  - An additional T2m values as postprocessing result can be added. Be careful with its analysis.
  - The close and equal values of TD2m and of T2m can indicate the high probability of fog.
- *Precipitation section:*
  - Additional to the vertical columns (1-hour sums) the 3-h sums are written.

- If the T2m is corrected by postprocessing techniques, the additional control of phase of precipitation is useful. In our case (Fig. 26) after T2m lapse rate correction it was warmer than 0 degrees. So, the predicted snow should be not snow, but in case of continuous heavy rain, forecaster could make a decision himself.
- In case of short precipitation and/or precipitation of convective origin. It is useful to analyze meteograms for other close grid- points. The radius of probable precipitation is about 3-4 grid- cells!

- *Cloud section:*
  - Middle level clouds are the most important and indicate with high clear-sky or overcast conditions.
  - Low level clouds have a lowest forecasting skill. This is feasible to control based on synoptic knowledge.
  - Convection existing or not can help to understand the origin of clouds.
  - Maximum convection height (yellow columns at the bottom of the page) can indicate the dangerous convective situations in case of extremely high (more than 10 km) of convection level. In these cases the weather hazards of convective origin have a high probability not only for the point of meteogram, but also around this place.

- *Wind section:*
  - Wind direction and speed at 10 m, 500 m, 850, 700, 500 hPa levels are presented. For specialized forecasts the other levels can be required by users.
  - Sharp changes in wind direction at the lower levels can indicate the time of front passage (in our case- at the first hours of forecast and at 3-rd forecast day).
  - Wind speed more than 25 m/s at 500 m altitude can indicate as a threat of squall at the near-surface level.

6.6 Conclusion

In the current document we shoved the key positions of experience of trainings for forecasters for Sochi forecaster team in 2012-2014 years. This experience could be useful for further trainings from one hand, and from other hand should be developed in further.

7 Acknowledgements

This work was carried out within the COSMO PT CORSO-A and WWRP FDP/RDP FROST-2014. The authors are grateful to Tatiana Dmitrieva (Roshydromet) for providing the information on weather cases during the winter 2014 and to Tiziana Paccagnella (ARPAE) for supporting the work.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

For any comments and questions, please contact the editor:

1 Introduction

As numerical weather prediction models began to increase considerably in resolution, it became clear that traditional grid-point-by-grid-point verification methods did not provide material information about forecast performance. Traditional verification scores often indicate poor performance because of the increased small-scale variability. Numerous methods have been proposed in order to assess the value of very-high-resolution forecasts, including spatial verification methods. Availability of radar and merged radar-station observations contributed to the growth of popularity of these methods. Furthermore, the plethora of spatial verification methods has led to the need to analyse how these methods relate to one another, how each method works, what information could be gleaned from each method, and whether any given method actually conveys any useful information or not. The ICP international project and its second phase MesoVICT (Mesoscale Verification Inter-Comparison over Complex Terrain) were initiated to study how these methods provide feedback about the forecast skill through well-structured experiments (http://www.ral.ucar.edu/projects/icp/). The main objectives of MesoVICT international project can be summarized as follows:

- To investigate the ability of existing and newly developed methods to verify fields other than deterministic precipitation forecasts
- To demonstrate the capability of spatial verification methods over complex terrain and gain an understanding of the issues that arise in such cases
- To encourage community participation in the improvement of spatial methods
- To provide the community with a test-bed with common datasets but also to provide assistance in developing and testing these methods

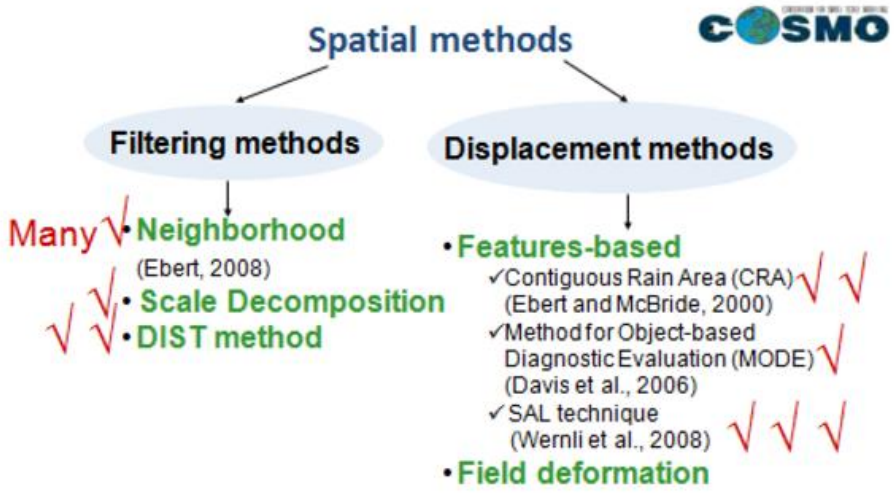

Figure 1: Classification of spatial verification methods and applications in COSMO within the INSPECT project (red signs).

The INSPECT project ran in parallel to MesoVICT to summarize the experience of applying spatial verification methods to COSMO forecast systems of very-high-resolution (1-3 km) compared to high-resolution models, providing criteria for deciding which methods are best suited to particular applications. In addition to targeting the goals of the MesoVICT project, PP-INSPECT provided COSMO users with more choice as to verification domains

and reference data, encouraging the participation of the COSMO community in the testing, development and improvement of spatial verification methods. Fig. 1 represents the classification of spatial verification methods and applications in COSMO within the INSPECT project indicated with red signs.

2 The main outcomes of PP INSPECT Summary

In this section, the main outcomes of the project are listed, while in the following paragraphs a detailed description will be given.

- A number of reruns of deterministic and ensemble forecast systems were performed for MesoVICT test cases (ARPAE-SIMC, MCH, RHM) (Table 1). All the reruns are interpolated into the same grid by M. Dorninger (Austria) in order to make easier the comparison, and are available by request at the MesoVICT site (http://www.ral.ucar.edu/projects/icp/).

- Scripts with examples for running neighbourhood, CRA, and SAL methods using free SpatialVx package are available at WG5 repository (HNMS, IMGW-PIB, RHM). Also examples of scripts to adapt radar and satellite data in a gridded format comparable with model output are available. For Neighbourhood (filtering) and SAL (object-based) methods, testing was performed by means of comparison of results from two independent software packages; bugs are reported to SpatialVx developer E. Gilleland (IMGW-PIB, HNMS). For Intensity Scale (IS) method (scale separation), MET software (NCAR) was also tested in addition to SpatialVx, but the graphical outputs of the packages were different and not comparable with those of SpatialVx. Further investigation is required for the differences in the application of the method.

- Several ways of compact visualization of neighbourhood, CRA and SAL methods were proposed (DWD, MCH, RHM). Especially for neighbourhood scores, such a cumulative framework can be implemented as part of the Common Verification activity.

- An object-based SAL (Structure-Amplitude-Location) method was found easier to implement than MODE and CRA methods as it does not require pair-wise matching of observed and forecast objects. The results however must be considered carefully as the method considers average characteristics over a domain. The accumulation precipitation range should not be small. It is recommended to calculate the SAL parameters with 6h precipitation range and higher, unless a highly convective case with significant precipitation amounts is tested. Object-based MODE and CRA methods provide more information compared to SAL about individual features of precipitation field, as they estimate matched pairs of observed and forecast objects. Smoothing of the fields can lead to the creation of bridges among different objects that are close to each other and unify them. This can significantly change the results of all object-based methods. On the other hand, smoothing can be undesirable for estimating objects with intense precipitation (or other variable of interest). The option to discard objects that are smaller than a certain size is found useful. When applied to observations, it eliminates small objects of any intensity that can be erroneous noise. Option for splitting objects is desirable sometimes. (HNMS, RHM, IMGW-PIB, ARPAE-SIMC).

- For MODE and CRA methods, it was found not feasible to identify one optimal universal matching function, in particular for high-resolution fields with objects of complex shape. For lower precipitation thresholds (and, consequently, wider features), more

Institution	Forecast system
MCH (P. Baumann)	COSMO-1 reruns for ALL MesoVICT cases are done and available at WG5 repository
ARPAE-SIMC (A. Montani)	ECMWF-IFS reruns (51 member) for cases 1 and 2 (8 initial dates)
MCH (A. Walser)	COSMO-E reruns (21 member) for cases 1 and 2 (8 initial dates)
RHM (D. Alferov and E. Astakhova)	COSMO-Ru2-EPS (51 member) for case 1 (1 initial date) and case 2 (1 initial date)

Table 1: Reruns of forecast system for MesoVICT cases.

reasonable results were obtained for a criterion based on matching observed and forecast objects if the distance between them is less than their average size. For higher thresholds, this criterion often does not allow for successful matches due to the small areas of features. A minimum boundary separation criterion seems more promising for intense events, but with a minimum boundary separation distance, beyond which, features should not be matched (RHM, IMGW-PIB).

- The IS scale separation method allows for the skill to be diagnosed as a function of the scale of the forecast error and intensity of the precipitation events. Results show that reduction of skill is mainly due to the small-scale misplacement of more intense (rare) precipitation events. Wavelet-based (Hier wavelets) scale-separation statistics are suitable for comparing models with different resolutions as the reference forecast accounts for the forecast variability. The method allows the analysis of precipitation instances, but it is not able to provide generalized information on the relative long term performance of a modelling system based on aggregated data.

- Applications of DIST, SAL and CRA methods to ensembles were made and new approaches on summarizing performance over various members and time accumulations were proposed.

- First results of experiments on introducing observation uncertainty into the spatial methods are given.

What was not completely fulfilled within the project and needs to be further studied:

- Introducing orography factor explicitly.

- Wind characteristics were only partially explored by M.S. Tesini (ARPAE-SIMC). The upscaling DIST method was applied, which analyses the statistical parameters of values in boxes of increasing size. For wind speed, the representative value of the box was defined as the median exceeding a predefined threshold; for wind direction, as the most populated category after having binned the direction in 8 categories. First results on DIST application to wind, were found not very satisfactory. The possible reasons were identified as follows:

  - possibly, the representative value of the box could be defined in another way;
  - the verification period was very short;
  - wind is too localized and the aggregation has benefit only if the boxes were chosen based on a different criteria that those of precipitation;
  - taking into consideration the orography (valley,) is required.

- Spatial applications to wind and other variables (e.g. Cloud cover) besides precipitation should be further developed.
- Only a limited number of applications to ensembles were performed. This direction of spatial method application is much demanded at present, and should be developed.
- Introducing observation uncertainty in the analyses was initiated by D. Boucouvala (HNMS) (see Sec. 4.1.3). This topic requires further study.
- Processing large amounts of data (for example nowcasting forecasts verification) will be of increased demand in the future. In Sec. 4.3.3, we describe an RHM experience of assessing the nowcasting scheme during the summer 2017 using the CRA method. The computational efficiency and the optimal organization of the data will be of utmost importance for processing large amounts of data.

Moreover, the PP INSPECT supported the efforts to increase COSMO visibility worldwide due to the active participation of COSMO members in the international project MesoVICT and its activities as well as in the WMO-JWGFVR workshops. Finally, it should be noted that the project was focused on the comparison of the spatial methods, and not on assessing the model performance, although some reflections to the advantages of different forecast systems were made.

3 Filtering methods

3.1 Neighbourhood Methods (Flora Gofa, HNMS)

3.1.1 Method applied (related to an INSPECT Task) and objectives

Neighbourhood verification is based on the principle of expanding the field of view to nearby (neighbours) data points in space, employing a spatial window around the forecast and observed points. In this way, the penalty for differences between modelled and observed values is relaxed. The size of this neighbourhood can be modified in order to verify model performance at several different scales, thus providing insight into the scales the model has the most skill at. Since the size of the neighbourhood can be varied, such approaches are well suited to verification of high-resolution models (Casati et al., 2008). In addition to neighbourhood size, the type and degree of filtering applied can also be modified. For example, extreme values may not be filtered out when examining severe weather events. Furthermore, in most cases, as in this research, the filter is applied to both the forecast and the observations. A more detailed review of neighbourhood approaches is available in Ebert (2008).

3.1.2 Short description of the dataset (forecast-observation data), adaptation required, software for the method application

The datasets used in the context of this study have been obtained from the Mesoscale Verication Inter-Comparison over Complex Terrain (MesoVICT) project. MesoVICT has been established in order to facilitate the application, capability and enhancement of spatial methods both for deterministic and ensemble forecasts (Dorninger, 2013). MesoVICT benefits from a huge data collection effort within the framework of the World Weather Research

Programme (WWRP) Project: Mesoscale Alpine Programme (MAP) D-PHASE over Central Europe in 2007. All six available test cases were analysed that cover a wide range of meteorological phenomena in and around the Alps. The example that is presented here is for the period 20-22 June 2007. With respect to the synoptic situation, the region of interest is ahead of a trough located over the British Isles, and warm moist air is being advected towards the Alpine Region. This leads to strong convective events on the evening of 20 June in the area north of the main mountain range. Subsequently, a cold front reaches the Alps from the west and moves to the east rather quickly while convective events are again observed ahead of the front (Fig. 2).

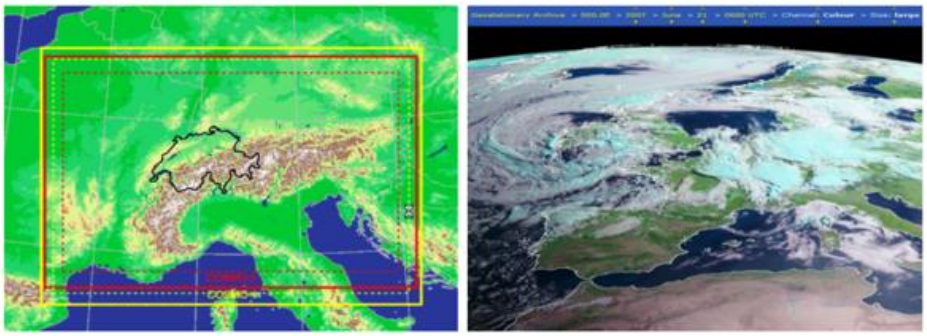

Figure 2: Left: COSMO-1 (dashed yellow), COSMO-2 (dashed red) integration domains, Right: Satellite image, cloudiness on 21.06.2007, 00UTC.

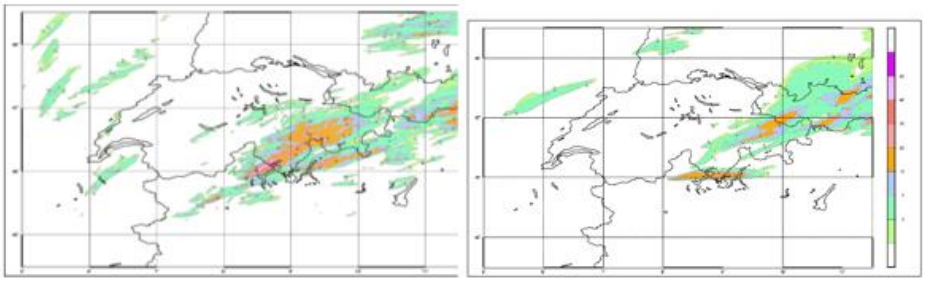

Figure 3: 12h accumulated precipitation at 21.06.08: 18UTC Left: COSMO-1, Right: COSMO-2.

From the multitude of NWP models with varying resolutions that are available through the MAP-D Phase, forecasts derived from COSMO-2 (2km res.) and COSMO-1 (1km res.) of the Swiss Meteorological Service were used. The domain of the COSMO model is shown in Fig. 3. Both models were nested on a coarser 7km COSMO model. Hourly precipitation forecasts from both models were upscaled prior to the application of neighbourhood methods in order to match the resolution of the observation fields in a final 8km grid spacing to match the observations.

3.1.3 Verification software

For the purposes of this research, the VAST (VERSUS Additional Statistical Techniques) software package, which was developed by the COSMO consortium and is based on Beth Eberts fuzzy verification IDL (Interface Design Language) code, was employed (Vela, 2017). VAST offers a number of neighbourhood verification tools, of which the following were tested

in the context of this research: upscaling, anywhere in the window, minimum coverage, fuzzy logic and joint probability. What distinguishes one method from another is the decision model, i.e. how strict or relaxed are the criterion that determine whether a forecast is successful or not. A large variety of methods and scores were calculated for a number of thresholds and window sizes, but only a selection of representative results are presented here.

3.1.4 Main findings (plots and explanation)

In this section, a short evaluation of the results of the application of some neighbourhood methods (Fig. 4) is given. Fractions skill score. The decision model is: "A forecast is useful if the frequency of forecast events is similar to the frequency of observed events", giving information on the spatial scales that the forecast resembles the observations, ranging from 0 to 1 (perfect). The score is most sensitive to rare events (e.g., small areas of precipitation); the useful scales are indicated in bold (Fig. 4). The FSS values for both COSMO forecasts are greater for light rain thresholds and larger scales, with useful skill displayed at spatial scales of around 130 km or larger for light rain and not at all for the heaviest rainfall rates. COSMO-1 forecasts exhibit similar behaviour with COSMO-2, being more useful for slightly smaller spatial scales (70km) for small to medium rainfall thresholds, while for higher thresholds COSMO-2 seems to be slightly more useful than COSMO-1.

Pragmatic approach. Instead of verifying the forecast probability within a neighbourhood against the observations within that same neighbourhood, the forecast is verified against the observed value in the central grid box. The decision model is that a useful forecast has a high probability of detecting events and non-events supported with the use of Brier skill score (BSS) to quantify the forecast success. The limited application of this method over the test case in Alps indicated that there is only minor improvement of the forecasts versus the reference, which is the sample climatology of the observations over the whole domain.

Upscaling method. It is the most widely used neighbourhood verification technique. Forecasts and observations are simply averaged to increasingly larger grid scales for comparison using a range of standard statistics. The decision model is that a good forecast has approximately the same mean rainfall amount as the observations. For this particular case, the ETS (equitable threat score) was calculated for each window size/threshold and, as shown, the scores generally improve with increasing scale and smaller rainfall thresholds, while the relative advantage of COSMO-1 forecasts is demonstrated.

Fuzzy logic approach. It is based on the fact that a forecast has a certain likelihood of being an event and a certain likelihood of being a non-event, and this is also the case for the observations. This likelihood is called the weight of support. This means that a forecast can be somewhat correct and somewhat incorrect at the same time (window). The decision model is, a forecast is useful if it is more correct than incorrect. From the categorical scores, BIAS is calculated in order to provide a more precise picture of the scales and thresholds that each model overestimates (BIAS > 1) or underestimates (BIAS < 1) hourly precipitation amounts. Other neighbourhood methods and scores for each method were calculated in an effort to explore the variability in the information that can be provided from their application to two different modelling systems which have not been included in this paper.

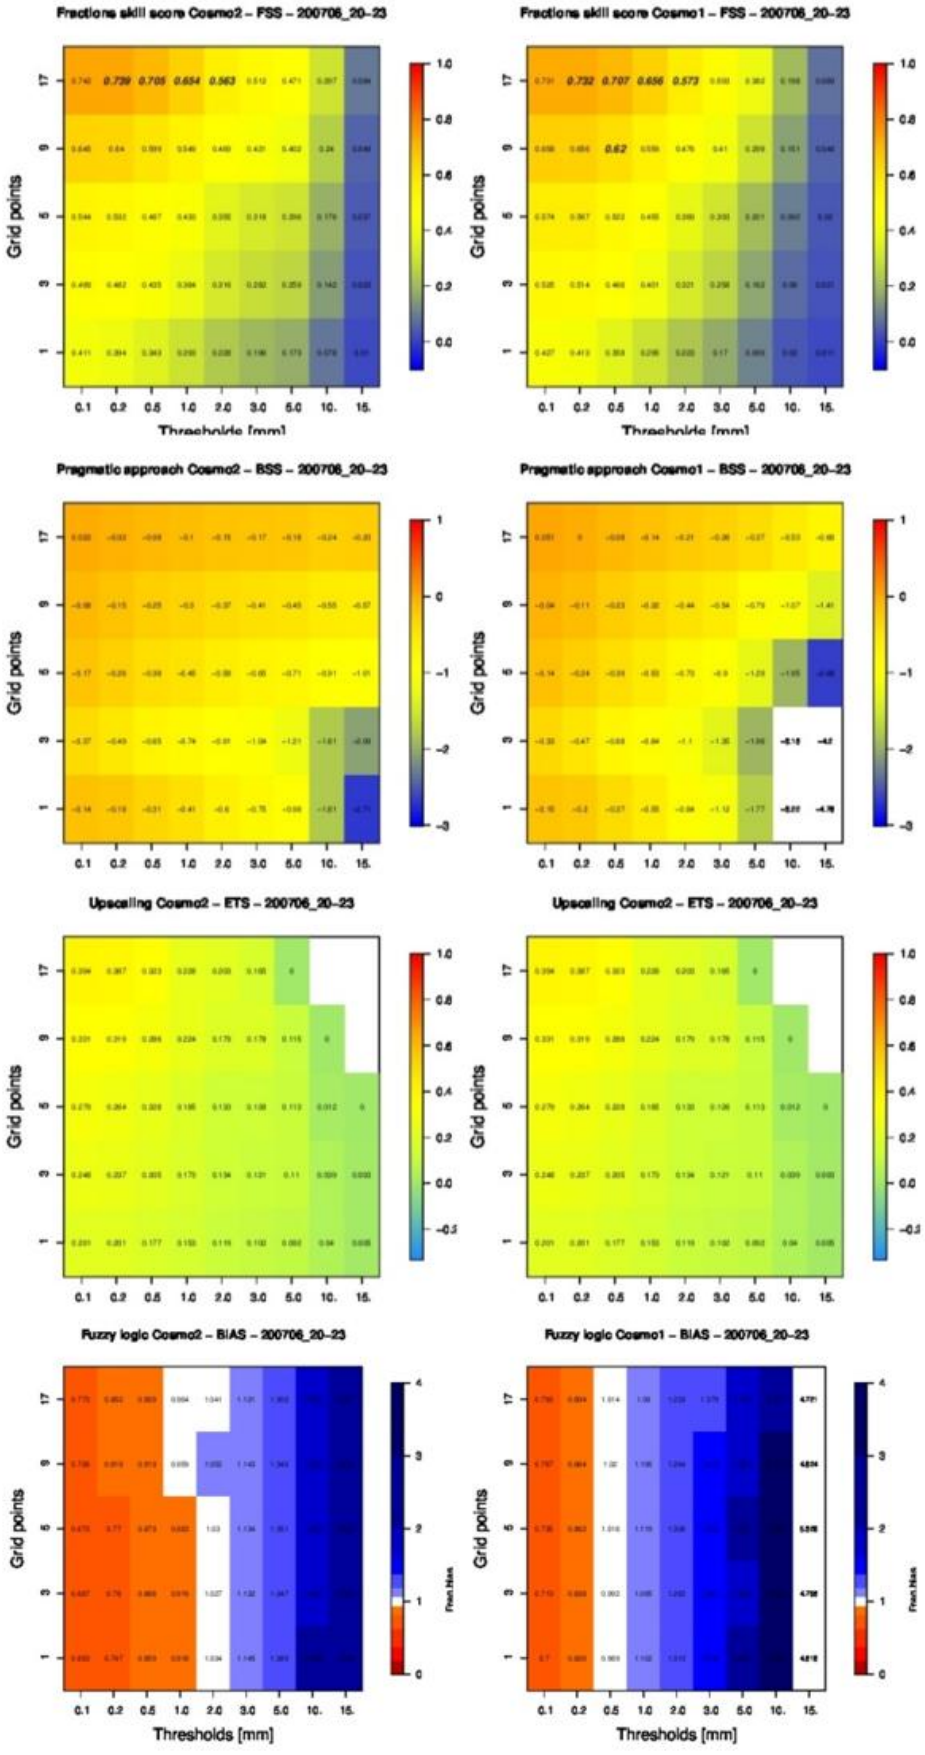

Figure 4: Fraction Skill Score (FSS) (first row), Pragmatic Approach (BSS) (second row), Upscaling (ETS) (third row), and Fuzzy Logic (BIAS) (fourth row) for COSMO-1 and COSMO-2.

3.1.5 Characteristics of the method applied)

- Efficiency in calculation time: the efficiency in time is quite satisfactory with respect to VAST. A significant effort is required to adapt the datasets and make them identical in size (grid dimension and resolution) prior to the application of VAST. If the user keeps the default amount of space windows (5) the calculation is rather fast, while it increases dramatically with the addition of even one additional space window. The adjustment of thresholds is easier and faster. No application was performed on time windows so far.

- Ability to deal with different density of observations: the method requires a complete set of gridded observations and forecasts with no gaps in the domain of verification. In case of inhomogeneous density of observations, the user has to adapt the dataset accordingly.

- Stability against observation errors: neighbourhood methods do not account for observation errors, as by relaxing the requirement of exact match in point and the use of averaged values over space windows for both forecast and observations, the weight of such errors on the verification results is eliminated.

- Ability to assess the added value of high-resolution models: neighbourhood methods provide a tool to compare modelling systems of various resolutions and are particularly valuable in the case of high resolution forecasts. However, before deciding on the methodology or score that is more suitable for a model evaluation, the first step in this approach involves carefully defining the attributes of a good forecast and subsequently identifying the specific methods and their associated decision models best suited to the particular application. Neighbourhood verification is particularly valuable in the case of high resolution forecasts, providing useful feedback on the scale and intensity for which each model configuration is advantageous. Precipitation events on different spatial scales are produced by different physical processes (e.g. large-scale frontal systems or small-scale convective events). Verification at different spatial scales provides greater insight into model performance to simulate these different processes.

Although the value of a neighbourhood verification framework has been demonstrated for this particular test case, its most sensible use is for evaluating sets of forecasts to determine typical forecast performance. For example, it can be used to monitor monthly or seasonal forecast performance in a region. It can also be used to evaluate updated versions of a model to identify at which scales and intensities, if any, skill has been improved (Gofa, 2017).

3.2 Analysis of long time series of neighbourhood scores (in particular: FSS, upscaling with ETS and FBI) for precipitation. Further investigation into the most informative and compact representation of scores.

3.2.1 DWD experience (U. Damrath)

At DWD, the spatial methods have been developed during many years. This section describes the analysis of long time series of the following scores: the Equitable Threat Score (ETS) for upscaling and the Fractions skill score (FSS). In (INTERP 2009), these scores were identified among the most useful. The analysis scheme is as follows:

- Getting the ETS for upscaling and FSS as monthly values from fuzzy verification

- No averaging over daily values is applied, but the calculation of scores from the contingency tables of the whole month is performed
- Calculation of running means of the results over one year
- Presentation of mean values and mean averages

Data sources that were used in this study:

- Precipitation forecasts of German COSMO-models and GME (with March 2015 ICON)
- Precipitation observations from radar data

Grid sizes and thresholds:

- Grid size from 0.025 (resolution of COSMO-DE) to 1.625 (65*resolution of COSMO-DE). For COSMO-EU the values are taken for the whole grid cell that is in this CDE-grid cell. Thus, there are about 9 points with equal values for the lowest window size
- Thresholds: 0.1, 0.2, 0.5, 1, 2, 5, 10, 20, 50 mm/12h or mm/24h

Fig. 5 gives an example of score visualization for the whole German territory. The red indicates that COSMO-EU is better, and the blue, that COSMO-DE. In this case, the higher resolution model advantage becomes evident only for the largest windows.

Overall, the results indicate that we are not able to make real forecasts for the lowest window size. A coarse value from the model with lower resolution has no double penalty.

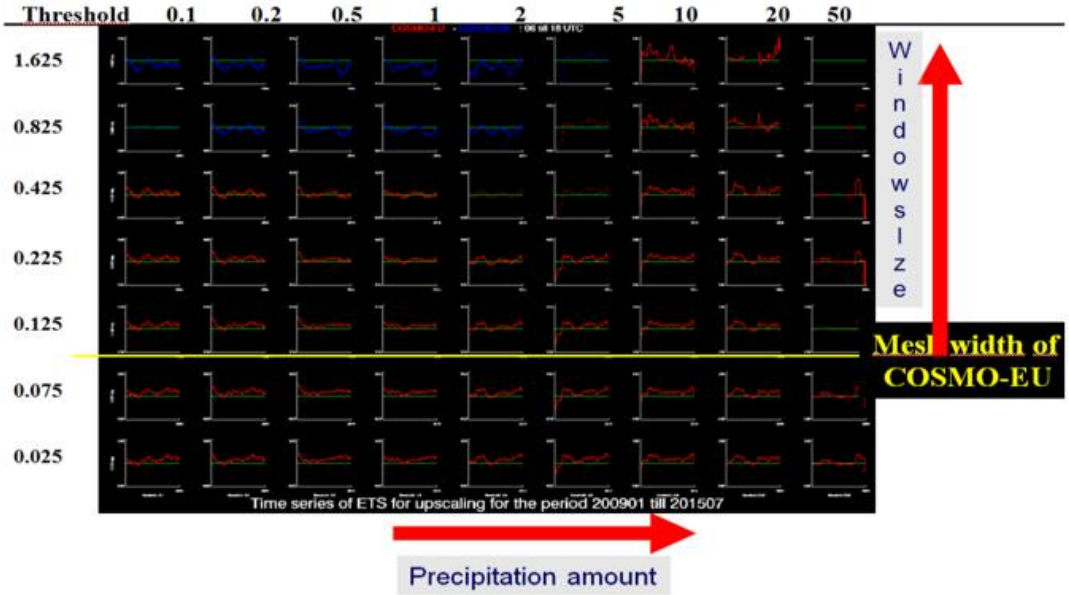

Figure 5: Comparison of COSMO-EU to COSMO-DE Differences of upscaling ETS. 06-18 UTC.

3.2.2 Evaluation of 4dVerif spatial verification visualization (X. Lapillonne, MeteoSwiss)

The use of spatial verification can bring new insight to the verification of model variables. It has a particular added value when it comes to verification of precipitation field since it can overcome the so called double penalty effect which occurs when a precipitation happen at a wrong geographical location in the model as compare to the observation. Because of its two dimensional structure it provides additional information as compared to stations based verification which needs to be visualized. In this report section we discuss some aspect of the visualization of these verification results and in particular how this information could be reduced so as to be easier to interpret.

Fraction skill score with 4dverif at Meteoswiss for precipitation verification

We focus here on the fraction skill score obtained with the 4dverif software run at MeteoSwiss. The fraction skill score (Roberts N.M., 2008) is one of possible available surface verification scheme. The basic idea of this score is to define an area or scale (here squares) and to count events in this region (fraction area) both in the model and in the observation. One then obtains a score for different scale see Fig. 6 and Fig. 7. A so called useful scale, see (Roberts N.M., 2008), is also defined above a certain score (in bold in Fig. 7).

The potential scale information introduces a new dimension in the verification parameter space, which is coming in addition to other existing parameters such as lead-time and initial forecast time. This provides potentially very detailed insight in the data which might be very useful for research purpose or to better understand the model but may be overwhelming for standard verification purpose, see Fig. 8.

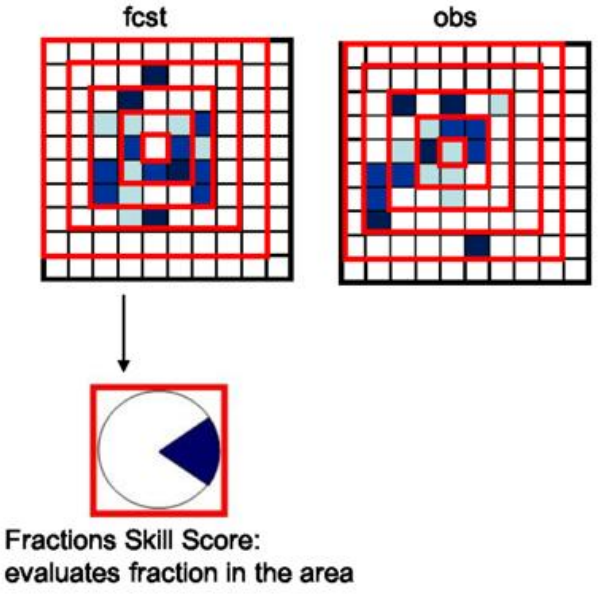

Figure 6: Surface evaluation area.

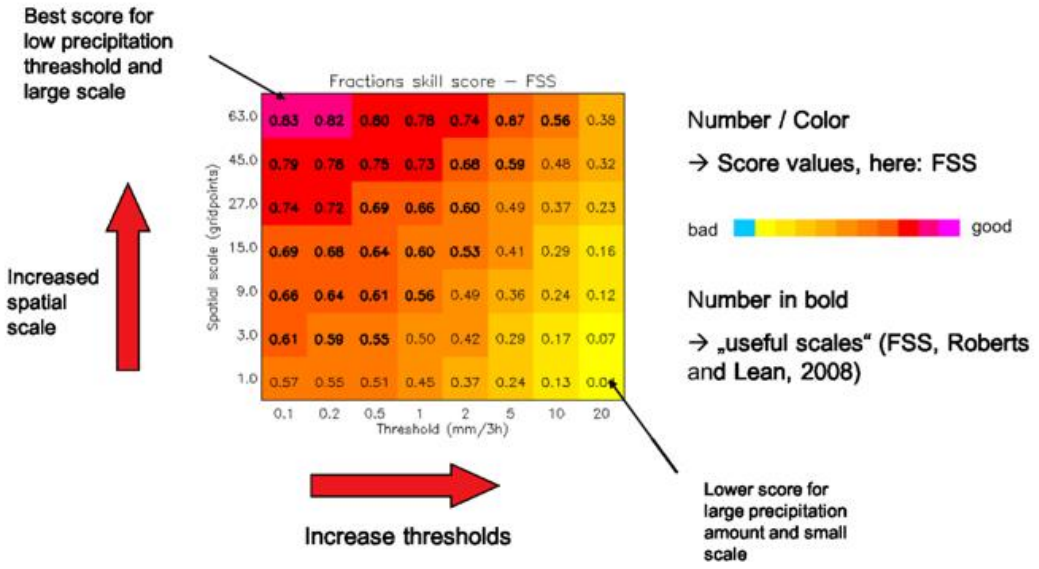

Figure 7: Fraction skill score (FSS).

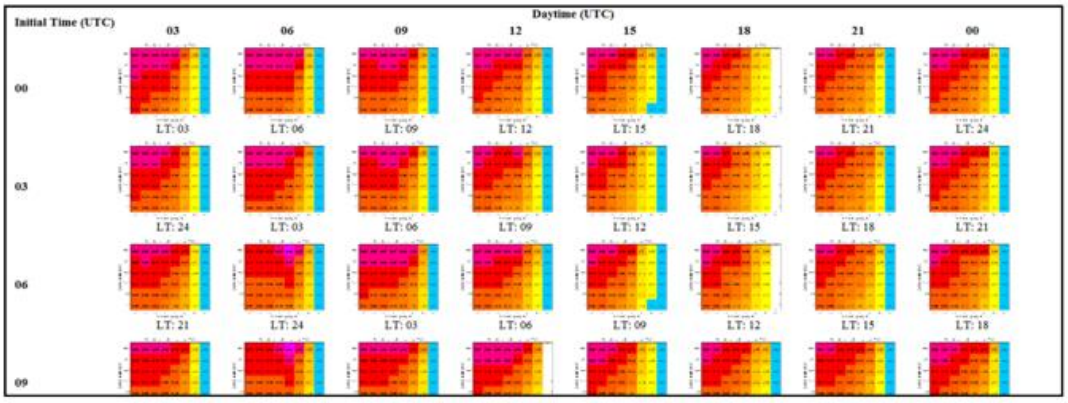

Figure 8: FSS for all lead times, initial time, scale and scores.

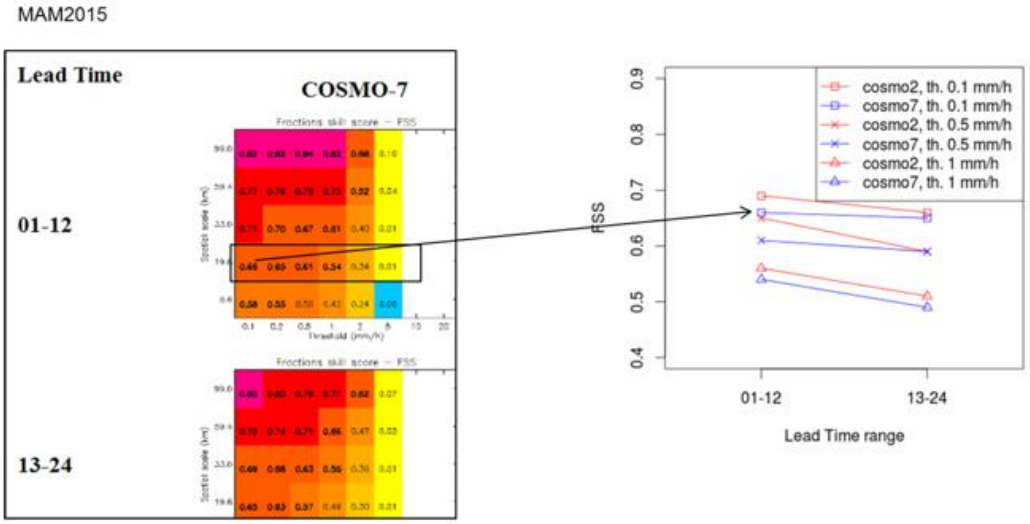
Simplified visualisation

It is suggested to reduce the available information by showing the most relevant part for standard verification on a one dimension plot which resembles usual station based verification or in a table. For the considered score and variable we propose for example 2 different cross sections of the data. The first one is to select a single meaningful scale and to show for selected threshold the score as a function of leadtime. In Fig. 9, we show the FSS for two models for the scale 19.6 km which roughly corresponds to the size of a warning region in Switzerland.



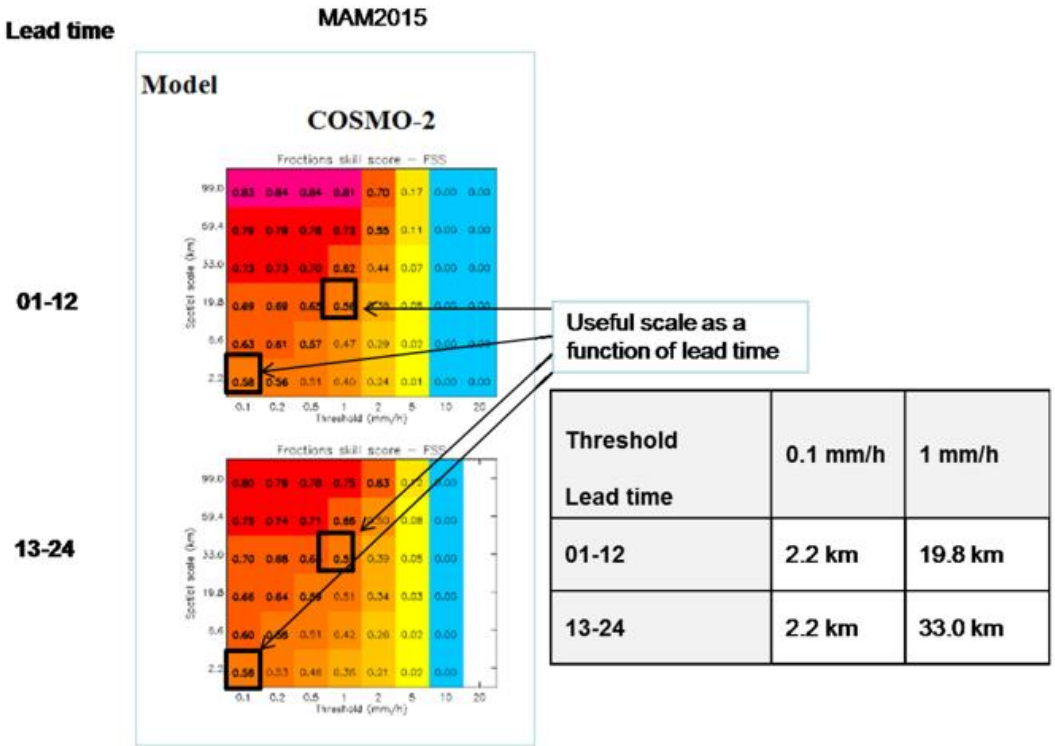


Figure 9: FSS for a selected spatial scale (19.6 km).

The second proposed way of displaying the data is to focus on the useful scale information. In Fig. 10, we show the useful scale as a function of lead time for different threshold. This could be interesting for example to help saying which model may be use for warning. Note that this information has a strong seasonal variability.

Threshold / Lead time	0.1 mm/h	1 mm/h
01-12	2.2 km	19.8 km
13-24	2.2 km	33.0 km

Figure 10: Useful scale as a function of lead time for different threshold.

Conclusions

The spatial verification provides new insight and information in comparison to standard station based verification. This additional information may be for some usage overwhelming and some reduction this information may be necessary. Here we propose for the fraction skill score two different potential ways of displaying the score. The first one is to look at the score for a given spatial scale while the other one focus on the so-called useful scale for a given lead-time and threshold.

3.3 Wind verification with DIST method: preliminary results (M. S. Tesini, ARPAE-SIMC)

3.3.1 Motivation of the study

Current wind forecast verification at ARPAE-SIMC is not completely satisfactory. It provides too local results difficult to summarize for a large number of stations. The DIST methodology (Marsigli et al., 2008) used operationally to verify precipitation has pointed out some advantages with interesting results. DIST provides the scores for different distribution parameters calculated for model and observed variables in boxes of increasing size. One of its main advantages is that it can be performed using both sparse point observations and gridded observation against gridded forecast (even if the grids are different). The size and even the shape of the box can be freely defined (e.g. alert areas for hydrological purposes). It provides simple information to forecaster or hydrologist about the performances of models in a single area of interest (e.g. Alert Area) or over the whole model domain aggregating the results of all boxes. The MesoVICT project encourages the investigation of the ability of existing or newly developed spatial verification methods to verify fields other than deterministic precipitation forecasts, e.g., wind forecasts.

3.3.2 Representative value of the box for wind characteristics and verification setup

It is important to define the representative value of the box for DIST application. Thinking to a more user-oriented verification we considered the median (e.g. the value below (or above) which 50% of the data may be found) and the 90th percentile (e.g. the value below which 90% of the data may be found, or above which 10% of data may be found) for wind speed. For wind direction, as a first step the values were binned into 8 category (N, NE, E, SE, S, SW,W,NW). Then the most populated category was taken as representative for the direction in the box. Since the direction for light wind may not be significant, another representative value has been evaluated considering only the direction for wind with intensity > 3 m/s. All the values of 3 consecutive hourly forecasts (and observations) that belong to the same area are put together to account for timing errors. The study was performed for all three MesoVICT cases (Dorninger, M.et al., 2013). The Swiss COSMO-2 and COSMO-1 model data were used. VERA gridded analysis was used as a reference data (Dorninger, M.et al., 2013).

3.3.3 First results

Fig. 11 represents three scores for events wind speed median exceeding a threshold. There is no clear increase of the forecast quality with increasing box size. In Fig. 12, the performance diagram is displayed for all three MesoVICT cases. In general, enlarging the box increases BIAS, but POD and FAR are slightly better. The scores move more or less linearly from 1

to 25 points in the box, but not from 100 to 400 pts. It is unclear if this behaviour depends on some scale of the considered phenomena or the data are not enough to produce consistent statistics. More investigation is needed to understand that. In Fig. 13, Wind speed threat score (TS) for COSMO-2 and COSMO-1 are given for boxes of increasing size. The event is defined here as 10% of points exceeding a predefined threshold. Scores (and trend of scores) considering boxes are nearly the same for the two models. COSMO-1 nearest grid point performs better than aggregation on 8 Km box. It is unclear if this can be explained with wind field characteristic or it is only an unlucky case. Maybe the choice of this percentile is not useful as was thought initially. Fig. 14 gives the PSS for wind direction for COSMO-2 and COSMO-1 for boxes of increasing size. The representative value is defined using all the data and considering only the direction for wind with intensity > 3 m/s. At larger scales, all the local information is filtered out. For boxes of smaller size, the information about local winds should be predominant. Another aspect is that it is not completely evident that VERA analysis is able to reproduce very local features.

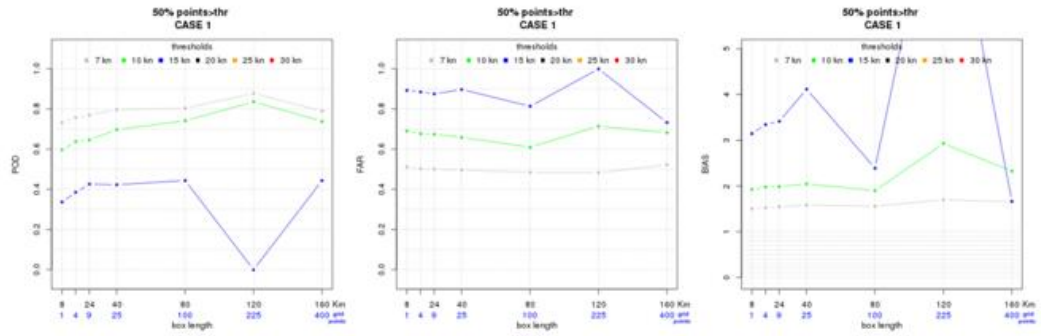

Figure 11: Probability of detection, False alarm rate, and frequency bias for wind speed (in knots), MesoVICT case 1, Cosmo-2 model. The event is defined as median exceeding a predefined threshold. The scores are plotted as a function of the box dimension.

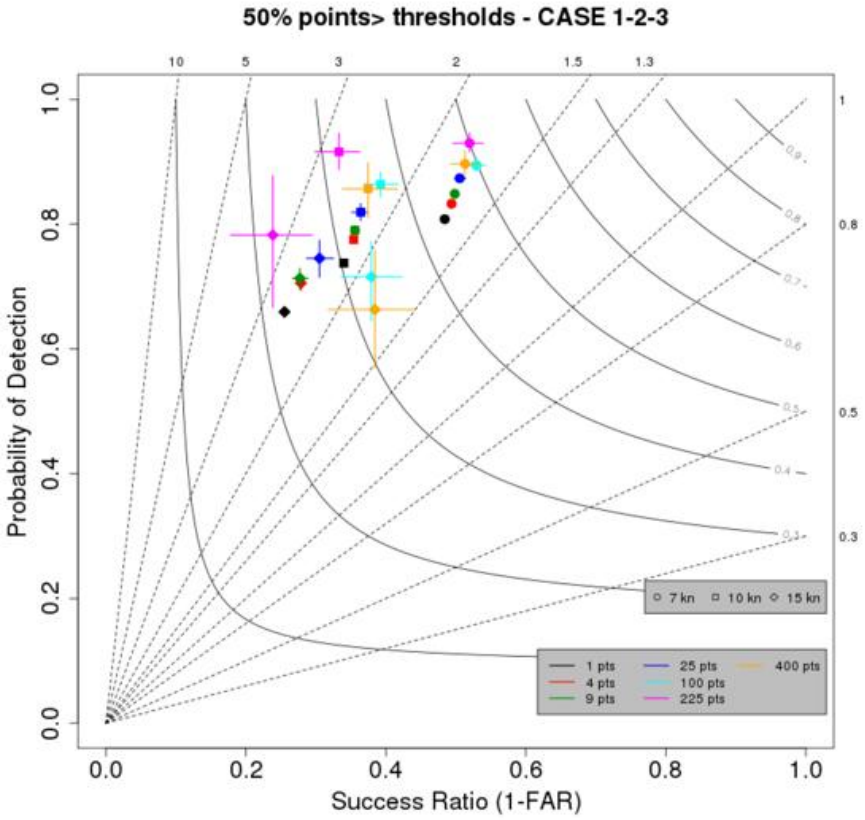

Figure 12: Performance diagram for wind speed (in knots), MesoVICT cases 1. 2. and 3, Cosmo-2 model. The event is defined as median exceeding a predefined threshold.

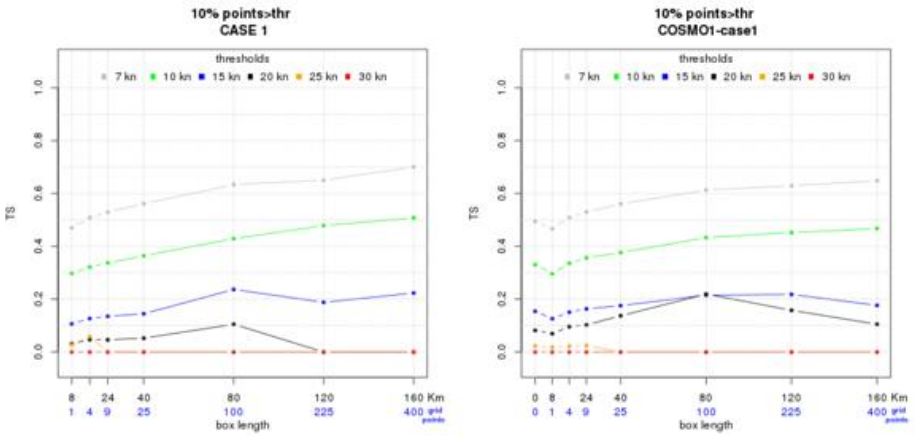

Figure 13: Wind speed threat score (TS) for COSMO-2 (a) and COSMO-1 (b) for boxes of increasing size. The event is 10% of points exceeding a predefined threshold.

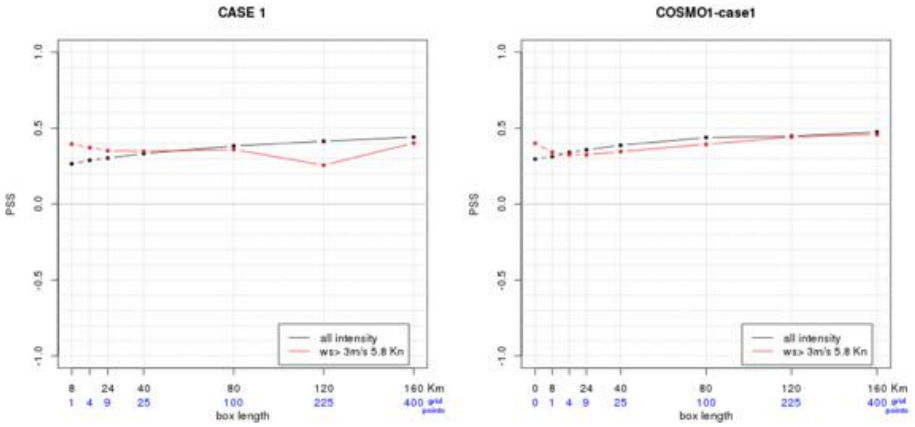

Figure 14: Wind direction, MesoVICT case 1, Cosmo-2 (a) and Cosmo-1 (b), PSS (Peirces skill score: What was the accuracy of the forecast in predicting the correct category, relative to that of random chance).

3.3.4 Conclusions

The first results on DIST application to wind were found not very satisfactory. The possible reasons were identified as follows:

- possibly, the representative value of the box could be defined in another way;
- the verification period was very short;
- wind is too local and the aggregation has is benefit only if the box were chosen differently;
- taking into account the orography (e.g., wind in valleys) is needed.

But before giving up tests are needed for other MesoVICT cases and using the JDC original observation (one of the main advantages of DIST was to deal with sparse point observations). It is also important to look at the geographical distribution of the scores.

3.4 Intensity-scale method (F. Gofa, HNMS)

3.4.1 Method applied (related to an INSPECT Task) and objectives

Scale Separation Methods: in general with these methods you decompose forecast and observation fields into the sum of spatial components on different scales by using spatial filters, and then you perform the verification on each scale component, separately. Verification on different scales can provide useful insight into NWP model representation of the different physical processes associated with phenomena on different scales. Scale-verification approaches aim to assess quality and skill of the forecasts for different spatial scales, analyse the scale-dependency of the forecast predictability (e.g. evaluate the no skill skill transition scale), and assess the forecast ability to reproduce scale spatial structure of observed precipitation fields. Precipitation fields are characterized by the presence of features on different spatial scales triggered by different physical phenomena. As an example, events such as

frontal systems are driven by the mesoscale dynamics of the atmosphere, whereas smaller scale events such as showers can be developed by local convective motions. Verification on different spatial scales can provide a deeper insight in the model performance at simulating different dynamics and give useful feedback for improvements. The intensity-scale technique for verifying spatial precipitation forecasts was tested in the framework of PP INSPECT. The technique provides a way of evaluating the forecast skill as a function of intensity of the precipitation rate and spatial scale of the error. The forecasts are assessed using the MSE skill score of binary images, obtained from the recalibrated forecasts and analyses by thresholding at different precipitation rate intensities. The skill score is decomposed on different spatial scales using a two-dimensional discrete Haar wavelet decomposition of the binary error images. Wavelets are functions characterized by a location and a scale (Daubechies, 1992). Similar to Fourier transforms, wavelets can be used to represent functions on different spatial scales, and so can be used to investigate scale properties of physical phenomena. Because of their local properties, wavelets are more suitable than Fourier series for representing spatially discontinuous fields such as precipitation. Moreover, because of their locality, wavelets are more efficient than Fourier components at representing sparse images containing few non-zero values. Different types of wavelets exist. Each wavelet type is defined by a mother and a father wavelet, characterized by different shapes and mathematical properties (e.g. smoothness, symmetry, etc.). In this study, Haar wavelets are used, because of their square shape which best captures the difference in binary variables. Fig. 15 shows the one- and two- dimensional Haar wavelets. Note that the two-dimensional wavelets are generated simply as the Cartesian product of the one dimensional wavelets.

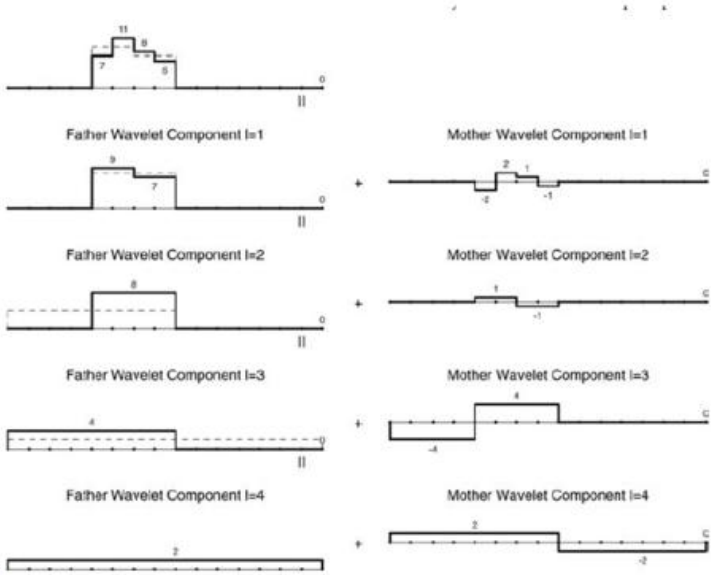

Figure 11. *Example of the one-dimensional discrete Haar wavelet filter applied to an example function (top left panel). At the first step the function is decomposed into the sum of a coarser* mean *function (the first father wavelet component) and a* variation-about-the-mean *function (the first mother wavelet component). At each step the Haar wavelet filter decomposes the father wavelet component obtained from the previous step into the sum of a coarser* mean *function (the l^{th} father wavelet component) and a* variation-about-the-mean *function (the l^{th} mother wavelet component). The l^{th} father wavelet component is obtained from the initial function by a spatial averaging over 2^l pixels. The process stops when the largest father wavelet component (mean over the whole domain) is found.*

Figure 15: One- and two- dimensional Haar wavelets.

Steps followed in Intensity Scale method application:

- Binary error decomposition: Thresholding is used to convert the forecast and analysis into binary images for each of the thresholds. Binary error is the difference of this:

$$Z = I_{y'} - I_x$$

- Binary error image is then expressed as the sum of components on different spatial scales by performing a 2-dimensional discrete Haer wavelet decomposition

$$Z = \sum_{l=1}^{L} Z_l$$

- Most substantial binary error image of the mother wavelet components are calculated for various spatial scales (l =1,..L=7 that corresponds to X km). The spatial scales refer to the spatial scale of the error and not that of the precipitation features or their displacement as it happens in the neighbourhood methods

- The MSE of the binary error image is calculated from:

$$MSE = \sum_{l=1}^{L} MSE_l \qquad MSE_l = \overline{Z_l{}^2}$$

  while for each threshold the skill score can be calculated from:

$$SS = \frac{MSE - MSE_{random}}{MSE_{best} - MSE_{random}}$$

  where and MSE_{random} is associated with a random forecast calculated from the bias and the base rate at each threshold

- Intensity scale verification technique is a spatial generalization of traditional binary verification (HSS, PSS).

3.4.2 Short description of the dataset (forecast-observation data), adaptation required, software for the method application

The datasets used in the context of this study have been obtained from the Mesoscale Verication Inter-Comparison over Complex Terrain (MesoVICT) project. All six available test cases were that analysed, cover a wide range of meteorological phenomena in and around the Alps. The example that is presented here is for the period 20-22 June 2007. From the multitude of NWP models with varying resolutions that are available through the MAP-D Phase, forecasts derived from COSMO-2 (2km res.) and COSMO-1 (1km res.) of the Swiss Meteorological Service were used. The domain of the COSMO model is shown in figure above. Both models were nested on a coarser 7km COSMO model. Hourly precipitation forecasts from both models were upscaled prior to the application in order to match the resolution of the observation fields in a final 8km grid spacing to match the observations. The software used was the R based SpatialVx and the waveIS routine. MET software (NCAR) was also tested but the graphical outputs of the methods were different and not comparable with those of SpatialVx. Further investigation is required for the differences in the application of the method.

3.4.3 Main findings (plots and explanation)

An example of the verification analysis is presented in Fig. 16 for 20070621-15UTC.

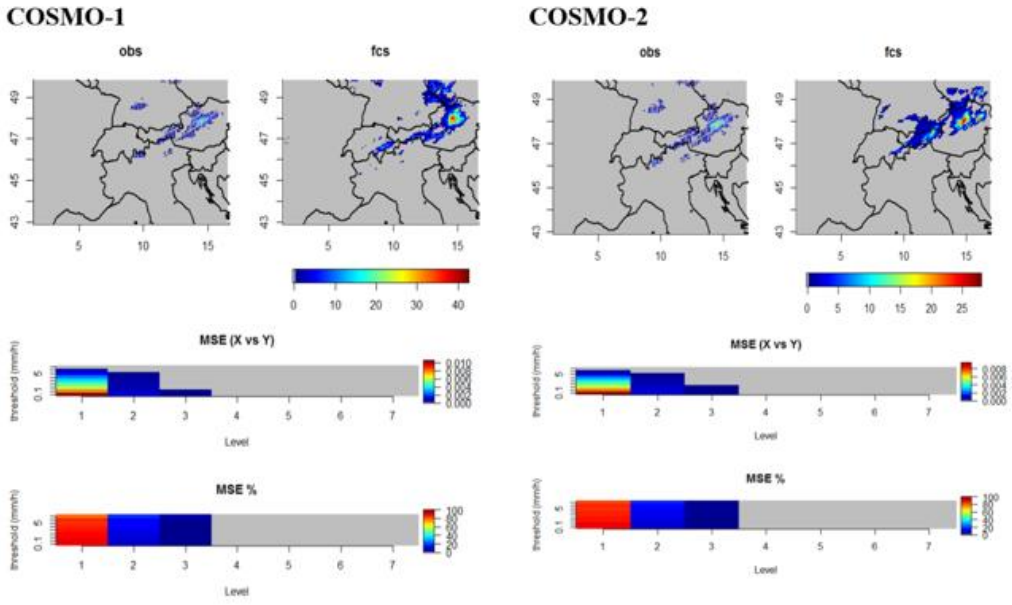

Figure 16: Example of the verification analysis for 20070621-15UTC.

From the analysis of this precipitation instant, it can be deducted that MSE almost disappears for error tiling of the order of 3x3 grid points. Comparing the two model performances, COSMO-1 shows slightly improved behaviour compared to COSMO-2. In Fig. 17, the results from the Skill score are given.

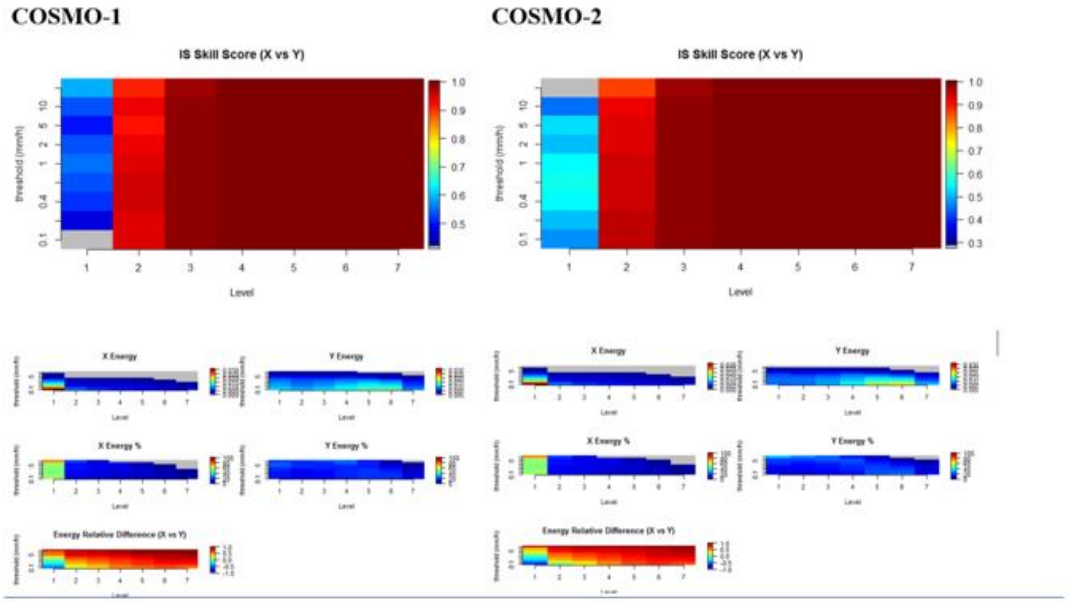

Figure 17: Results from the Skill score.

Small error scales (l=1) have skill close to zero as it is shown in the graphs, while slightly large scales exhibit large skill. COSMO1 ISS graphs exhibit that errors due to displacement of small spatial scale features are more important compared to those of COSMO-2. As a summary, both models have **small skills at the smallest scale** but skill improves when

considering larger spatial scales. ISS decreases as the precipitation threshold is increased and this is due to the **poor ability of the models to go beyond just the yes/no rain discrimination**.

3.4.4 Characteristics of the method applied

This filtering method allows the skill to be diagnosed as a function of the scale of the forecast error and intensity of the precipitation events. Results show that reduction of skill is mainly due to the small-scale misplacement of more intense (rare) precipitation events.

Wavelet-based scale-separation MSE skill score and scale-separation statistics are suitable for comparing models with different resolutions as the reference forecast accounts for the forecast variability. IS method constraints are related to the request to have precipitation analysis available for each grid point of the forecast field, and to the fact that Haar wavelet decomposition is designed for a square domain. Computationally, the method was easy to be applied and to derive numerical and graphical results, while their interpretation is not so straightforward and easy to comprehend from a non-experienced user.

The method allows the analysis of precipitation instances but it is not able to provide a generalized information on the relative long term performance of a modelling system based on aggregated data.

4 Object-based methods

4.1 SAL Method for deterministic and ensemble precipitation verification at HNMS (D. Boucouvala)

4.1.1 Description of the Method

SAL method (Wernli et. al 2008, 2009) is a spatial three component object- based quality measure which quantifies a precipitation forecast in terms of 3 parameters which correspond to a global field measure of Structure (S), Amplitude (A) and Location (L). An object is defined when it exceeds a fixed or statistically defined threshold value. The objects of the observed and forecast fields do not require one-to one matching and are identified separately. The fields are then transformed into binary representations of 1 (grids exceeding the threshold) or 0 (grids not exceeding the threshold).

The **A** component represents a normalized difference between the domain-averaged forecast D(R_{mod}) and observation fields D(R_{obs}) and it is the only one that **is independent of the identification of features** as it depends on the total precipitation amount. A positive value indicates overestimation of total precipitation, and negative indicates underestimation. The value of A is in the range of [-2,2], with 0 value corresponding to the perfect forecast for a system-averaged precipitation intensity. Values close to -2 show almost missed events and values close to 2 almost false alarms. A value of A=1 indicates an overestimation by a factor of 3.

$$A = \frac{D(R_{mod}) - D(R_{obs})}{0.5(D(R_{mod}) - D(R_{obs}))}$$

The **S** component compares the total of volumes of the normalized precipitation objects (scaled over the maximum value for each object), and provides information about their size

and shape. The range of S is [-2,2]. A positive value indicates that modelled precipitation objects are too large or too flat, and a negative value indicates that objects are too sharp and too small.

$$S = \frac{V(R_{mod}) - V(R_{obs})}{0.5(V(R_{mod}) - V(R_{obs}))}$$

The **L** component combines information about the distance of predicted and forecast mass centres and the error of a weighted average distance between the precipitation objects and centre of masses. It consists of two parts. $L = L_1 + L_2$. L_1 measures the normalized distance between the mass centres of the forecast x(R_{mod}) and observation fields x(R_{obs}), where d is the maximum distance found in the given domain between two boundary points. Its value range is [0,1]. The value of 0 indicates that the two fields mass centres are identical. However many different precipitation fields can have the same mass centres without being identical, therefore $L_1 = 0$ does not necessarily indicate a perfect forecast. L_1 **is independent of identification of features**.

$$L_1 = \frac{|x(R_{mod}) - x(R_{obs})|}{d}$$

L_2 is the difference of weighed mean normalized distance between the mass centre and the individual precipitation objects over observed r(R_{obs}) and forecast r(R_{mod}) fields and is a measure of difference of scattering of identified objects between the two fields. L_2 ranges between [0,1]. Therefore, L ranges between 0 and 2.

$$L_2 = 2\frac{|r(R_{mod}) - r(R_{obs})|}{d}$$

A perfect forecast is therefore characterized by zero values for all three SAL components. A **taSAL** index $=(|S| + |A| + |L|)$ is suggested by Lawson et al. (2016) (as an objective skill score in order to quantify the forecast quality by means of one only parameter. The bigger the index is the worse is the forecast.

4.1.2 SAL Calculation

Dataset

- In order to apply the method, precipitation objects need to be identified within a **gridded** verification domain which should be the same for both observed and forecast fields. In the case of MesoVICT data used for INSPECT project, gridded data in ASCII are already available. However, if the method is used for comparison with grib observations and bufr model data, a software for reading the files in such format should be available. A file with latitude and longitude of the gridded fields is also necessary.
- **The domain size is important**. It should be identical for both observed and forecast fields. It is not recommended to be too large as components from different precipitation regimes can override each other.
- **The accumulation precipitation range should not be small**. Hourly precipitation fields are often noisy, with not well defined objects. It is recommended to calculate the SAL parameters with 6h precipitation range and up, unless a specific case with significant precipitation amounts is tested.

Software required

In order to calculate the SAL components, after reading the input files, the following software are available:

- The original code (in Fortran) which can be provided by the authors.
- The libary SpatialVx (Gilleland, 2017) which is part of the free R language software with available documentation online. The advantage of this method is that by using featurefinder (function for defining objects) a the user can easily view objects and specify thresholds, smooth fields and discard small scale noise. The SAL parameters are then calculated by using the smaller function.

Object Identification Methodology and examples of SAL calculation

The selection of a threshold value for objects identification is required for this method and it can be critical if the fields contain objects with different local maxima. A small change in the threshold can lead to a different number and size of objects and therefore different L_2 and S values. The possibilities of setting a threshold R are the following:

- Constant fixed user defined threshold (e.g. 2 mm) for forecast and observed fields. (This method is more subjective)
- $R = f \cdot R^{max}$: threshold is a fraction of R^{max} (the maximum value of the field) and f is subjectively chosen factor with a value of 1/15 suggested by Wernli et al. (2008) as the most appropriate to identify objects. Higher values of f result in threshold increase
- $R = f \cdot R^{95}$: threshold is a fraction of the 95^{th} percentile of all gridpoint values in the domain which are larger than 0.1mm. (This is the method suggested by Wernli et al., 2009) and is used in the original code. This is sensitive to outliers. (eg. Single grid points with very intense precipitation)

Examples of SAL are given in Fig. 18, (calculated with method 3) where CMH S value is positive indicating that objects are flatter than observed (precipitation is more stratiform), and negative S for COSMO-2 means that modelled objects are sharper than observed. Positive (negative) values of A for CMH (COSMO-2) indicate overestimation (underestimation) of total domain precipitation. L values are slightly higher for COSMO-2 as there are fewer and more localized objects. TaSAL is lower for CMH, which indicates overall better forecast.

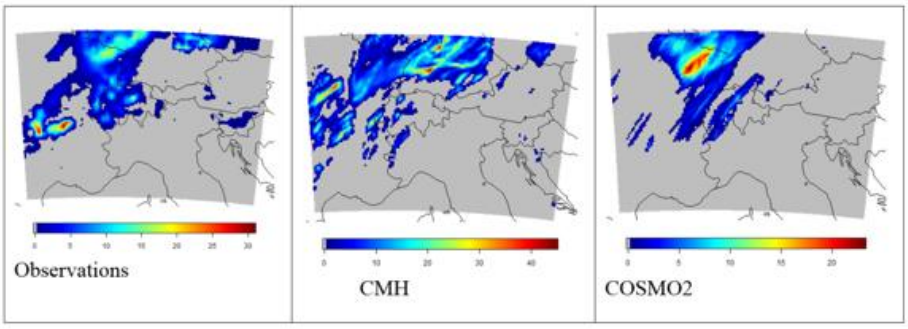

Figure 18: CMH and COSMO-2 forecasts versus Observations for MESOVICT case of 12 hourly Precipitation of 18h for 19/7/2007.

Model	S	A	L	taSAL
CMH	0.22	0.48	0.18	0.88
COSMO-2	-0.12	-0.55	0.25	0.92

Object Identification Options

- Smoothing: smoothing option is available on featurefinder function by setting do.smooth=TRUE and giving a value to smoothpar (which can also be different for observed and forecast fields). Specifically, by applying smoothing, the value at each grid is replaced by the mean value over a disk with a radius of a number of grid points given by the parameter smoothpar. The convolved data is **then** thresholded yielding a binary mask, so mostly affected are the object boundaries which are smoothed. Also small scale noise is filtered out. The selection of smoothing radius is not straightforward (Weniger et al., 2016) and it is not obvious how to select it for a given set of data. It is also relative to grid size. So, the same smoothpar can lead to light smoothing when applied to a grid of 1km but significant when applied to 7km. Smoothing for example can lead to bridges creation among different objects that are close to each other and unify them. If the selected smoothing factor affects one domain (forecast or observations) more than the other, then S and L_2 parameters may completely change with only a small smoothpar change. In general, the increase of smoothing radius does not necessarily improve the results of the parameters, as it may unify or separate objects depending on the threshold, therefore alter the number of objects. Examples of effects of smoothing for the case of Fig. 18 are shown in Fig. 19. The effects of smoothing on S in this example are apparent when moving from smoothpar=3 (Fig. 19b) to smoothpar=4 (Fig. 19d) as the unification of the objects in observed field results in a complete S change (even on sign). Flatter objects were predicted in Fig. 19b due to the larger modelled yellow object, while the observed objects unification in Fig. 19c resulted in slightly sharper objects now predicted by the model. The bigger smoothing in Fig. 19d resulted in unification of almost all objects and made small objects disappear.

- Omission of small objects: the min.size option of featurefinder (min.size=c(n_min_obs, nmin_fcs)) defines objects as cohesive threshold exceedances and objects with less than n.min are omitted. The interpretation of this parameter is more straightforward that smoothing (Weniger et al., 2016) and it is easier to foresee the consequences of a particular choice of a parameter value on the objects as it does not unify or separate objects. It does not affect shape of large objects. If the selection of factor removes small objects and affects object spread for one domain (forecast or observations) more than the other, the S and L_2 parameter may increase or decrease. Examples of effects of using min.size are shown in Fig. 20, where omitted modelled objects resulted in more widespread forecast precipitation with a slight and stable increase of S and L_2 values with min.size increase. User can visualize objects after using the function featurefinder in order to decide about the best threshold and smoothing selection, but this selection is more straightforward for one specific case and not for a series of data with different precipitation regimes, that will be plotted afterwards on a SAL Plot.

  Errors in observations (too big values) can be discarded in the calculations when threshold is a fraction of a percentile of all gridpoint values in the domain. Also, by applying the min.size option in the observed field, small objects of any intensity that can be erroneous noise vanish. However, erroneous values within normal range can lead to wrong observation objects and therefore SAL components.

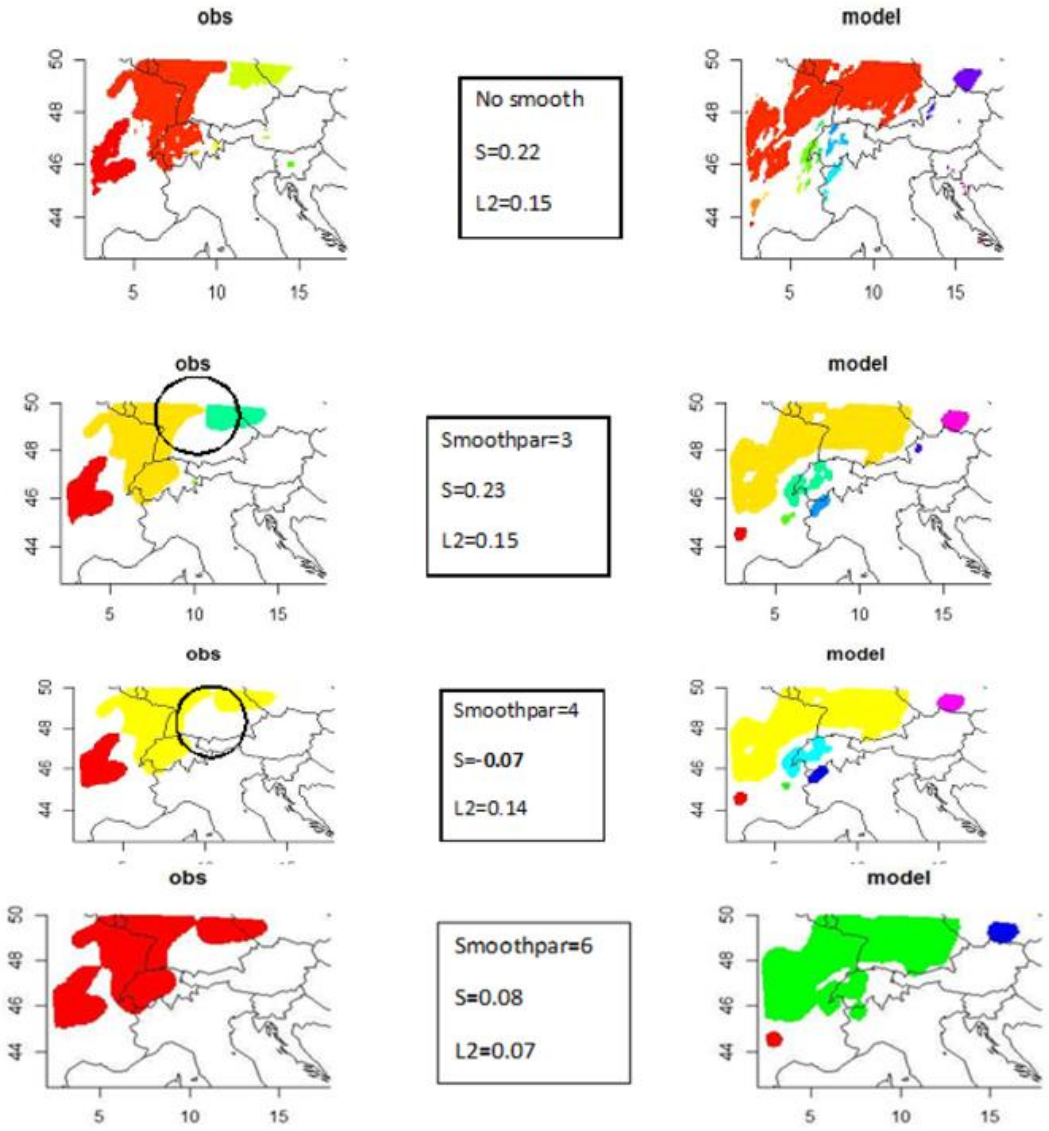

Figure 19: Examples of different smoothing factors and their impacts on objects and S / L_2 applied on the case of Fig. 18.

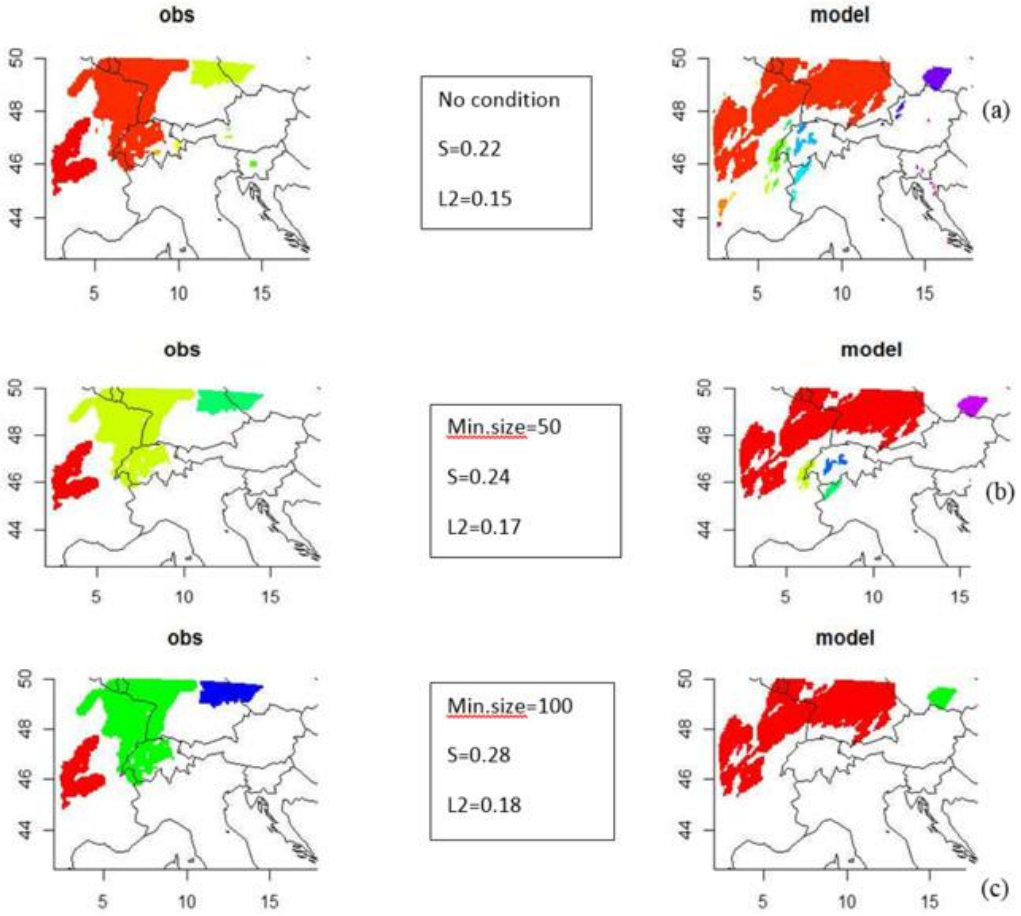

Figure 20: Examples of different min.size options and their impacts on objects and S / L_2 applied on the case of Fig. 18.

SAL Plots

The SAL method can be applied to a set of forecasts performed by the same model in order to define a general model tendency of predicting each of the three SAL components. This is done by the SAL diagram in which each point represents one case. The median value of S and A together with the 25^{th} to 75^{th} percentile box can also be plotted. The L component value for each point is depicted with a colour scale. Example of this plot is shown in Fig. 21.

Warning: if no features are found in either or both forecast and observed fields, the SAL values cannot be defined. In this case (no objects found by featurefinder in forecast, observed, or both fields), saller function cannot be executed and the case is defined as Miss, False Alarm, or Correct Negative respectively. The use of extreme values of SAL parameters (-2.2) in case of lack of objects is not recommended and cases are simply omitted.

Statistically Specified thresholds (with selection of appropriate scaling factor) can be used when dealing with a significant number of cases in one SAL plot, as the precipitation amounts are different for each one, and a fixed threshold can be too big for some cases of them and exclude them. However, for one particular case, or for a number of cases with similar situation (ex. only convective) or if only extreme events exceeding a specified threshold are studied, then a fixed threshold can be used. SAL parameters can also be used to test the performance

of an EPS ensemble by plotting the SAL values of each of the members on a SAL plot and get an estimate of the ensemble forecast for one particular time (Barrett et al, 2015).

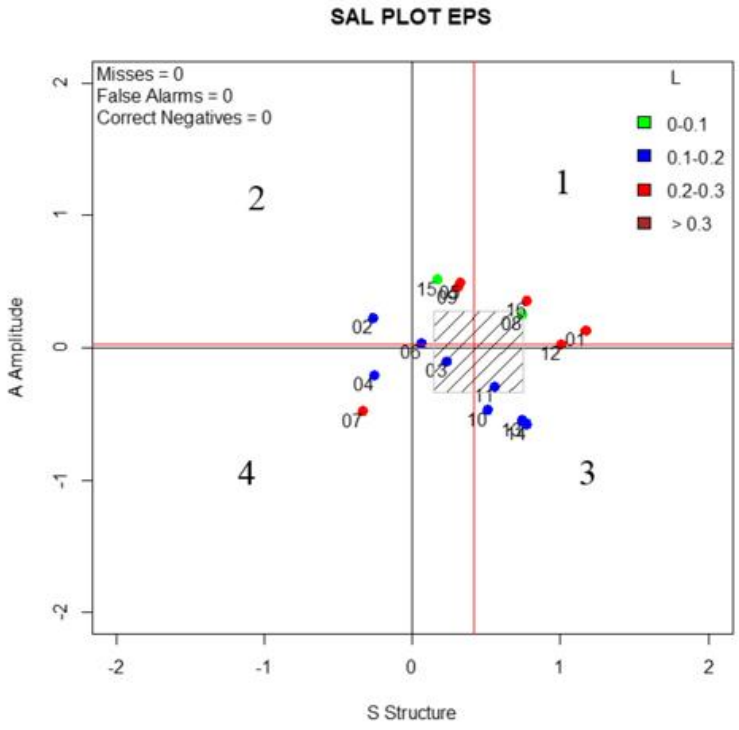

Figure 21: SAL diagram for COSMO-LEPS 3h precipitation for 21/6/2007 12UTC. The red lines denote the median values of A and L, the gray box is the area of 25^{th} to 75^{th} percentile.

In Fig. 21, an example of a SAL diagram with 16 members of COSMO-LEPS indicates that median S is positive, meaning that as an ensemble, predicted objects are flatter and larger than observed. The A median parameter is close to zero and slightly positive which means that amplitudes of observed and modelled fields are comparable. Members in quadrant 1 produce too much rain with too large or flat objects. L values are relatively low and less than 0.5. The forecast fields for each member may be significantly different. Therefore, fixed thresholds applied to a set of members may be too big for some of them, resulting in no object formation for some members, therefore S and L may be calculated with fewer of them. On the other side statistically specified thresholds for each member, imply a different threshold for each of them when compared to the observed field. It is up to the user and the specific case to select the appropriate method.

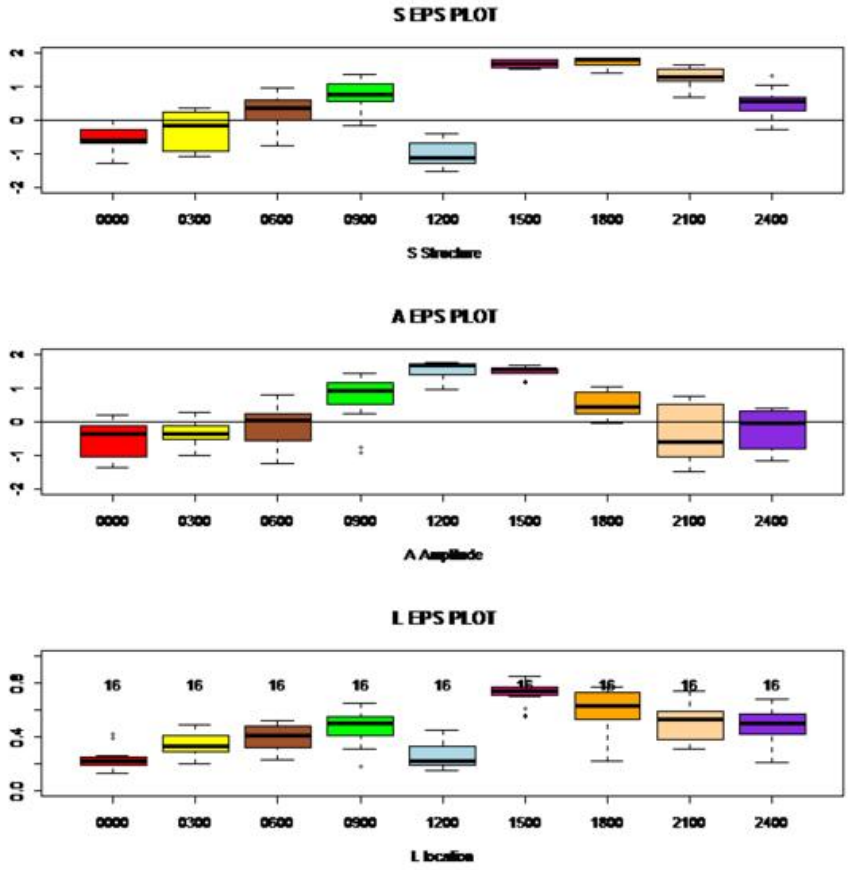

Figure 22: COSMO-LEPS hourly variation of ensemble SAL parameters (Statistically Specified threshold) for 20/6/07 with a Run beginning on 19/6/07.

EPS forecasts hourly variation can also be plotted as boxplots (each one representing the distribution of the members) of each parameter as a function of time lead (Fig. 22). The L parameter distribution is now also better represented than SAL Plots. The R SAL plot and boxplots are written in R language. The calculation time can be significant if the program reads a large number of files and plots many cases for one SAL Plot In order to perform a SAL plot over a set of many different forecasts of an EPS model, there are two possibilities:

- **Medians** of the SAL parameters over the members for each case are calculated and then plotted on a SAL plot. The number of points will be equal to the number of cases;
- **Medians** of the SAL parameters over all cases for each member are calculated and then plotted on a SAL plot. The number of points will be equal to the number of members.

Examples for MESOVICT COSMO-LEPS 3 hourly forecasts of the Run beginning on 18/07 12 UTC (from 20 to 22/7) with the two methods given in Fig. 23. The two methods give comparable A and S median values with different spreads, as expected.

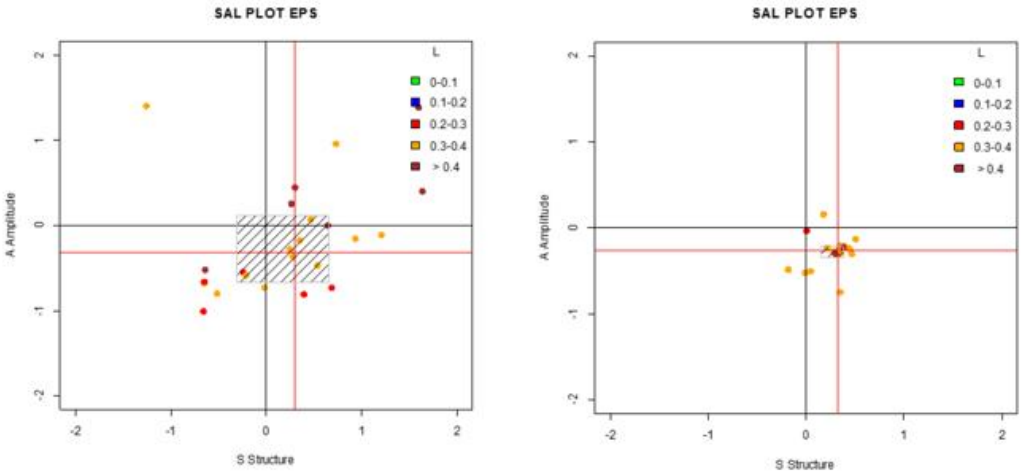

Figure 23: COSMO-LEPS SAL parameters for all 3-hourly forecasts from 20-22/7/07 with a run beginning on 18/6/07.

Further research on SAL applied to EPS models includes comparison of objects in fields of probability (Radanovics et al, 2015), and consideration of observation uncertainty.

4.1.3 EPS in terms of probability (a research topic)

Further research on SAL applied to EPS models includes comparison of objects in fields of probability (Radanovics et al, 2015) with consideration (if available) of observation uncertainty. In an effort to apply this concept to MESOVICT dataset the following ideas (which require further research) are presented in this document:

- *when the observation domain is constant and uncertainty is applied only for LEPS*

  First, the setting of precipitation threshold to be tested is needed (eg. 2mm). The fraction of the 16 LEPS members that predict precipitation above this specified threshold applied on every grid point consists the probability field in the model domain (range 0-1). In Fig. 24, different colours represent the different probabilities and the brown objects are of probability 1(all the 16 members predict precipitation above the threshold). When uncertainty is applied only to the model domain, these objects (in order for the comparison to be fair) can be compared to the observation objects which reflect the real conditions, and can also be represented by probability 1 (Fig. 24). In this case, A parameter will be only calculated for the 2 fields by taking into account only the objects with value 1 and setting to zero the remaining grid points for observed and modelled domains (because in the observations field the remaining grid points cannot be represented as probabilities) . Also, S parameter will reflect only their size and not sharpness. These objects are detected by the featurefinder function (Fig. 25) and the resulting SAL parameters will be a measure of how the objects over a specified threshold can be forecasted by all 16 members of EPS model. In this particular case S=1, A=0.38, L=0.3;

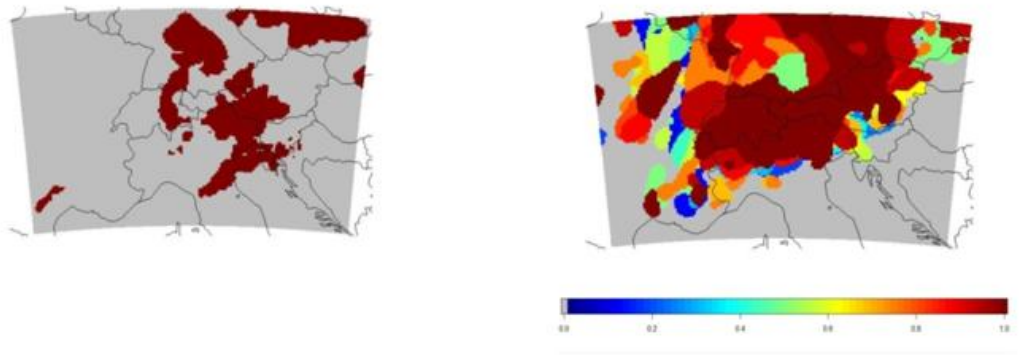

Figure 24: Probabilities of 3h precipitation threshold > 2mm for observations (left) and LEPS (right). 21/06 12UTC. The colour scale is the probability range.

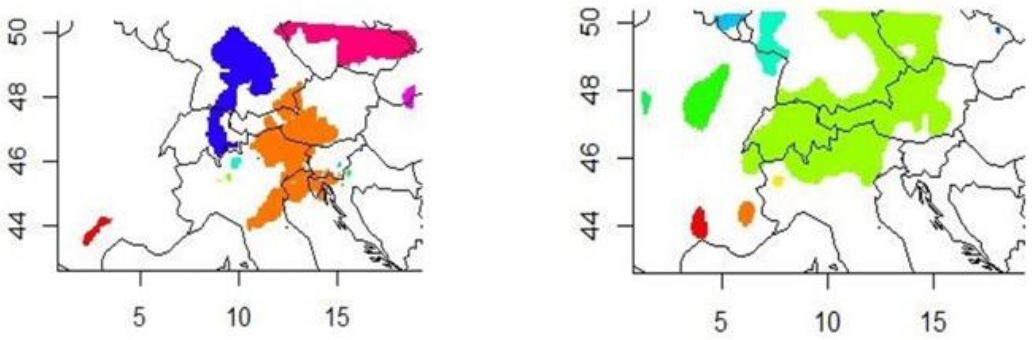

Figure 25: Objects of probability=1 as detected by the featurefinder function for observations (left) and model (right). Colours indicate different objects.

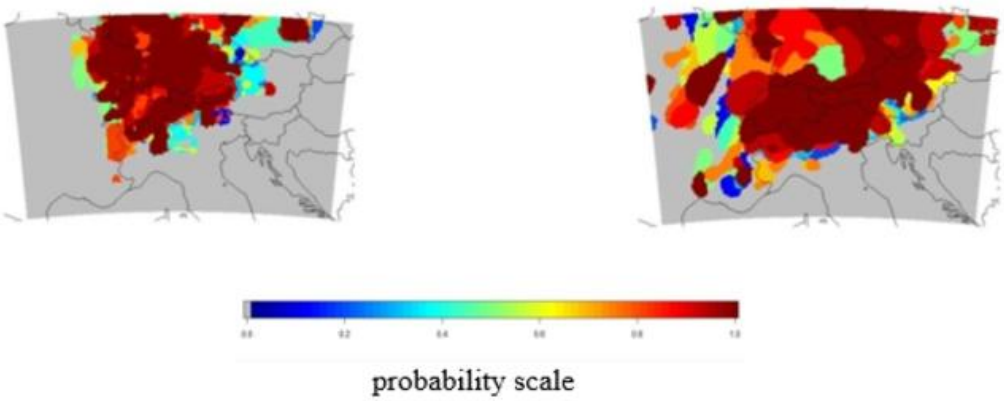

- *when uncertainty is applied also to observations (in this case 16 members of VERA ensemble)*

  When uncertainty is also applied to observations (Gorgas and Dorninger, 2012a), the concept of the fraction of the members exceeding the specified threshold can be applied in the same way to observed and LEPS domains, and fields of probability can now be created in both of them. In this case, probability thresholds of less than 1 can also be tested. For example, for precipitation threshold 2mm, the objects of each field created by the different probabilities exceeding it, are shown in Fig. 26a. In Fig. 26b, the objects of probability=1 (all members in observation and VERA fields predict precipitation above 2mm) detected by featurefinder in both domains are shown. In this case, S=0.37, A=0.6, L=0.1. The objects of probability threshold < 1 (0.5 in the case of Fig. 26b, which denote that at least half of members predict precipitation above the threshold) are bigger and include also higher probabilities can be compared with the SAL method for the two domains. In this case, S=0.65, A=0.5, L=0.05. Further research on LEPS SAL parameters includes the introduction of a SAL index (Radanovics, 2017a) for LEPS (Ensemble SAL) with average means over the members of the equation parameters for observed and model fields. This formulas that may be introduced in SpatialVx (Radanovics, 2017b), will be a more efficient way of SAL parameters estimation for Ensemble Forecasts.

$$L_1 = \frac{|\langle x(rr_{mod})\rangle - \langle x(rr_{obs})\rangle|}{d}$$

$$L_2 = 2 \times CRPS(P(\frac{r_{mod}}{d}), P(\frac{r_{obs}}{d}))$$

$$S = \frac{\langle V(mod)\rangle - \langle V(obs)\rangle}{0.5\langle V(mod)\rangle + \langle V(obs)\rangle}$$

b)

c)

Figure 26: a) Probabilities of 3h precipitation threshold > 2mm for VERA ensemble (left) and LEPS (21/06 12h). b) Objects of probability threshold=1 as detected by the featurefinder function for VERA ensemble (left) and LEPS (right). Colours denote different objects. c) Same as b with probability threshold=0.5.

4.2 MODE, CRA, SAL: IMGW-PIB experience

The experience described in this section is unique in INSPECT, as IMGW-PIB applied three different object-based methods, which facilitated their intercomparison.

4.2.1 Method applied (related to an INSPECT Task) and objectives

MODE - Method for Object-Based Diagnostic Evaluation, its objective is to identify localized features of interest in scalar fields, merge and/or match features and compare features in two fields to identify which features best correspond to each other. CRA Contiguous Rain Area, identifies features of interest, uses pattern matching techniques to determine the location error, errors in area, mean and maximum intensity, and spatial pattern. The total MSE (Mean Square Error) is decomposed into components due to location, volume, and pattern error (MSE displacement, MSE volume, MSE pattern) (see also Chapter 4.3) SAL - Structure, Amplitude, and Location, requires a preselection of a domain of interest, a definition of a threshold to identify objects in the observational data and model forecast, one-to-one matching between the identified objects in the observed and forecasted fields is not required. A forecast is perfect if S = A = L = 0. (see also Sec. 4.1.1.)

4.2.2 Short description of the dataset (forecast-observation data), adaptation required, software for the method application

- Radar data
  - OPERA (Operational Programme for the Exchange of Weather Radar Information), 1 hour rainfall accumulation. The composites cover the entire Europe in a Lambert Equal Area projection. For the project data in HDF5 format was used. The HDF5 files are read directly in the R software by using "HDF5 interface to R". The data are adopted to geographical coordinates (latlon geographical projection) in terms of verification against COSMO PL data
  - Polish national RADAR (POLRAD network) data composite. The data are available in Rainbow binary XML format and can be processed with additional php5 tool available at IMGW-PIB to extract rainfall accumulation and geographical locations.

  Both data sets require a procedure of matching to COSMO PL model domain.
- Vienna Enhanced Resolution Analysis - VERA data
- Forecast data
  - COSMO-PL 7 km, COSMO-PL 2.8 km
  - COSMO-2 data - interpolated on the VERA grid.

4.2.3 Main findings (plots and explanation)

The all plots and statistics below were obtained using SpatialVx R-package developed at NCAR (Gilleland, 2015).

- MODE example. MODE graphical output shows matched objects (e.g. Hits) and unmatched objects (e.g. False alarm in forecast field, Misses in observation field), which are based on the interest value. The interest value is an overall measure of similarity between objects in the observed and forecast fields, ranges from 0 to 1. The value of 0.70 is used for objects to be considered matched. COSMO-PL7 precipitation model output was verified against OPERA radar data. The result of MODE method shows a good correspondence of the precipitation objects between COSMO-PL7 and radar data.

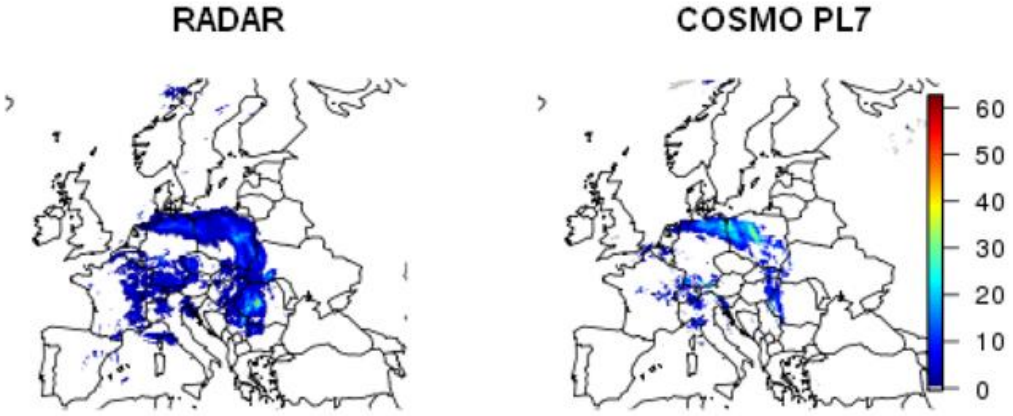

Figure 27: 24h QPF ending at 00 UTC on 05.05.2017.

Figure 28: Identified, matched objects, threshold 5mm, Matched objects are indicated in the same colour in both the observed and the forecast fields .Grey colour corresponds to unmatched objects.

- CRA example. CRA verification was used to verify forecast model COSMO-2 against VERA data. One of the cases was chosen for the verification. For object pairs 2 and 4 the total error is associated with the error in location, while for object pairs 1 and 3 the total error is associated with the fine scale structure.

Observation feature	Forecast feature	Total interest
1	1	0.85
2	2	0.7
2	1	0.46
1	2	0.42

main.tex

- SAL example. SAL verification was used to verify 1 hour accumulated precipitation output of forecast model COSMO 2.8 against radar data of POLRAD network. The verified period was from 05 18UTC to 07 06UTC August 2016. Almost all SAL entries are found in the top right quadrant of the diagram. The bottom right quadrant contains only a few of them. For all entries component S is positive which means that the predicted forecast objects are too large or widespread with respect to the observed objects. For most entries component A is positive which indicates an overestimation of the domain-averaged precipitation coming from the model. There are only a few entries when the model underestimates the precipitation (negative A component). No entries were found in top and bottom left quadrants.

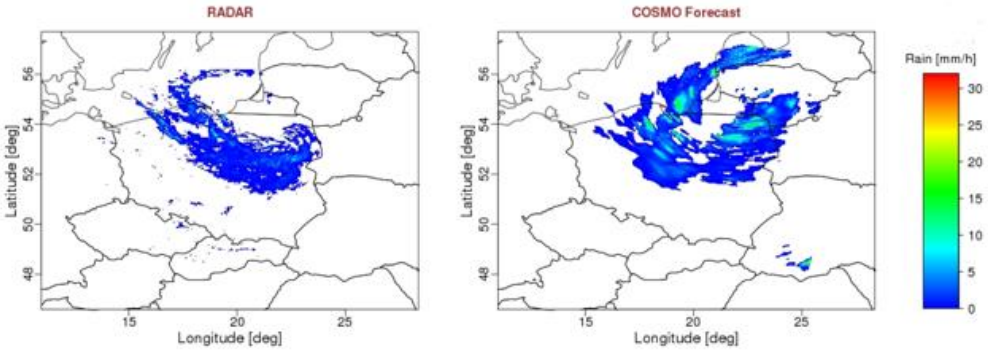

Figure 31: 1h accumulated precipitation, Radar data composite (POLRAD) against COSMO-PL 2.8, 06.07.2016, 20 UTC.

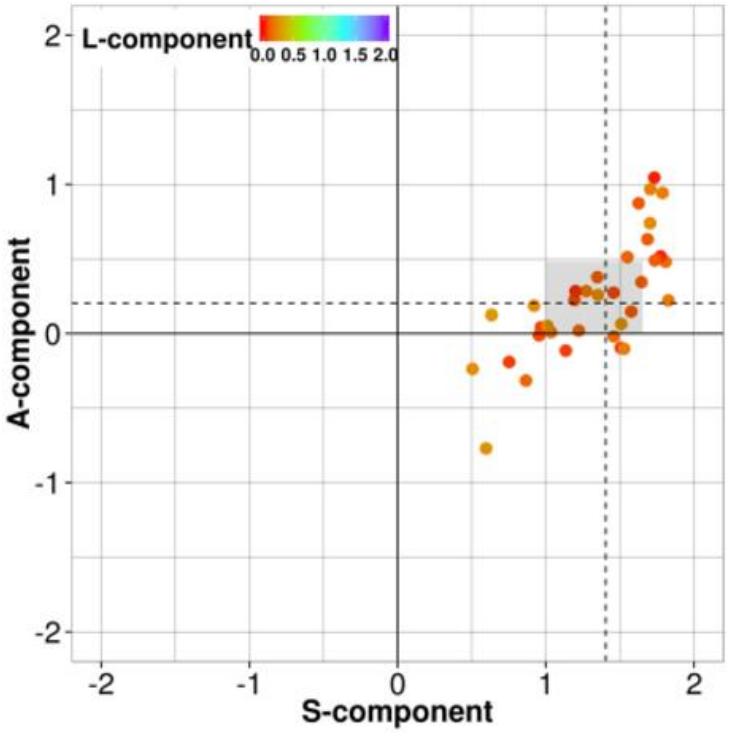

Figure 32: SAL verification, 1h accumulated precipitation, 05 18UTC 07 06UTC August 2016. Every dot shows the values of the three components of SAL for a particular forecast. L component is indicated by the colour of the dots. The grey area extends from the 25th to the 75th percentile of the distribution of S and A, respectively. The dashed lines depict the median values of S and A components.

4.2.4 Characteristics of the method applied

Identification in MODE is done separately in observation and forecast fields by using two parameters such as convolution radius and threshold. The method looks at characteristics of the objects such as intensity distribution, centroid location, area, curvature, orientation, and attempts to match objects in the forecast and observed field based on these characteristics. Objects nearby can be merged. CRA method gives useful information of the forecast errors. The total mean square error is decomposed due to location, pattern and intensity. The method depends on pattern matching. To find the optimal rigid transformation between two features can be difficult. SAL components correspond to aspect of amplitude, location and structure of precipitation field in a preselected area. All three methods MODE, CRA, SAL require identification features first. Applied method calculation time using SpatialVx library can depend on chosen merging/matching function, additionally all these methods are able to deal with different density of observation. Depending on the model resolution object features may have different pattern complexities and fine structures which further affects merging algorithm performance and computed scores.

4.3 CRA experiments in Roshydromet for MesoVICT (A.Bundel and A. Muraviev))

In the framework of MesoVICT (Mesoscale Verification Intercomparison over Complex Terrain, phase 2 of the ICP, https://ral.ucar.edu/projects/icp/), a set of cases is provided to compare various spatial verification methods. The object-based CRA (Contiguous Rain Area) method is used (Ebert, McBride, 2000). First, the objects are identified in observed and forecast fields. Then, the objects pairs are identified using some matching criterion based on the distance between the objects. Then, an optimal shift of the forecast object to the observed object is found by minimizing the error. Here also, different criteria can be used, such as the correlation coefficient and the mean squared error (MSE). In this study, the MSE criterion was used. Then, the difference is found between the initial MSE (represented as $MSE.total = MSE.displacement + MSE.volume + MSE.pattern$) and the MSE after the shift. This difference is the error due to forecast displacement: $MSE.displacement = MSE.total - MSE.shifted$. The MSE, which is left, consists of the squared difference between the mean precipitation volume in the forecast and observed object $MSE.volume = (\mathbf{F} - \mathbf{X})^2$ and of fine scale pattern discrepancies $MSE.pattern = MSE.shift - MSE.volume$. To calculate the CRA scores, free R SpatialVx package (https://cran.r-project.org/web/packages/SpatialVx/index.html) was used. It is developed by E. Gilleland contains most part of existing spatial methods, including identifying, matching, and merging features in observed and forecasted fields.

4.3.1 Deterministic study

Setup of experiments

- Mesovict core case: 20-22 June 2007;
- 1-h precipitation accumulations;
- Vienna Enhanced Resolution Analysis (VERA) observation analysis (Dorninger, M.et al., 2013) is used as reference data in this study;
- the Swiss COSMO-2 deterministic model is used as model data (2.2 km grid step).

Fig. 33 shows the time series of domain precipitation maximum during the MesoVICT core case. It can be seen that the absolute VERA maximum on 20 June 2007, 21h UTC, (49.84 mm/h) falls within the COSMO-2 domain. Most of other observed maximums were within the COSMO-2 domain. Overall, COSMO-2 reproduces well the time series of maximums, but gives the highest maximum 12 hours later, on 2007062020 much later, on 2007062108.

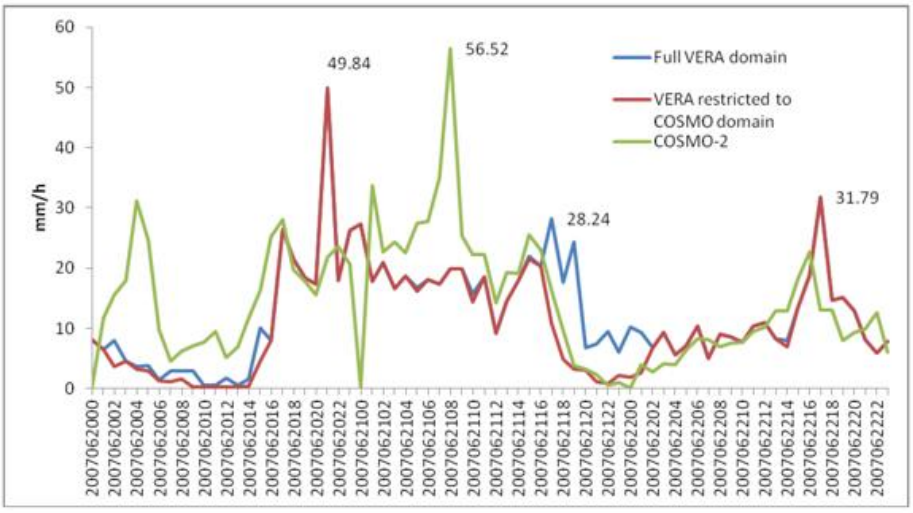

Figure 33: Time series of domain 1h precipitation maximums during the MesoVICT core case of 20-22 June 2007.

Identification of objects in R SpatialVx

Function FeatureFinder is used to identify objects in both observed and model fields. First, the field is smoothed using a convolution smoother, and then it is set to a binary image where everything above a given threshold is set to one (Davis et al, 2006). Features are identified by groups of contiguous events (or connected components in the computer vision/image analysis literature). Option min.size enables eliminating features with a size less than determined value from the analysis. Through a set of experiments, the reasonable value was determined as min.size = 20 grid points or ~36*36 km.

The effects of smoothing

By applying smoothing, the value at each grid is replaced by the mean value over a disk with a radius of a number of grid points given by the parameter smoothpar (see also Chapter 4.1 about the effects of smoothing). The FeatureFinder option uses disc kernel smoother from the R package smoothie.

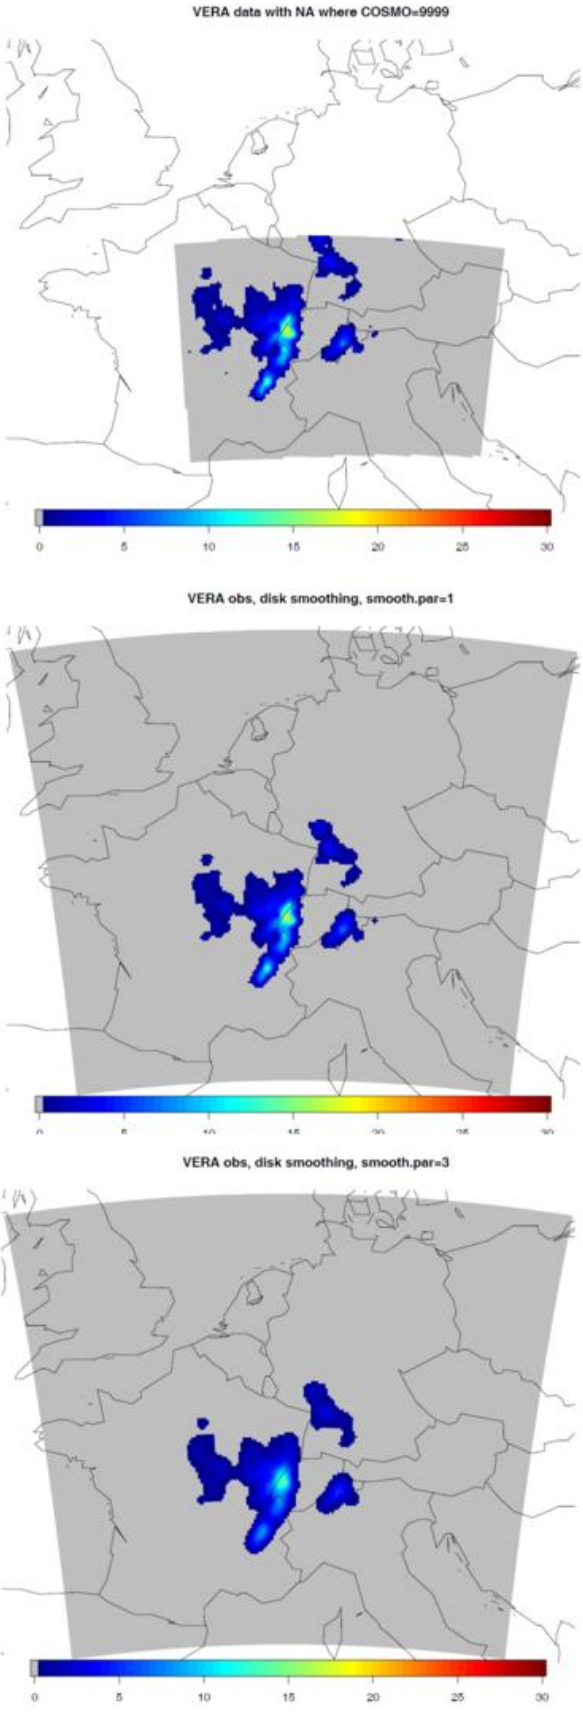

Figure 34: VERA gridded observation analysis on 2007062106: no smoothing (top), smoothing parameter =1 (middle), smoothing parameter = 3 (bottom).

Smoothing spreads the maximum over wider areas (Figure 4.3.1.2). Therefore, no or minimal degree of smoothing is needed in estimating intense precipitation areas. Smoothing parameter = 1 is chosen for the experiments described in this chapter. Functions for matching objects in R SpatialVx used in this study are as follows:

- Minboundmatch, the minimum boundary separation is calculated by first finding the distance map for every feature in the observed field, masking it by each feature in the forecast field, and then finding the minimum of the resulting masked distance map (Eric Gilleland, SpatialVx Manual). The distance map is found using distmap. The function distmap of point pattern computes the distance from each pixel to the nearest point in the given point pattern. If type is single, then the features are matched by the smallest minimum boundary separation per feature in each field. If type is multiple, then every feature is matched so long as their minimum boundary separation (measured in grid squares) is less than or equal to a specified value
- Centmatch is based on the method proposed by Davis et al. (2006a). It is possible for more than one object to be matched to the same object in another field. Objects are matched, if the centroid distance D is less than
  - the sum of the sizes of the two objects in question (size is the square root of the area of the object) (Centmatch 1)
  - the average size of the two objects in question (Centmatch 2)

  Centmatch does not merge objects explicitly, but determines possible merges applied if MergeForce function is run after centmatch (used in this study). The merging algorithm is described in (Eric Gilleland, SpatialVx Manual, deltamm and centmatch functions). It merges objects according to the minimum of distance metric between the objects.

Examples of CRA application

In Fig. 35 1h precipitation maps are given for 2007062021, VERA max precipitation during MesoVICT core case.

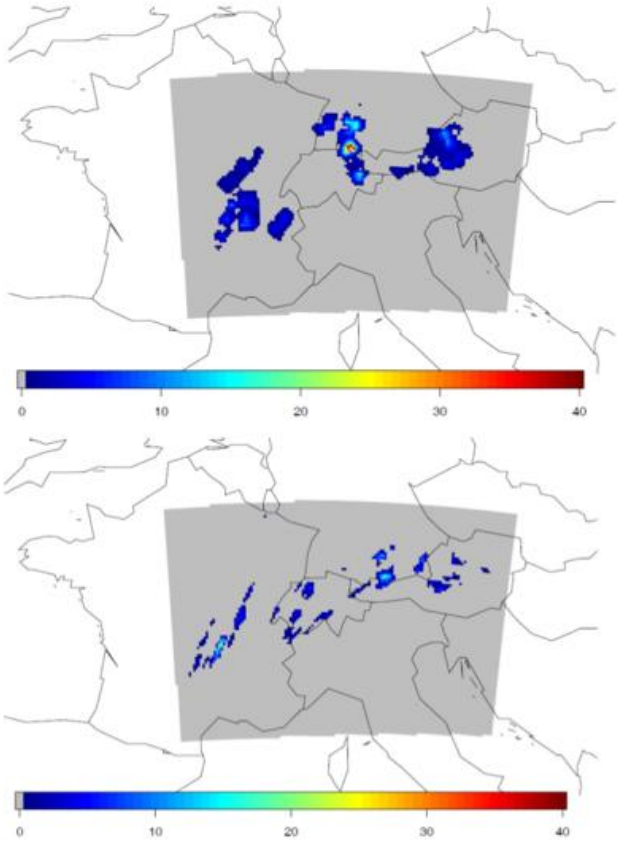

Figure 35: 1h precipitation maps from 2007062021 in mm/h: VERA observations (top), COSMO-2 (bottom).

Fig. 36 gives the matched features for a precipitation threshold 0.5 mm/h as an output of different matching functions for 2007062021.

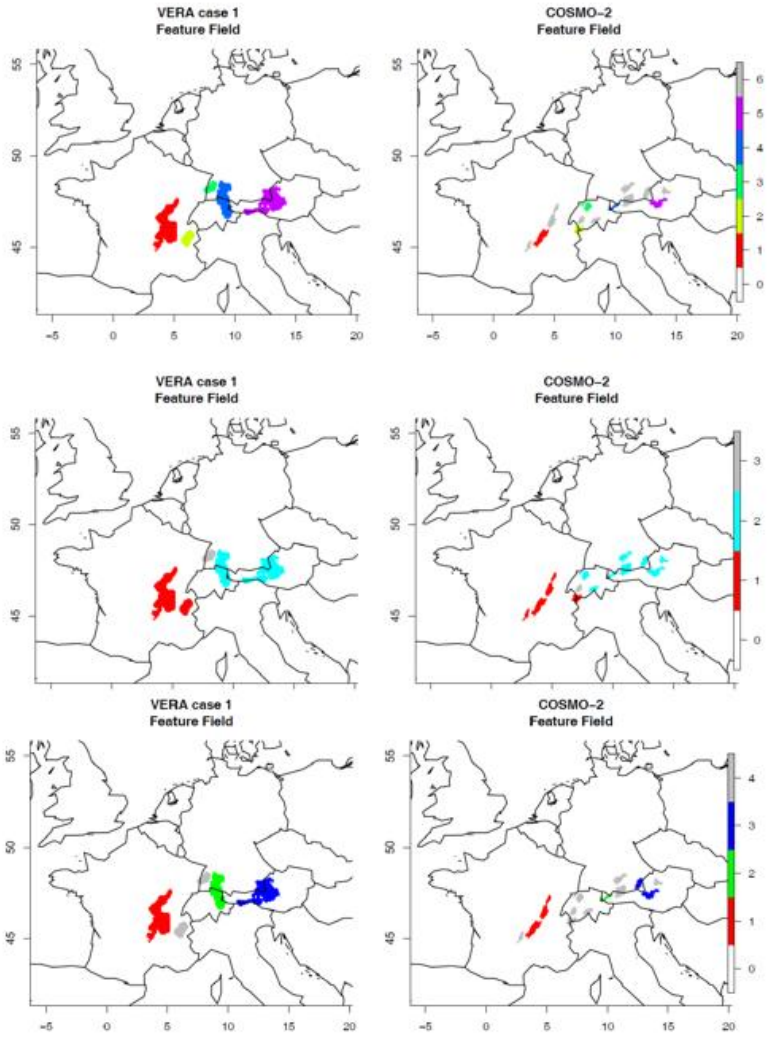

Figure 36: Matched objects pairs using (for precipitation > 0.5 mm/h) using different matching functions for 2007062021: Minboundmatch (top), Centmatch 1 (middle), Centmatch 2 (bottom). Same colours indicate paired objects.

It can be seen from Fig. 36 that it is difficult to objectively choose a best matching function. All methods are acceptable. The choice depends on the user preferences. Centmatch 1 makes implicit merging. In Fig. 37 the objects matched using minboundmatch are given for the same date, 2007062021, but for precipitation threshold > 5 mm/h. The functions Centmatch 1 and 2 do not make any matching in case of intense precipitation. Thus, these matching criteria are too strict for small features.

	displacement	volume	pattern
first pair	0.0006	0	0.0006
second pair	0.0007	0	0.0018

Table 4: CRA error components

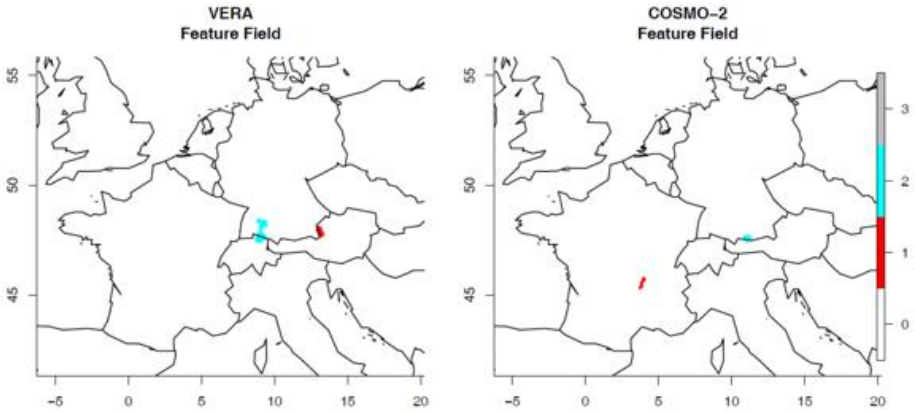

Figure 37: Matched objects pairs using minboundmatch, 2007062021, precipitation threshold > 5 mm/h.

The CRA scores (Table 4) show that the fine scale pattern error contributes most to the total mean squared error in this case. Let us consider another time slot from the MesoVICT case 1, 2007062115, when COSMO-2 made a good forecast (Fig. 38) with higher maximum intensities at the northeast of the domain. Fig. 39 for precipitation threshold 0.5 mm/h demonstrates that Centmatch 1 merges several features in the observed field to match them with one big precipitation object in the COSMO-2 field, while Centmatch 2 and Minboundmatch, which imply stricter distance criteria, do not merge separate objects. The CRA scores show that the fine scale pattern error is most important also in this case.

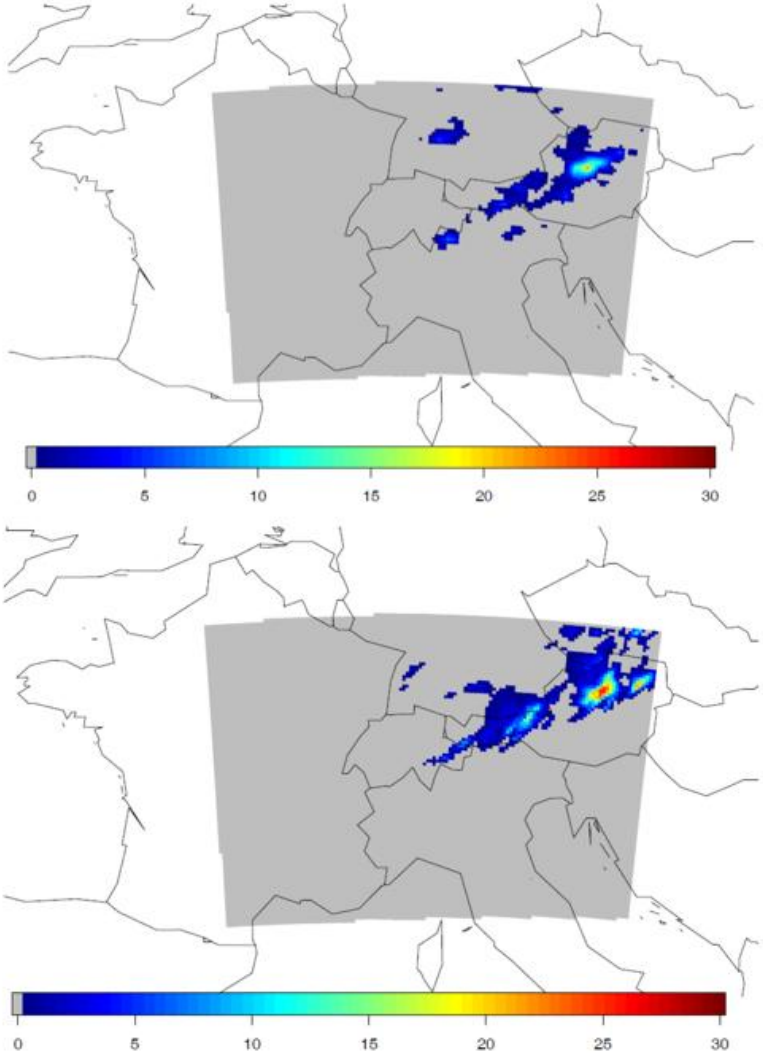

Figure 38: Matched objects pairs using (for precipitation > 0.5 mm/h) using different matching functions for 2007062021: Minboundmatch (top), Centmatch 1 (middle), Centmatch 2 (bottom). Same colours indicate paired objects.

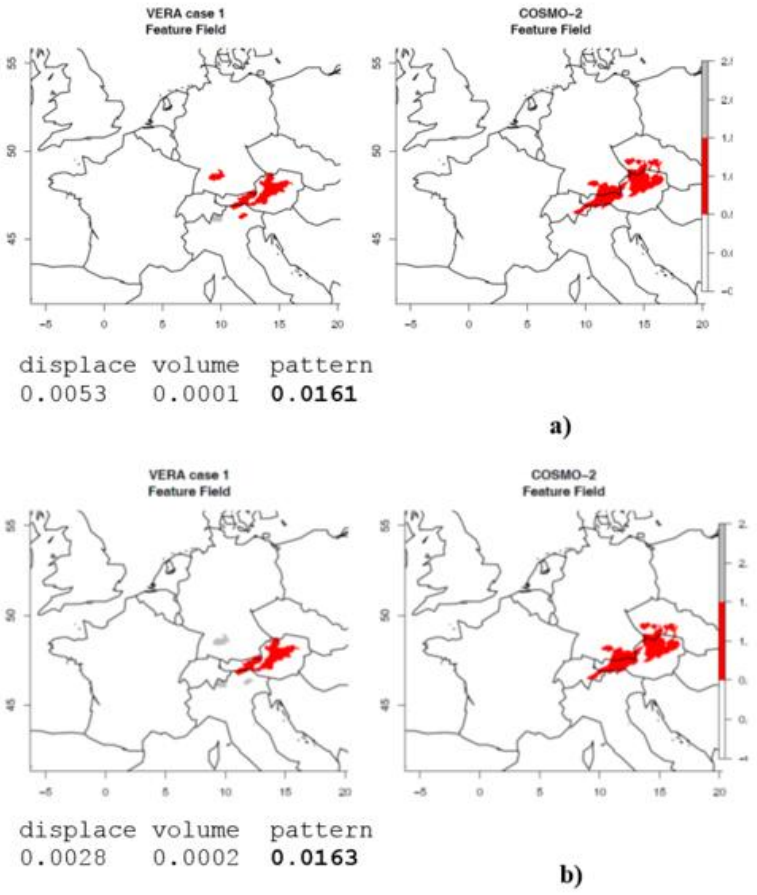

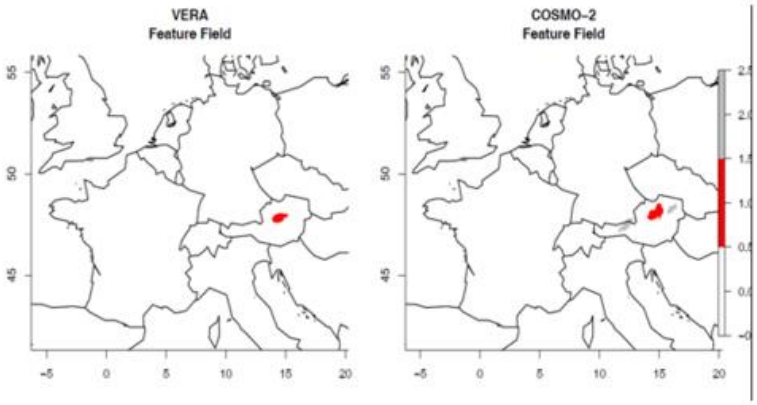

Figure 39: Matched objects pairs and corresponding CRA error components using (for precipitation > 0.5 mm/h) using different matching functions for 2007062115: a) Centmatch 1 b) Centmatch 2 and Minboundmatch (give same matches in this case), same colours indicate paired objects.

For higher precipitation threshold (Fig. 40), all matching functions give the same result. The best match is detected (the central object in COSMO-2 field with precipitation maximum). It should be noted that there were another two intense precipitation areas forecasted, which represent false alarms. In this method, the false alarms are discarded.

displace	volume	pattern
0.0009	0.0000	0.0008

Figure 40: Matched objects pairs and corresponding CRA error components (for precipitation > 5 mm/h) for 2007062115. All matching functions (Centmatch 1, Centmatch 2, and Minboundmatch) give the same matches in this case), same colors indicate paired objects.

Other time slots and synoptic situations were considered, which are not given here.

Conclusions

Smoothing can be undesirable for intense precipitation estimation, although it depends on the user requirements. Option for splitting objects is desirable sometimes. For lower precipitation thresholds and thus wider features, centmatch 2 gives more reasonable results overall. Centmatch 1 makes more merging. For higher thresholds, centmatch often leaves all the objects unmatched due to small areas of features. Minboundmatch seems more promising, but with a minimum boundary separation distance beyond which features should not be matched. According to CRA, most of the error usually comes from the fine structure of the fields (MSE.pattern) for lower precipitation thresholds. For higher thresholds, displacement error contribution increases. The optimal choice of matching procedure can be rather difficult. Each case should be considered before application of particular matching function. Aggregation of results is difficult. The SAL method seems easier to apply because it does not require pair-wise matching.

Ideas for future work

It seems useful to formalize the complexity of situations when the application of metrics is useless. Below is the list of possible approaches to that. It should be noted that it is only an idea at the present state:

- by the maximum number of different features in the field;
- by the complexity of their boundaries (fractals?);
- simple spatial dispersion of the field;
- by the number of holes in a feature (Betti number?);
- other criteria?

4.3.2 An object-based approach to assess the MesoVICT ensemble data

This chapter contains an exploratory study with a goal to transfer the object-based method to ensemble data. The results are preliminary. The starting point was the method proposed in (Johnson and Wang, 2012). The forecast probability is generated for each forecast object as the fraction of ensemble members forecasting the object of interest. In this case, the objects of interest are the observed objects unlike (Johnson and Wang, 2012) where one of the ensemble members was taken as reference to calculate object probabilities. In our approach, performance of the ensemble system could be assessed a posteriori, but the probabilities of objects defined in this way could not be forecasted in the real time, as the observations are not yet known at the time of the forecast. If we want to assess the real forecasts, we need to choose the objects of interest from the ensemble. Then, the member defining the forecast objects should be randomly chosen so that the results were not improved by attempts to select a "best" member. Then, the probability of each observed object can be estimated using the traditional probabilistic scores, the BSS, for example, but verification was not yet implemented. The setup of the experiments is as in Sec. 4.3.1, but COSMO-E ensemble of Swiss meteoservice is taken as model data. In Fig. 41, the upper map represents the VERA observed objects, and the pairs of maps below are the matched observed and model objects for the first six ensemble members from a 21st member ensemble. The colours indicate matched pairs. Then we can calculate the probability of predicting each of observed objects. For example, the VERA object painted in yellow colour in the upper map was matched to an object in 20 of 21 ensemble fields, thus, its probability is 20/21.

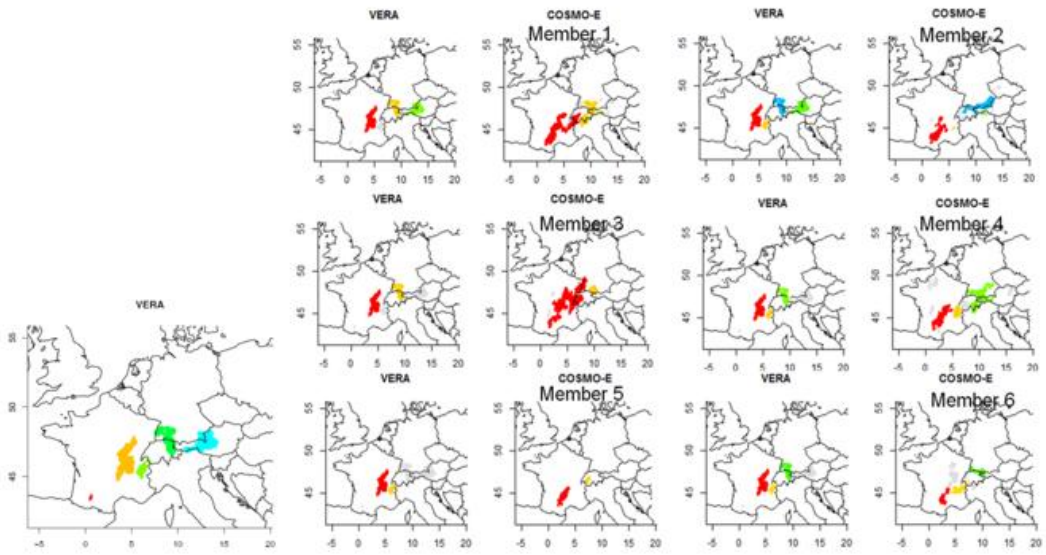

Figure 41: Minboundmatch: 2007062021, COSMO-E ensemble, first 6 of 21 members, precipitation threshold > 0.5 mm/1h. Probabilities of each of 5 observed objects: 1/21 20/21 10/21 19/21 14/21.

A deficiency of such an approach is that the CRA method itself cannot be applied, only the usual probabilistic measures, such as the BSS, can be calculated when a large number of forecasts is aggregated. Another drawback is that no merging of objects is possible as the list of observed objects must be the same for matching with all ensemble members, thus centmatch matching function, which produces merging, cannot be applied. To apply CRA, the possible approaches could be:

- to calculate location, volume, fine pattern errors for each ensemble member, and to average them;
- to identify objects using the probability threshold (Gallus, 2010).

An example of the second approach to object-based method is given in Sec. 4.1 (by D. Boucouvala).

4.3.3 Processing nowcasting forecasts using CRA at RHM (A. Muraviev)

The studies on test cases, such as MesoVICT cases, were conducted having in mind the main goal to verify operational forecasts, in particular, short-range and very-short-range forecasts. Below are the first results of verification of a nowcasting system implemented at the Hydrometcentre of Russia of Roshydromet (Muravev et al., 2018). The core of the system is the statistical STEPS scheme (Short Term Ensemble Prediction System) (Bowler N. et al., 2006) constructed as a multiplicative cascade model with an optical flow technology (the radar fields sequences are considered as an optical flow). Its motto is "seamless, stochastic, scaling, spectral, self-learning". STEPS can run in deterministic and ensemble modes. The results below are obtained with deterministic version. This chapter focuses on verification technology rather than on the scientific findings described in (Muravev et al., 2018).

Verification setup

Period: May 1, 2017 September 30, 2017(∼22000 forecasts). Nine radars over the Central Russia with a total area of about 1100x1300 km were used. For each radar, the area is 500*500 km was considered. The STEPS precipitation intensity forecast calculates fields up to 2.5 h lead time with 10-min time step (15 consequent fields for each forecast) with about 2km grid step. For verification, only 169 situations with intense precipitation were chosen by visual analysis. The SpatialVx package was used to identify objects and to calculate CRA scores. The objects with areas less than 1225=35*35 grid points (about 7070 km) and lager than 16384=128128 grid points (about 250250 km) were excluded from analysis using min.size and max.size option in FeatureFinder function. The radius of averaging for convolution smoothing was chosen empirically as 9 grid points (18 km).

Analysis

Let us consider a case from 17 May 2017. It can be seen from Fig. 42 that the nowcasting system forecasted well the rain object at the first lead time, but by the end of the forecast, the single object in the radar field splitted in two. In Fig. 43, it is reflected in the abrupt change in x_shift (shift in object mass centre in longitude) from positive to negative values at the last two lead times (14 and 15), because the system of object recognition and matching switched to a new object when the single object in the radar field (Fig. 42, lower right field) splitted in two. It follows from the CRA scores that the nowcast object is shifted eastward relative to the corresponding radar object. This case demonstrates the difficulties in matching objects during intense convection cases, as the objects appear and disappear chaotically and it is difficult to follow their history in both reference and forecast fields.

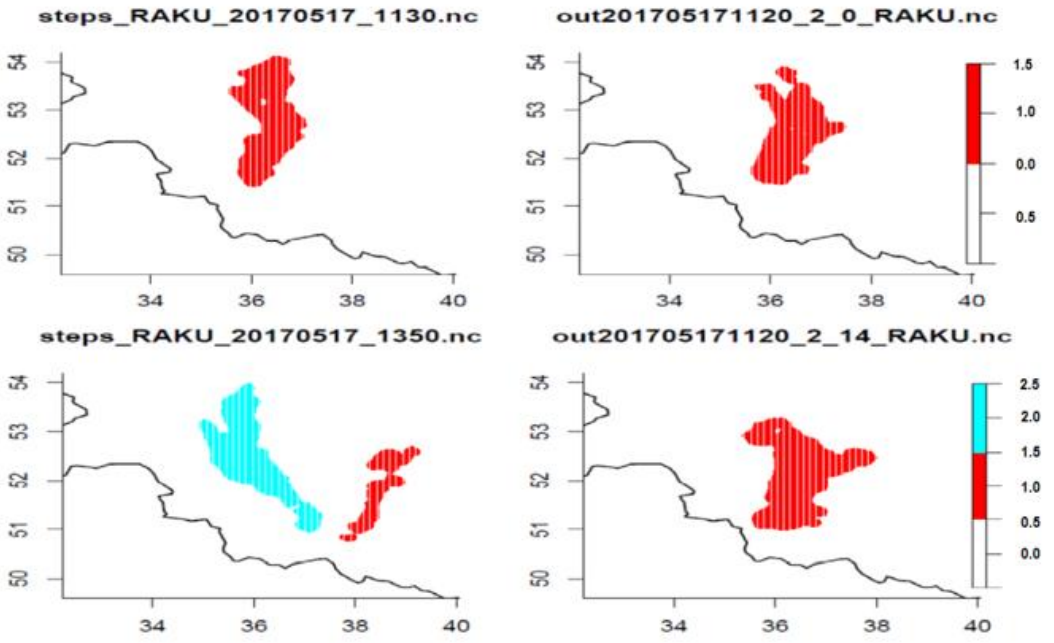

Figure 42: Objects matched using SpatialVx matching function Centmatch 1 (see Sec. 3.2.1) on 17 May 2017. Upper panel: the first nowcast time (11:30 UTC), lower panel: the penultimate nowcast time (13:50 UTC); on the left, the radar fields, on the right, the nowcast fields. Colours indicate matched pairs. Kursk (RAKU) radar.

Figure 43: CRA scores for the case of Fig. 42.

Aggregation of the scores and conclusions

To assess the forecast (or nowcast) system, we need to aggregate a large number of cases. The following method was proposed in this study: the distribution parameters of CRA scores were calculated: the mean, median, upper and lower quartiles, and minimum and maximum values. In Fig. 44, an example for the x_shift (longitudinal shift of the forecast object relative to the reference one) is given. A critical shift error value was introduced from the following

reasoning: the larger object areas intersect, the better. If the smallest object size is 35 by 35 grid points, the reasonable shift error in each of two horizontal axes could be chosen as 35 grid points (about 70 km in this case), that is the radius of round objects of 35 by 35 grid points. The green frame indicates that no less than 50% of object shifts do not exceed the critical value. The red frame indicates that all forecast object shifts do not exceed the critical value. It follows that not less than half of the objects are forecasted with an admissible shift in longitude (green frame) up to 90 min. In Fig. 44, the scores are displayed for one radar only (radar in the Kursk town, RAKU). The same aggregation was performed for nine radars in the Central region of Russia. This analysis enabled the following conclusions about the systematic object shift in longitude: the forecast objects are shifted westward (thus going too fast) for radars RAKU and RAVN and eastward (going too slow) for radars RUDK, RUDN, and RUWJ.

RAKU: CRA x_shift statistics OVER SITUATIONS

lead	min	q25	med	mean	q75	max

9	-48.090	-12.640	-8.150	-5.302	10.428	27.000

Figure 44: Statistical parameters (mean, median (med), upper (q75) and lower (q25) quartiles, and minimum and maximum values) of CRA x_shift score (longitudinal shift of the forecast object relative to the reference one) calculated over the whole verification period May 1, 2017 September 30, 2017. The green frame indicates that no less than 50% of object shifts do not exceed the critical value, the red frame indicates that all forecast objects do not exceed the critical value. Kursk (RAKU) radar.

The same analysis for the latitudinal shift error showed that the systematic shift is to the north for all nine radars. This can be a feature of the optical flow organization in STEPS. The error does not exceed the empirical critical value of 35 km up to 90 minutes in both latitude and longitude for all the radars.

4.4 SAL deterministic study in ARPAE-SIMC (M. S. Tesini and D. D'Alessandro)

4.4.1 Method applied (related to an INSPECT Task) and objectives

The SAL method has been applied; it is an object-oriented method proposed by Wernli et al. in 2008 and provides information about structure (S), amplitude (A) and location (L) of a quantitative precipitation forecast (QPF) (See also Sec. 4.1.1) The definition of a threshold allow to identify the precipitation features inside the domain; a smooth parameter is used to filter small scale noise.

4.4.2 Short description of the dataset (forecast-observation data), adaptation required, software for the method application

The JDC dataset has been used as observations. This dataset consists of reports from more than 12.000 stations over Central Europe which results in a mean station distance of approximately 16 km. With the aim to interpolate irregularly distributed observations to a regular grid in mountainous terrain, the Vienna Enhanced Resolution Analysis (VERA) scheme has been used (horizontal grid resolution of 8 km). The forecast precipitation fields comes from the run 00 of COSMO-2 (horizontal grid resolution of 2.8 km). Due to the different resolutions, the forecast fields have been interpolated on the VERA grid. The COSMO domain extension has been adapted to the observational domain. The R software (SpatialVx package) has been used to apply the SAL method to six interesting cases occurred during the summer of 2017.

4.4.3 Main findings (plots and explanation)

The main result which comes out from the SAL application is that its verification ability is not constant but changes relatively to the considered configurations, in particular it seems to be higher with the decrease in the precipitation fields complexity. A single parameter to evaluate the structure, the amplitude or the location error in forecast is not enough in that cases in which the precipitation field complexity is too high; this becomes evident in Fig. 45: the precipitation intensity is overestimated in Germany and underestimated in France; these errors in forecast compensate each other and determine an amplitude value, referred to the total domain, which is approximately null.

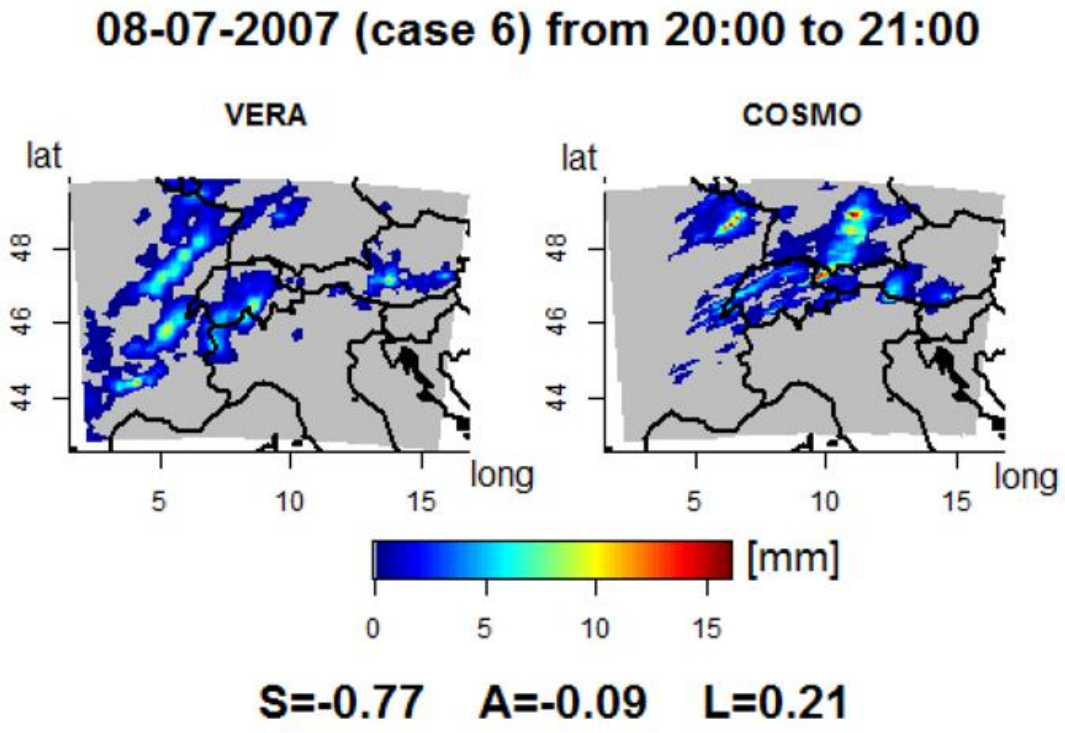

Figure 45: Precipitation intensity and SAL scores, MesoVICT case 6.

As evident from Fig. 46, the SAL scores derived from domains with reduced dimensions are more reliable because they refer to a restricted number of precipitation systems with similar characteristics, avoiding the problem of the loss of information over small scale due to the averaging over the complete domain. This suggests that the choice of the verification domain extension should be done taking it into account. It is clear that this kind of issue emerges for verification over limited accumulation period (1-3h); considering longer periods, the precipitation structures tend to be less fragmented and articulated, allowing the SAL to better evaluate the forecast.

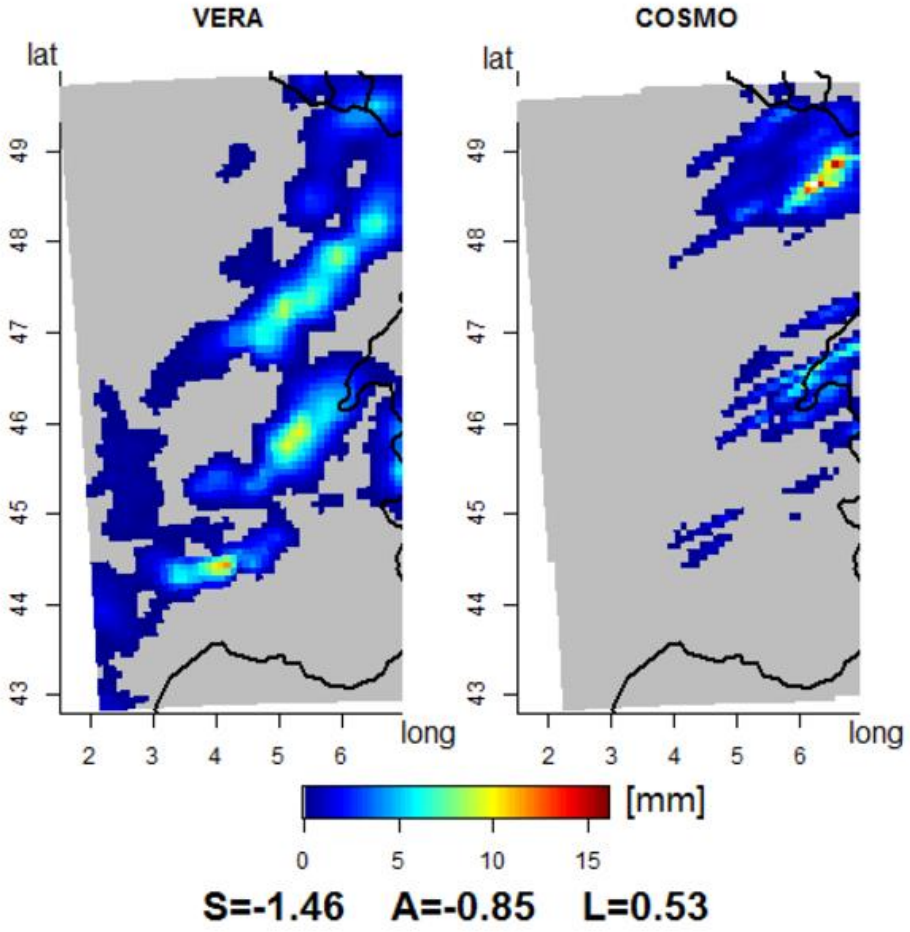

Figure 46: Precipitation intensity and SAL scores, MesoVICT case 6, smaller domain.

4.4.4 Characteristics of the method applied

The SAL has not required an excessive computational time for the verification of the considered cases.

The three scores provided by this method allow pointing out the characteristics of a high resolution model. For instance, the structure component S clearly emphasizes the ability of a high resolution model to predict more realistic precipitation features compared to coarser models. The threshold allows identification of the precipitation objects in the domains; the SAL is able to provide information about the location, amplitude and structure errors of these detected features. With respect to the location component L, this is provided as a sum of a L1 and L2 components; L1 gives a measure of the distance between the centres

of mass of the modelled and observed precipitation fields, while L2 takes into account the average distance between the centre of mass of the total precipitation fields and individual precipitation objects. Both L1 and L2 ranges from 0 to +1, so the final component L lies within the range [0,+2]. Based on this definition, different situations can yield the same value of L, in particular there is no sensibility to the rotation around the centre of mass. Furthermore the L value is strictly connected to the maximum dimension of the considered domain. In practical terms it means that, considering the same absolute displacement error, the smaller the domain dimensions, the bigger is L. The amplitude component A is defined as the difference of the domain-averaged precipitation values. The values of A are within [-2,+2] with A = 0 representing the best forecast. Although a zero value is desirable, it is important to remark that it does not necessarily represents a perfect forecast due to the infinity number of possible situations which can lead to identical values of the domain-averaged precipitation. A better indication is obtained integrating the structure component S. The threshold parameter can be a fixed value or a flexible one. The advantage of a fixed threshold is that verification can focus on a particular category, for instance, of intense events, and the statistical results are not blurred by weak events that might be of less interest. However, specification of a fixed threshold excludes poor forecasts from an object-oriented verification in situations in which the threshold is not exceeded in either the model (missed events) or the observations (false alarms).

5 Sensitivity of COSMO-LEPS forecast skill to the verification network: application to MesoVICT cases (A. Montani, C. Marsigli, T. Paccagnella, ARPAE-SIMC)

5.1 Overall aims

- To test the forecast skill of COSMO-LEPS in terms of total precipitation for different verification networks and different verification methods;
- to understand the meaning of the differences in the verification scores.

5.2 Verification datasets

Reference data are the verification networks available in 2007 (Fig. 47):

- **JDC** (**J**oint **D**Phase-**C**ops) dataset. About 12000 observations (mean station distance $\sim$ 12 km);
- **VERA** (**V**ienna **E**nhanced **R**esolution **A**nalysis), gridded analysis at the resolution of 8 km (Dorninger M. et al., 2013).

The model data come from the COSMO-LEPS suite available in 2007 at ECMWF (Montani et al., 2011).

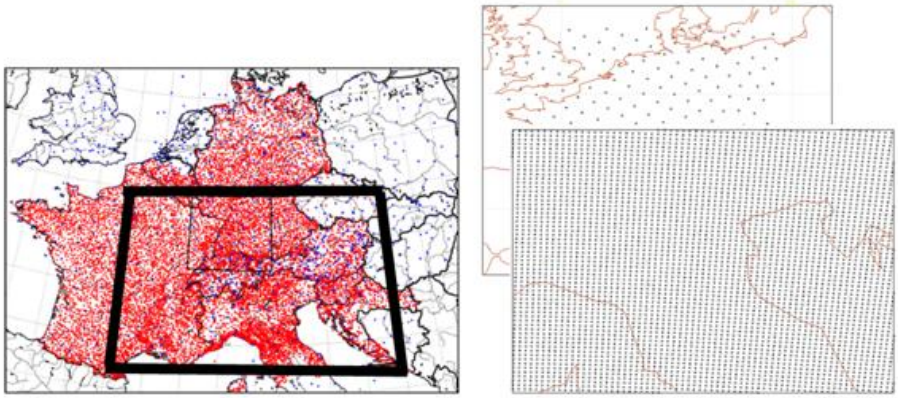

Figure 47: Verification area: DPHASE area (43-50N, 2-18E) (bold black frame).

5.3 Verification setup

- variable: 6h cumulated precipitation (0-6, ..., 18-24 UTC);
- period: all 6 mesoVICT cases (Jun Sep 2007);
- region: 43-50N, 2-18E (D-PHASE area);
- method: nearest grid point, bilinear interpolation, boxes of different sizes;
- forecast ranges: 0-6h, 6-12h, ..., 126-132h;
- thresholds: 1, 5, 10, 15, 25, 50 mm/6h;
- probabilistic scores: ROC area, RPS, Outliers.

5.4 Results

In Fig. 48, the precipitation ROC area scores are displayed for two interpolation methods using two different reference datasets (JDC and VERA). For precipitation threshold 1mm/6h (Fig. 48a), the system performance is similar with respect to the 2 verification networks. For precipitation threshold 10 mm/6h (Fig. 48b), higher skill is observed when COSMO-LEPS is verified against VERA gridded analysis. There is almost no impact of the verification technique (nearest grid point versus bilinear interpolation) for both thresholds.

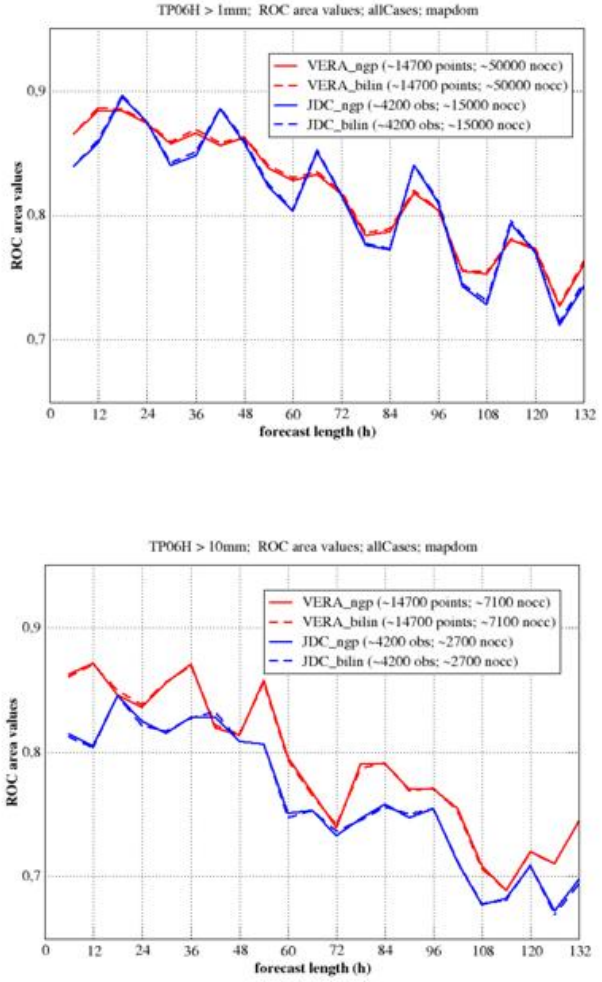

Figure 48: ROC area scores for two interpolation methods using two different reference datasets (JDC and VERA) for precipitation threshold 1mm/6h (top) and 10mm/6h (bottom).

In Fig. 49, a comparison is given between the probabilistic scores in DIST boxes of different size calculated using different reference datasets (JDC and VERA). DIST method is described in Sec. 3.3. It is seen that slightly higher skill is observed when COSMO-LEPS is verified against VERA gridded analysis. The skill increases with increasing box size. There is increasingly less dependence of the score on the verification network for larger boxes.

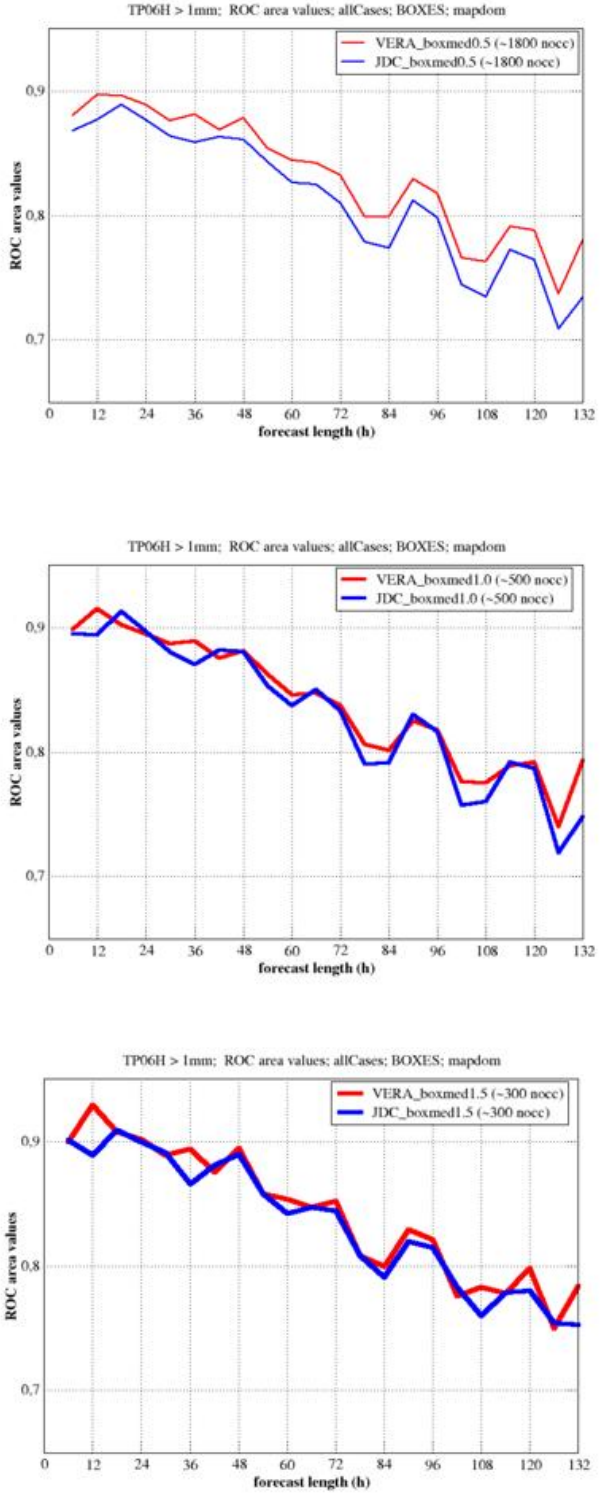

Figure 49: ROC area scores in DIST boxes of different size calculated using different reference datasets, JDC (blue) and VERA(red).

5.5 Conclusions

- For nearest grid point versus bilinear interpolation methods, the similar COSMO-LEPS forecast skill is observed using either gridded analysis or sparse observations (VERA or JDC) for verification network;
- for average precipitation in DIST boxes, there are similar scores for verification against gridded analysis or sparse obs for larger and larger boxes;
- as long as we "throw" everything in a box and compare average values (similar results considering the max values), the verification network does not make too much difference.

5.6 Future work

- To consider observation uncertainty: work with ensembles of VERA analysis and quantify scores variability;
- to work on higher-resolution ensembles (COSMO-E reruns).

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction

Radiation transfer schemes are critical part of numerical weather prediction (NWP) models since solar energy is the engine for atmospheric dynamics. The seasonal and diurnal cycles are governed by attenuations in sunshine duration and intensity. The first and most important factor which determines the solar irradiance is the solar zenith angle. This angle is defined by the location on earth and the time and can be accurately calculated from deterministic equations. The second most important effect is the cloud cover, and not less important, the cloud optical thickness. The radiation-clouds are coupled in a two-way manner. The hitting of land and sea surfaces causes the thermodynamic instability that is needed for cloud formation and precipitation but also creates a mask that prevents solar fluxes to penetrate the atmosphere hence reducing the instability. Other constituents that impact the atmosphere opacity are the gasses, mainly H_2O, O_3 and CO_2, and aerosols.

The radiation scheme is a computationally expensive part of most NWP models although many simplifications are considered. Some of the simplifying assumptions used are the reduction of the dimension of the problem from 3D to a 1D problem namely the two-stream approximation in which only upward/downward fluxes are calculated. Another generalization is the use of only few spectral intervals (bands), in COSMO only 8, to describe the entire shortwave (SW) incoming solar radiation and the outgoing long wave (LW) radiation. This is a rough approximation especially for the description of the gasses absorption spectra which is rapidly changing as a function of wavelength. In COSMO radiation scheme the k-distribution method is applied to solve this problem and will be described later in section 4. As for clouds, parametrizations are used to describe the radiation-cloud interaction. First, the bulk cloud properties such as effective size and number concentration are defined from ice and water contents and assumptions about the size distribution functions. Second are the optical properties of the hydrometeors which are parametrized as a function of the effective size. In this project both steps were re-visited. The water droplets and ice particles number concentrations were calculated by more realistic schemes using forecasted aerosols contents to better define the effective size. The optical properties parametrizations of water droplets and ice particles were recalculated using sophisticated spectral integration with an elegant formulation that covers a very wide particles size range therefor allowing the inclusion of both rain and snow in the radiative transfer scheme. In addition, for the first time, the asymmetry factor for which defines the amount of forward vs. backwards scattering, was evaluated as a function of aspect ratio of the ice particles instead of their effective size (the reasoning for this is discussed by Fu, 2007).

In this project we also experimented a new approach for the aerosols input for the radiation. Usually NWP models either use climatology i.e. by Tanre (1983), or by Tegen (1997) which is a computationally cheap choice, or running a fully coupled aerosols-chemistry-atmosphere modules such as COSMO-ART, ICON-ART which are very costly. Here we proposed and realized a quasi-forecasted aerosols scheme. The forecasted aerosols by the full coupled models (in our case CAMS or ICON-ART) are interpolated in space and time into COSMO boundary files by *Int2lm* and are used by the radiation scheme. Of course that in cases of disagreement between COSMO and the aerosols model dynamics, the aerosols input is not ideal, i.e. when washout is present. Nevertheless, the performance is equal or better compared with monthly climatology option with only small computational price.

2 Tasks and achievements

This project was constructed of 12 tasks:

1. Testing and tuning of the new cloud-radiation scheme performance
2. Analysis/Revision of SGS cloudiness in the radiation scheme including LES simulations of cumulus clouds
3. Implementation of CAMS forecasted aerosols in the radiation scheme
4. Adapting switchable single/double precision to the radiation scheme
5. Implementation and testing of the MCSI method
6. Testing the radiation scheme against experimental datasets and benchmark models for clear/cloudy sky conditions
7. Implementation of new ice and water droplets optical properties in ICON-RRTM radiation scheme
8. Implementation and testing of ICON-ART forecasted aerosols in COSMO radiation scheme
9. Implementation and testing of CAMS forecasted aerosols in COSMO microphysical scheme
10. SAM LES utilization for parametrization of sub-grid scale shallow cumulus cloud cover and its testing
11. Updating the COSMO latest version - block structure and GPU compatible
12. Summary and documentations including web-app for cloud optics in COSMO webpage: http://www.cosmo-model.org/content/tasks/operational/ims/cloudOptics/.

The project lasted 4.5 years from September 2015 to March 2020. With the total amount of 10.77 FTEs in human resources coming from 5 institutions. The main achievements in this project are:

1. New optical properties for water and ice hydrometeors. The extinction coefficient, single scattering albedo and asymmetry factors were parametrized following Fu (1996, 1998) and Hu and Stamnes (1993). Extension of the effective size range allowing the inclusion of snow, graupel and rain. For the first time the asymmetry factor is defined as function of aspect ratio. The new parametrizations were applied in both COSMO and ICON models. Results published in Muskatel et al. (2021).
2. The Monte-Carlo Spectral Integration (MCSI) was realized in COSMO. A wise sampling technique that allows a reduction of calculations in the spectral space as an alternative to the usual time or space resolution reduction of the radiation scheme.
3. Implementation of CAMS forecasted aerosols as an input for the radiation (direct effect) and the microphysical processes (indirect effect). These aerosols fields can be used as input for droplet activation applying Segal and Khain (2006) scheme. Ice heterogeneous nucleation of these aerosols can be parametrized using Phillips (2008) or DeMott (2015) ice nucleation schemes.

4. Implementation of ICON-ART forecasted dust as an input for the radiation scheme. Global ICON-ART dust forecast runs semi-operationally twice a day in DWD. Now these 3 aerosols dust species can be used as an input for COSMO radiation scheme while other species of aerosols are taken from Tegen climatology.

5. Implementation of Kinne (2013) aerosols climatology as an input for radiation. This state-of-the-art climatology is based on observational data with finer resolution compared to the previous Tegen (1997) climatology.

6. A new parametrization of effective radius of shallow cumulus clouds using an adiabatic parcel model. As a result, a new sub-grid scale clouds LWC calculation is also applied.

7. A tuning procedure of the new radiation scheme. Around 30 new parameters were introduced in both $(RC)^2$ priority task and the following $T^2(RC)^2$ priority project. These parameters and switches were reduced to only 8 by a sensitivity analysis using the CALMO methodology and the IDEAL COSMO framework. These 8 parameters were fine-tuned by performing repeated 4-months period runs with many different name lists applying the CALMO method. A set of recommended default values is now available.

8. Massive testing of the new radiation scheme in Israel, Russia, Germany and Switzerland performed by IMS, RHM and MCH in many different atmospheric situations. All the mentioned new featured were tested against ground base measurements as well as benchmark models. Different aerosols inputs were compared and evaluated. In IMS the new scheme is semi-operational for two years.

9. The new radiation scheme, CLOUDRAD, with all its features is now available in the official COSMO release and is single/double precision as well as GPU compatible.

10. A web application for cloud optics is available for the public in COSMO webpage. It is suitable for any cloud-radiation modelling scheme in which the user can define the wavelengths intervals and calculate the optical properties parametrizations for both liquid and ice hydrometeors including dynamical graphics and text outputs.

3 New optical properties for water droplets and ice particles in COSMO model

(H. Muskatel, U. Blahak P. Khain)

3.1 Introduction

Radiation transfer through clouds is a key factor in earth's energy cycle and greatly effects the dynamics in the atmosphere. The numerical weather prediction model needs to forecast the amount of clouds, their thickness (LWC, IWC), the hydrometeors concentration and their effective size in order to calculate the amount of radiation transferred, absorbed and scattered by clouds. Having these parameters correctly described, the radiation module can calculate the clouds interaction with the radiation using three optical properties: the extinction coefficient, the single scattering albedo and the asymmetry factor (β_{ext}, ϖ, g). These properties needs to be defines for each hydrometeor separately (ice, liquid and aerosols) but also for each wavelength interval and each particle effective size. In this project we introduced a practical parametrization of both liquid droplets and ice particles optical properties

based on the single wavelength data of Fu (1996, 1998) and Hu and Stamnes (1993). We used an ensemble of 7500 particle size distributions (PSD) which enabled the effective size range to be extended to include larger hydrometeor categories such as rain, snow and graupel.

3.2 Ice Particles

The default COSMO optical properties parametrizations for ice hydrometeors, is based on IWC only. In more advanced models the effective size R_{eff} is used. We adopted the generalized effective size, $\mathrm{D_{ge}}$. It quantities the ratio between the volume and the statistically averaged projected area ($\overline{\mathrm{A}}$) of a randomly oriented needle particle (Fu, 1996):

$$\mathrm{D_{ge}}=\frac{\int_{\mathrm{Lmin}}^{\mathrm{Lmax}}\mathrm{DDL}\cdot\mathrm{n(L)dL}}{\int_{\mathrm{Lmin}}^{\mathrm{Lmax}}\left[\mathrm{DL}+\frac{\sqrt{3}}{4}\mathrm{D}^2\right]\mathrm{n\,(L)\,dL}}=\frac{2\int_{\mathrm{Lmin}}^{\mathrm{Lmax}}\mathrm{V(L)}\cdot\mathrm{n(L)dL}}{\sqrt{3}\int_{\mathrm{Lmin}}^{\mathrm{Lmax}}\overline{\mathrm{A}}\mathrm{(L)}\cdot\mathrm{n(L)dL}} \tag{1}$$

Where D and L are the width and length of the particle, n(L) is the particles size distribution (PSD). In our case we used an ensemble of particles which is assumed to follow a four-parameter modified gamma distribution (MGD):

$$\mathrm{N(L)}=\mathrm{N_0}L^{\mu}e^{-\lambda L^{\nu}} \tag{2}$$

$$M_i=\int_0^{\infty}L^iN\left(L\right)dL=\frac{N_0}{\nu}\frac{\Gamma(\frac{\mu+i+1}{\nu})}{\lambda^{\frac{\mu+i+1}{\nu}}} \tag{3}$$

$$\overline{L}=\frac{M_1}{M_0}=\frac{\Gamma(\frac{\mu+2}{\nu})}{\Gamma(\frac{\mu+1}{\nu})}\lambda^{\frac{-1}{\nu}} \tag{4}$$

where No is the scale parameter and μ, ν, λ control the shape of the distribution, M_i is the size distribution ith moment, and $\overline{L}$ is the mean particle length. A simpler gamma distribution is obtained by setting $\nu = 1$ hence:

$$\overline{L}=\frac{\mu+1}{\lambda} \tag{5}$$

We compose 7500 PSD ensemble by a systematic variation of the PSD parameters within a wide range. We change $\overline{L}$ in the range of 5-3000 μm in 500 logarithmically equidistant steps, while μ is changed from 0 to 14 which resulted $\mathrm{D_{ge}}$ to be in the range of 5-600 μm.

The asymmetry factor, as proved from ray scattering simulations for many types of ice crystals, dependents less on size and shape rather on the particle's effective aspect ratio (Fu, 2007):

$$\mathrm{AR}=\int_{\mathrm{Lmin}}^{\mathrm{Lmax}}(\frac{\mathrm{D}}{\mathrm{L}})\cdot\overline{\mathrm{A}}\cdot\mathrm{n(L)}/\int_{\mathrm{Lmin}}^{\mathrm{Lmax}}\overline{\mathrm{A}}\cdot\mathrm{n\,(L)\,dL} \tag{6}$$

The optical properties can be parametrized as a function of D_{ge} and IWC which for hexagonal particles is:

$$\mathrm{IWC}=\frac{3\sqrt{3}}{8}\rho_{\mathrm{ice}}\int_{\mathrm{Lmin}}^{\mathrm{Lmax}}\mathrm{D}\cdot\mathrm{D}\cdot\mathrm{L}\cdot\mathrm{n(L)dL} \tag{7}$$

ρ_{ice} is the bulk ice density ($0.917\ g\cdot cm^{-3}$). $\mathrm{D_{ge}}$ and AR can be evaluated from the mass-size relation used by the cloud microphysics scheme, for example, $m{=}aL^b$ where m is the particle mass. The raw data for the single particle extinction and scattering cross sections (σ_{ext}, σ_{sca}), asymmetry factor (g_p) and the forward scattering δ-function peak (f_δ) were taken from Fu (1996) and Fu et al. (1998).

The technique of spectral averaging over wide bands depends on the parameter one desires to compute the spectral integration technique is explained in details in Muskatel et al. (2021).

We parametrize $\overline{\beta'_{ext}}, \overline{\omega}, \overline{g}, \overline{f_d}$ as function of D_{ge} and AR by fitting rational functions division in the Padé approximation form:

$$f_{(x)}=\frac{\sum_i^N a_i x^i}{\sum_i^M b_i x^i} \tag{8}$$

Where x can be D_{ge} or AR and a_i, b_i are fitting coefficients. This requires a non-linear fitting algorithm like Levenberg-Marquardt, but it is very flexible and can reproduce nearly any asymptotic behaviour if N, M are chosen adequately. If $N= M$, an asymptotic convergence to a constant for $x\to\infty$ results. If $N< M$, the function converges to 0. For $\beta'_{ext}(D_{ge})$ we chose $N= 2$; $M= 3$, for $\omega(D_{ge})$ and $f_d(AR)$ we defined $N= 3;M= 3$ while for $g(AR)$ we put $N= 3;M= 2$. An example for the parametrization fit can be seen in Fig. 1 The asymmetry factor presented in Fig. 1 was calculated for particles with smooth surfaces, where the forward scattered peak (delta fraction f_d) is large because of the plane-parallel surfaces of the ice particles. However, real particles might have rough surfaces, where the forward scattering is smaller. The asymmetry factor for rough surfaces can be defined as (Fu 2007):

$$g_r=\frac{g-f_d}{1-f_d} \tag{9}$$

An example for f_d and g_r parametrization fit can be seen in Fig. 2.

In the original RG92-formulation, the scattering phase function is approximated by the so-called δup-Eddington approximation, which is a sum of a general two-term Legendre-polynomial expansion of the phase function plus a delta-forward peak, weighted by the forward scattered fraction f (Joseph et al. 1976). This approximation is "tuned" to the original phase function by matching of g, which is the first moment of the phase function, and by requiring that $f=g^2$, which follows from the matching of the second moment of the phase function with that of the Henvey-Greenstein function.

For ice particles in the visible spectral range, we now allow the formulation in a way that f is an independent free parameter (Fu 2007):

$$f_{rough}=\frac{1}{2\omega(D_{ge})} \qquad and \qquad f_{smooth}=\frac{1}{2\omega(D_{ge})}+f_d \tag{10}$$

where f is limited so that it cannot be larger than g^2.

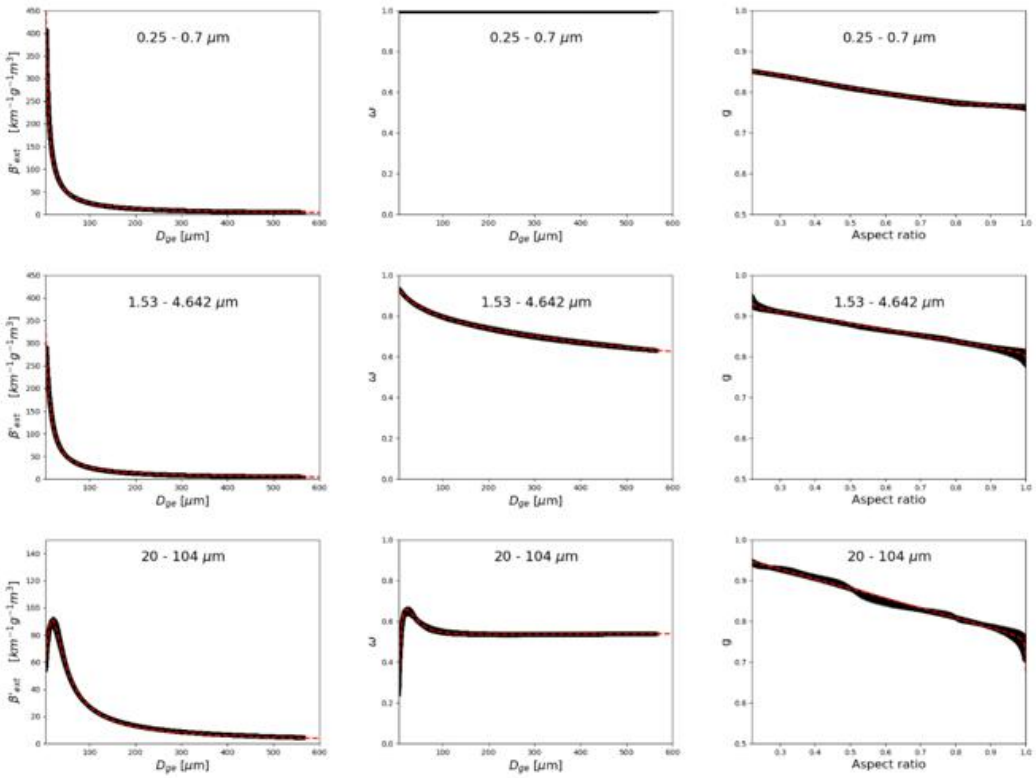

Figure 1: Parametrizations for β'_{ext} (volume extinction coefficient divided by IWC, i.e., mass extinction coefficient) (left column), single scattering albedo (centre column) and asymmetry factor (right column). The upper, middle and lower rows refers to wavelengths of 0.25-0.7 μm, 1.53-4.64 μm and 20-104 μm COSMO intervals respectively. The black line is composed of 7500 individual points, each represents a different PSD, and the red dashed line denotes the parametrization fit model.

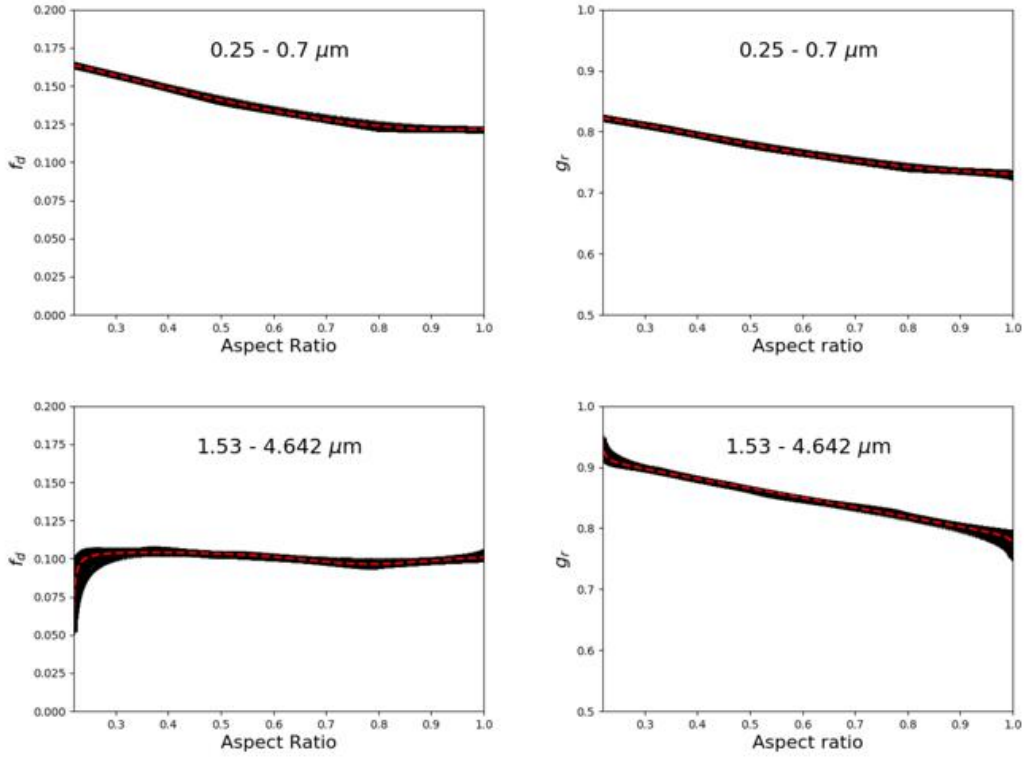

Figure 2: Parametrizations for delta fraction (left) and rough surface particle asymmetry factor (right). The upper and lower rows refers to wavelengths of 0.25-0.7 μm and 1.53-4.64 μm intervals respectively.

3.3 Water droplets

The default COSMO optical properties parametrizations are based on Mie calculations by Stephens (1989) and the parametrizations proposed by Slingo and Schrecker (1982) for water clouds. The effective radius for the quasi-spherical water droplets is define as:

$$R_e = \frac{1}{2} \int_0^\infty D^3 N(D)\, dD / \int_0^\infty D^2 N(D)\, dD = M_3/(2M_2) \tag{11}$$

This definition is motivated by the large-size limit where β'_{ext} is directly proportional to R_e^{-1}:

$$\lim_{D/\lambda \to \infty} \frac{\sigma_{ext}}{A_{geo}} \; ; \quad A_{geo} = \frac{\pi}{4} D^2 \tag{12}$$

$$\beta'_{ext} \equiv \frac{\beta_{ext}}{LWC} = \frac{2\frac{\pi}{4} M_2}{\frac{\pi}{6} \rho_w M_3} = \frac{3}{2\rho_w R_e} \tag{13}$$

$$R_e = \frac{1}{2} \frac{M_3}{M_2} = c_1 \left(\frac{LWC}{n_w} \right)^{c_2} \tag{14}$$

Where A_{geo} is the geometric cross section of a spherical droplet, LWC is the liquid water content, n_w, ρ_w are the number concentration and bulk density of water, respectively. The constant coefficients c_1, c_2 depend on the constant mass-size-relation parameters and on the size distribution parameters. Based on Mie calculations performed by Hu and Stamnes (1993) (HS93) and using the spectral averaging technique described in the previous section,

we applied the calculation to the 8 COSMO wavelength intervals. The same choices for $\rho_{w,max}= 1\ gm^{-3}$, $\Delta z_{min}= 100\ m$ and $\Delta z_{max}= 600\ m$ as was chosen for ice, are used here. We used the same fitting formula as for ice but with $N= 3$; $M= 4$, for $\beta'_{ext}(R_e)$ while for $\omega(R_e)$ and $g(R_e)$ we defined $N= 3; M= 3$. The three size sub-ranges of fitting used by HS93 where replaced with one formula that fits all ranges and is valid in the range $2.5\ \mu m \rightarrow \infty$. An example for the parametrization fit can be seen in Fig. 3.

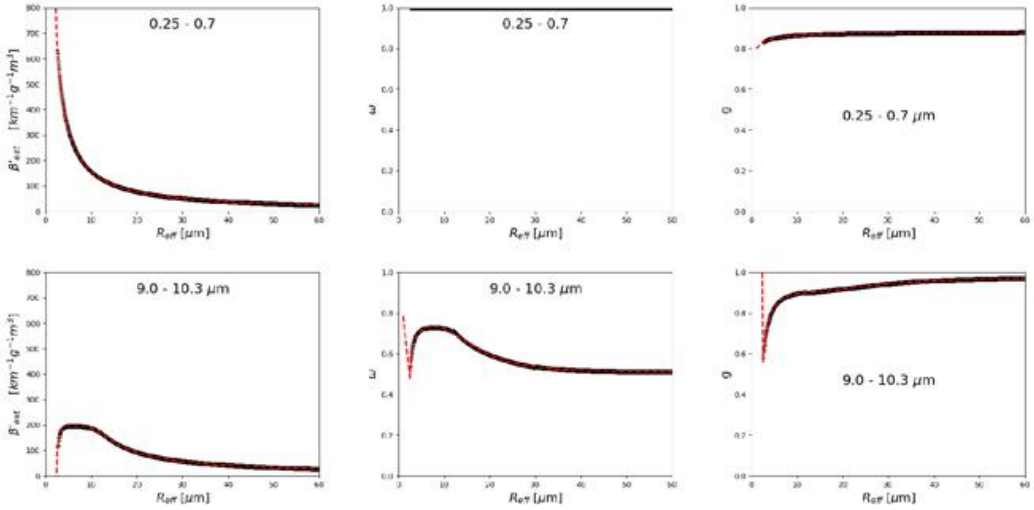

Figure 3: Parametrizations for volume extinction coefficient divided by LWC (left), single scattering albedo (centre) and asymmetry factor (right). The upper and lower rows refers to wavelengths of 0.25-0.7 μm and 9.0 - 10.3 μm intervals respectively. The black line is composed of HS93 original data spectrally averaged for our wavelength intervals and the red dashed line denotes the parametrization fit model. As can be seen from the plots, the fit is invalid for effective radius smaller than 2.5 μm. These fits showed asymptotic behaviour up to 7000 μm (not shown here).

3.4 Sensitivity Experiments

We examined the impact of the new optical properties parametrizations on the radiation transfer, and compare it with the default COSMO radiation scheme (RG92 thereafter) under different cloudiness situations. For that purpose, we have utilized the idealized version of the COSMO model to simulate radiation transfer through two types of clouds: warm stratus and cirrus. The characteristics of the simulated clouds are summarized in Table 1.

The implementation of new parametrizations generally influences the global radiation both directly and indirectly. The change in radiative heating leads to different evolution of the simulated cloud, which in turn influences the radiation transfer. For simplification, we ignored this feedback mechanism, namely removed the radiative heating term in the equation for temperature tendency. All the idealized COSMO simulations were performed between 10:00 and 16:00 UTC, while the zenith angle was fixed to 30°. The domain was chosen to be 100x100 km^2 around 30° N, with periodic boundary conditions and horizontal resolution of 0.025° (~2.5 km). Both deep and shallow convection Tiedtke-type schemes were switched off. Each simulation was initiated with vertical profiles of temperature and humidity suitable for stratiform cloud formation at the chosen heights. During the run period the simulated clouds slightly changed due to evaporation, particles sedimentation, and other processes.

Experiment	Warm stratus	Cirrus
1	2.2-2.7km, 279.2-281.4K	9.5-10.75km, 230.8-218.8K
2	2.0-2.7km, 280.0-281.4K	7.5-10.75km, 250.0-218.8K
3	2.0-3.3km, 280.0-279.0K	7.5-12.20km, 250.0-214.8K
4	1.7-3.3km, 280.4-278.2K	
5	1.5-3.3km, 282.0-279.0K	
6	1.2-3.3km, 284.4-280.2K	
7	1.0-3.3km, 286.0-281.0K	

Table 1: Characteristics of the simulated clouds in sensitivity tests using ideal COSMO framework.

However, they continuously covered the entire simulation domain homogeneously. For each simulation, the output fields (global radiation, total water path, etc.) at 5 min steps were averaged over the domain. Ignoring the first 50 min stabilization period, we obtained 51 values for each field for each simulation. Fig. 4 compares the global radiation of default RG92 and new parametrization for the 7 experiments of warm stratus. The global radiation is shown versus liquid water path. Obviously, the global radiation is smaller for thicker clouds. One can see that in the new version the clouds are optically thinner than in RG92. The global radiation difference is larger for thicker clouds, reaching 20%.

As explained in Section 3, the new scheme parametrizes the effect of cloud water number concentration on the effective radius, which influences the optical properties and the global radiation. Thus, for warm stratus of experiment 5, six more runs were performed with various number concentrations. Fig. 4b shows the effect of cloud water number concentration on the global radiation in the new scheme. In contrast to RG92 where the effective radius was not dependent on number concentration, the new scheme shows significant effect of number concentration and effective radius on the global radiation. Having the same liquid water path, a pristine cloud (number concentration of 10 cm^{-3}) may double the global radiation compared to a polluted one (1000 cm^{-3}).

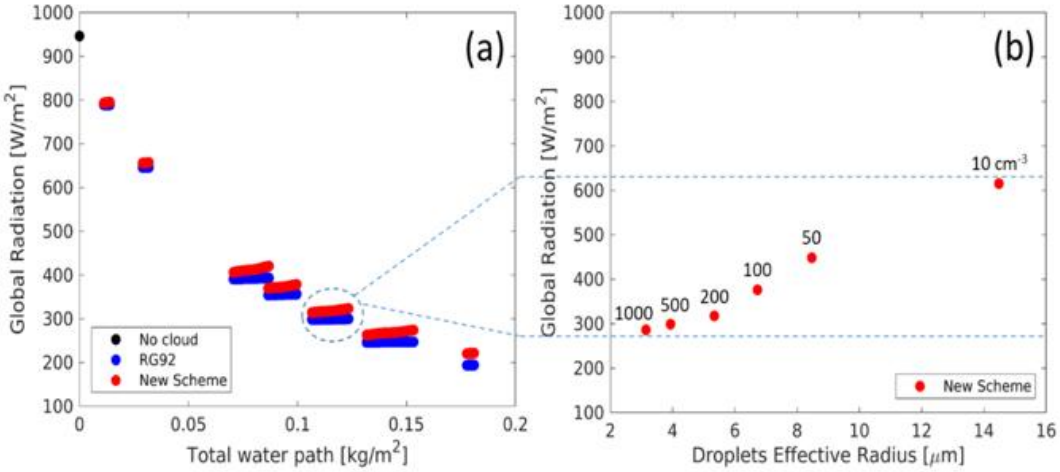

Figure 4: (a) Global radiation versus liquid water path for 7 experiments of warm stratus assuming cloud water number concentration of 500 cm-3. The clear sky reference is marked by black dot. The default COSMO radiation scheme RG92 (blue dots) and the new scheme (red dots) are presented. (b) Global radiation (red dots) in the new scheme versus cloud-averaged droplets effective radius for experiment 5 of warm stratus (see Table 1) marked by dashed circle. The red dots from left to right correspond to cloud water number concentrations of 1000, 500, 200, 100, 50, 10 cm^{-3}. The range of variation in global radiation due to change in effective radius is marked by dashed lines.

Similarly to warm stratus presented in Fig. 4a, Fig. 5a shows the global radiation versus ice water path for the 3 experiments of cirrus (see Table 1). In addition to the default RG92 (blue dots), four more versions of the new parametrization are presented (see Section 2 for details): First assumes rough ice particles surfaces (red dots), the second is similar to the first but adding snow particles into consideration (lime green), the third is similar to the second but assuming smooth surfaces (magenta) and the last is similar to the previous but using the forward scattered fraction approximation of $f = g^2$ instead of the Fu (2007) formulas (cyan). Obviously the global radiation is smaller for thicker clouds. In contrast to warm stratus, the cirrus cloud in the new versions is optically thicker than in RG92. The largest difference from RG92 occurs when assuming rough ice particles and considering snow effect on radiation, where the effect on the global radiation reaches 15% (for thick cirrus - experiment 3). Note that considering snow significantly reduces the global radiation (from red to lime green). Note also that assumption of smooth surfaces makes the clouds optically thinner (from lime green to magenta and cyan), and that there is no significant effect of the different assumptions for forward scattered fraction f (cyan and magenta).

As mentioned, D_{ge} is calculated in the model from ice water content and number concentration which is a function of temperature. In order to highlight the sensitivity of global radiation to D_{ge}, we artificially determine a constant D_{ge} value at all cloudy grid points. Thus, for cirrus of experiment 2, six more runs were performed with various D_{ge} values between 5 and 200 micron. The new version with the assumption of rough needles ignoring snow effect (red dots in Fig. 5a) was chosen for these runs. Fig. 5b shows the influence of D_{ge} on the global radiation in the new scheme. In contrast to RG92 where D_{ge} was not even introduced, the new scheme shows significant effect of D_{ge} on the global radiation. Having the same ice water path, a cirrus cloud with large particles (effective diameter of 200 micron) may yield 10% higher global radiation than an identical cloud with small particles (effective diameter of 5 micron).

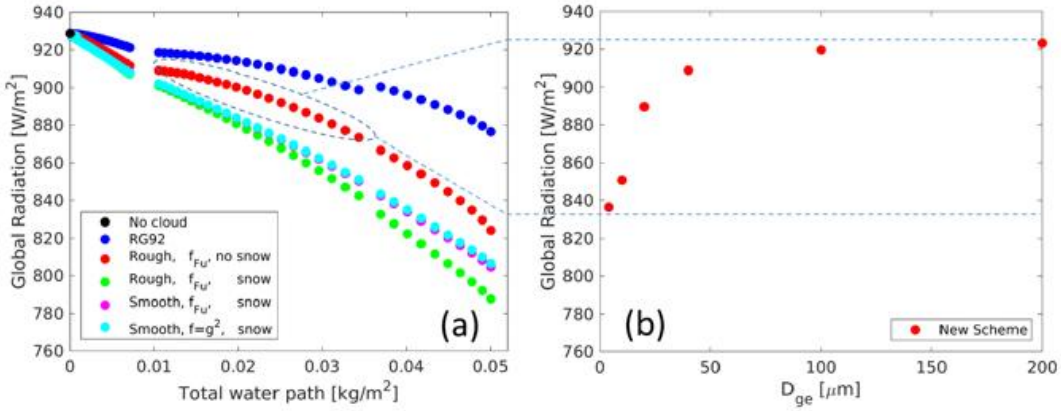

Figure 5: (a) Global radiation versus liquid water path for 3 experiments of cirrus. The clear sky reference is marked by black dot. In blue dots - the default COSMO radiation scheme RG92, red dots represents simulation which assumes rough ice particles surfaces and ignoring snow particles, lime grin dots is the result when snow particles are considered, the same but assuming smooth surfaces are in magenta and the last, in cyan, is similar to the previous but using the forward scattered fraction approximation of $f=g^2$ instead of the Fu (2007) formulas. (b) Global radiation in the Third version of the new scheme (red dots) versus cloud-averaged ice particles effective diameter for experiment 2 of cirrus (see Table 1) marked by dashed circle. The range of variation in global radiation due to change in ice particles effective diameter is marked by dashed lines.

The important quantity for climate applications is the net heating/cooling effect of the clouds. Usually during the day time the SW incoming radiation heats the atmosphere, which is then cooled down via LW outgoing radiation during night time. We cannot discuss this quantity here since our 6 hour long simulations. However, we can check the effect of the new scheme on the net radiation at top-of-atmosphere (incoming minus outgoing). Fig. 6 presents net top-of-atmosphere radiation difference between the new scheme and RG92 versus liquid water path for 7 experiments of warm stratus (Fig. 6a) and versus liquid water path for 3 experiments of cirrus (Fig. 6b). Positive (negative) values indicate warming (cooling) effect by the new scheme with respect to RG92. In Fig. 6b the differences (with respect to RG92) are calculated for the same 4 versions of the new scheme as described in Fig. 5. One can see that the new scheme has warming effect with respect to RG92 for warm stratus, and cooling effect for cirrus. Generally these effects are enhanced (in absolute values) for optically thicker clouds. Note that the assumptions regarding the roughness of the needles surfaces are of low importance for the net radiation (compare cyan, magenta and red dots on Fig. 6b). It is nicely seen that the consideration of snow enhances the net cooling, which can be explained by increase of the cloud albedo.

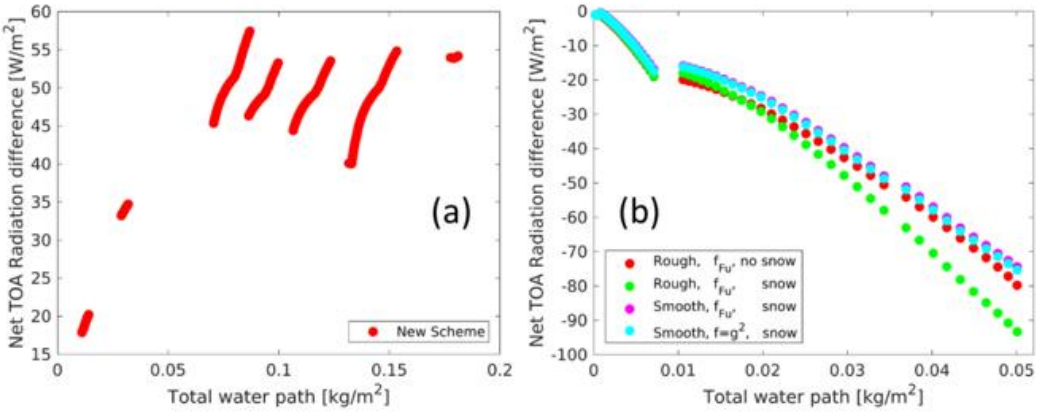

Figure 6: (a) Net (incoming minus outgoing) top-of-atmosphere radiation difference between the new scheme and RG92, versus liquid water path for 7 experiments of warm stratus. Positive values indicate warming effect by the new scheme with respect to RG92. (b) Net top-of-atmosphere radiation difference between the 4 versions of the new scheme and RG92, versus liquid water path for 3 experiments of cirrus (colours details are in the legend of Fig. 5a). Negative values indicate cooling effect by the new scheme with respect to RG92.

3.5 Conclusions and recommendations

The new cloud optics were tested not only in the ideal setup, as detailed in the previous section, but also tested in numerous test cases which will be described in the following sections. We recommend applying the new optics by using iradpar_cloud = 4 with minimal risk. We also recommend choosing lrad_ice_smooth_surfaces = .false. which means that the ice particles will be treated as having rough surfaces. The reasoning behind this recommendation is that rough surfaces ice particles better represents the shape variability. The net radiation on ground will be reduced by few percent having large amounts of ice and snow due to the reduction of forward scattering.

Other recommendation for the new cloud-optics would be: lrad_ice_fd_is_gsquared = .false. which means calculating the forward scattering peak using Fu (2007) formula, lrad_incl_qrqsqg=.true. to include rain, snow and graupel in the radiation scheme and using the large-size approximation by choosing lrad_use_largesizeapprox=.true. Other namelist recommendations can be seen in the appendix of section 3 (upper Air) in COSMO Newsletter No. 19 (October 2019).

A web application for ice and liquid hydrometeors optical properties parametrizations based on this work was created and available for the use of radiation models developers in COSMO webpage. In this web application (www.cosmo-model.org/content/tasks/operational/ims/cloudOptics) developers can insert model spectral integrals and produce parametrizations for ice and liquid hydrometeors including editable graphics.

4 Monte-Carlo Spectral Integration

(H. Muskatel)

4.1 Radiation scheme call-time temporal resolution

Radiation transfer schemes are one of the most computational expensive components in numerical weather prediction (NWP) models. In COSMO model, with only eight spectral intervals, a full radiation calculation costs as much as eight times the cost of the entire COSMO model run. Most of NWP models compromise on the spatial and/or temporal resolution of the radiation scheme. In the operational setup of COSMO-2.8 km, with a full spatial resolution and with a temporal resolution of 15 minutes, the computational cost of radiation is only 3% of the entire model (see Fig. 7).

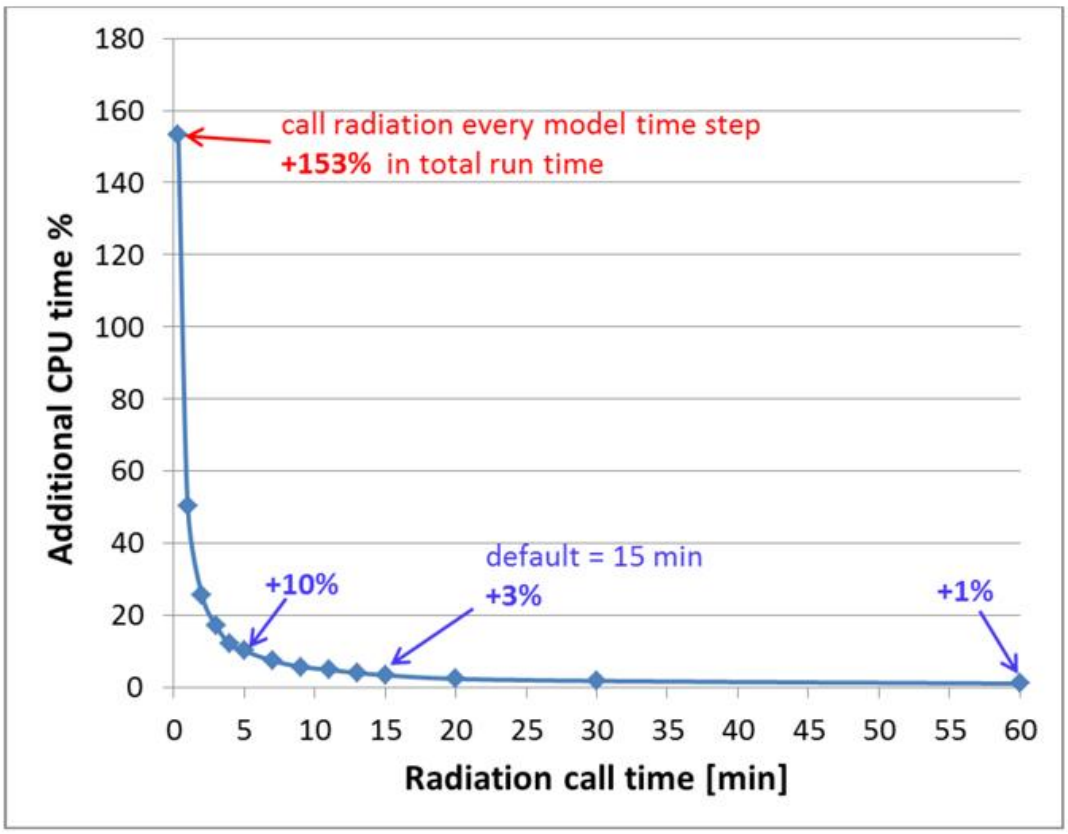

Figure 7: The additional COSMO-2.8km model runtime as function of radiation scheme call temporal resolution. I.e. calling the radiation scheme every 60 minutes adds 1% to total runtime, default resolution of 15 minutes costs 3% increase and calling evry model time step will result more than a double runtime compared with running COSMO with no radiation calculation.

This compromise can lead to local biases in net downward radiation and surface temperatures. To evaluate the magnitude of this effect we chose the 23-25 of April 2015 test case in the IMS-COSMO-2.8km domain. At this period, partial cloudiness and high wind speeds were experienced. The multiple model runs were performed with different radiation temporal resolutions from every model time step (20 seconds) up to 60 minutes. We treat the model

highest temporal resolution as the control run. The model's net downward radiation (global radiation) and 2m temperatures biases for three temporal resolutions: 60, 15, 5 minutes are displayed in Fig. 8. It is clear that the biases appears in the presence of clouds. Also, the biases grow larger in area and magnitudes when the radiation calls separation is larger. In Fig. 9 a domain average of the same experiment are presented. The three lines represents different lead time. It is shown here that there is almost a linear dependency of radiation (left panel) and temperature (right panel) biases as function of temporal resolution and that the biases grow larger for longer runtime. Notice that the line for the 34 hours lead time (blue) is almost flat meaning that there is very weak dependency on temporal resolution at this time. The reason is the clear skies conditions in the second day compared with the cloudiness in the first and third day of the simulation.

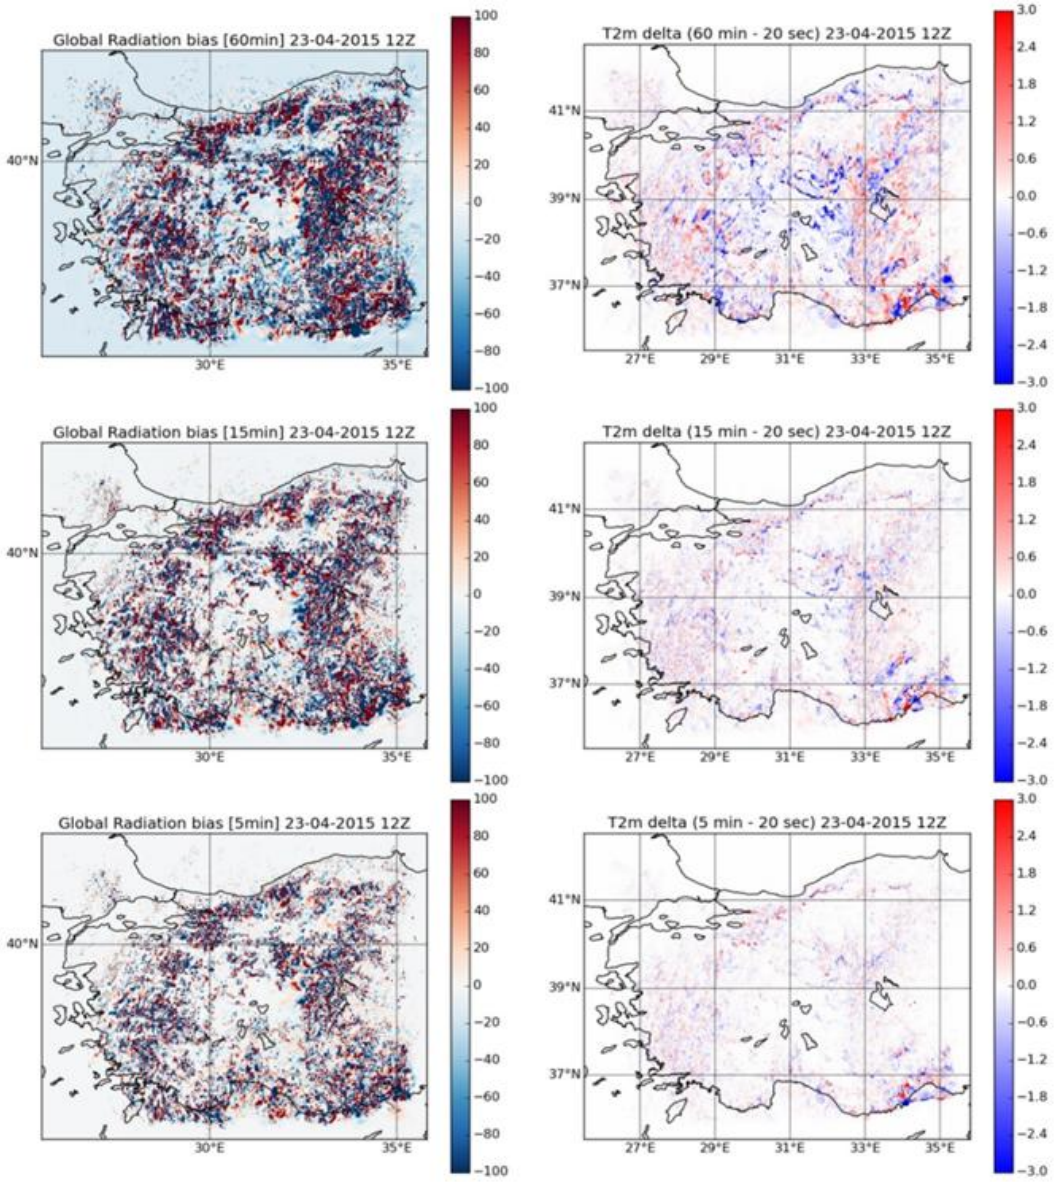

Figure 8: Global radiation (left panels) and 2m Temperature biases (right panels) for three different radiation scheme temporal resolutions 60 min. (upper), 15 min. (middle) and 5 min. (lower) compared with a full temporal resolution (every model time step of 20 seconds). A three days simulation of COSMO-2.8km in IMS domain 23-25 April 2015.

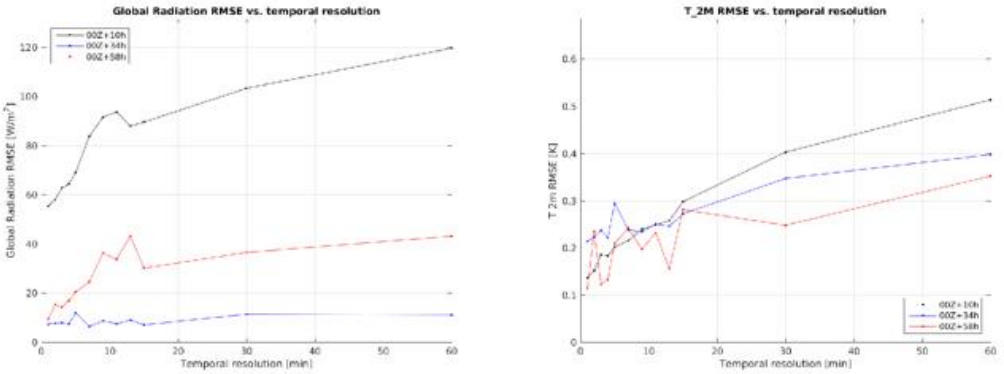

Figure 9: Domain average global radiation (left panel) and 2m temperature (right panel) biases (compared with a control run of full temporal resolution). Three lead times are presented: 10 hours (black), 34 hours (blue) and 58 hours (red). Results plotted as function of radiation call time temporal resolution. The black line represents the lead time with cloudy conditions and the blue line for clear skies conditions. The red line is intermediate conditions.

4.2 The Monte-Carlo Spectral Integration method

In an attempt to both reduce errors and to decrease the run-time we implemented a different approach which is to decrease the spectral resolution by a wise sampling technique, a method known as Monte Carlo Spectral Integration (MCSI). Many radiative transfer schemes and also COSMO RG92 scheme, uses the k-distribution method for the gases-radiation interaction calculations (Fu & Liou 1992). In this method the spectrum is transferred from wavelength space to cumulative probability space. This space is divided to intervals named *g-points*. In COSMO for each gas and for each spectral interval there are between two to eight g-points. In the operational mode of COSMO the Fast Exponential Sum Fitting Technique (FESFT) is used to fully calculate all of the mentioned g-points (Ritter & Geleyn 1992). In MCSI only one g-point is calculated in each time step according to its probability. In COSMO we used a softer version of MCSI where a g-point is selected in each of the spectral intervals which increases the computational cos but does neglect either of the spectral intervals in every time step. In the basic most expensive COSMO radiation scheme, the Exponential Sum Fitting Technique (ESFT), the fluxes calculation subroutines are called for each g-point which belong to the 8 COSMO bands and each of their combinations at each time step, a total of 301 times. In the FESFT, these subroutines are being called only 87 times for each of the g-points in the COSMO radiation scheme. This only are supposed to reduce the CPU effort by a factor of 3. If the radiation scheme is called every 15 minutes only (45 20-seconds time steps) as in the default setup, the runtime for radiation is ∼45 times faster. If the soft-MCSI method is used, only one g-point is selected for each spectral interval at each time step meaning only 8 times ($\sim$ 37 times faster). But using this method needs much frequent call time than the default 15-minutes temporal resolution. Since the radiation is by definition miscalculated at each time step, but the frequent call to the radiation scheme cancels out the errors on the long run since the g-point selection was based on their probability weights. We found out the using the MCSI with full temporal resolution (calling the radiation scheme every time step) in COSMO-2.8km setup can increase runtime by 33% with only slight reduction of global radiation and 2-meter temperature biases compared to FESFT. But using MCSI with a 100 seconds temporal resolution (every 5 time steps) can give the same benefits but

with only 4% increase in runtime. In the upper panel of Fig. 10, the 2m Temperature RMSE of different setups for the same experiment as explained for Figs. 8 and 9 are plotted against the model runtime divided by the model runtime for the default scheme (FESFT with 15 minutes temporal resolution). The RMSE is calculated against a full radiation scheme calculation (ESFT for every model time step) which serves as the control run. We see that the RMSE decreases for the MCSI method (red dots) when the temporal resolution is increased but with the price of CPU runtime. One can clearly see that the default setup (magenta) gives law RMSE values but with minimum model runtime compared with other methods and temporal resolutions seems like the ideal setup as was correctly assumed by previous COSMO model experts. Using the default setup but with a course resolution spatial resolution gives a slightly larger RMSE and slightly reduced model runtime. The lower panel of Fig. 10 shows the T2m bias as function of model runtime differences. As expected the bias is very small for all MSCI experiments and steady even for lower temporal resolutions. Nevertheless, the default setup is at least comparable to the best MCSI set up with 100 seconds resolution but with better runtime.

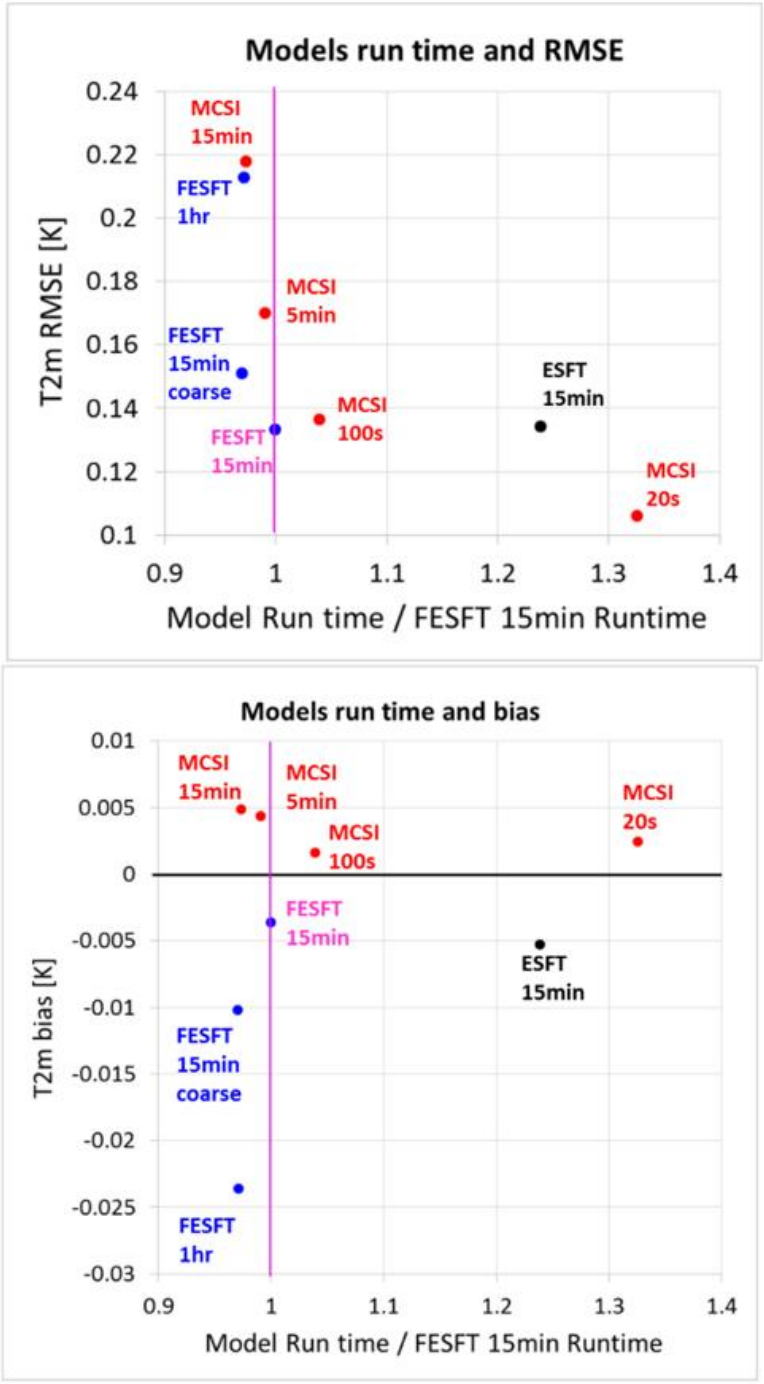

Figure 10: 2m-temperature domain average RMSE (upper panel) and bias (lower panel) compared with a control run of full temporal resolution using ESFT method (see text). The x-axis represents the model runtime compared with the default setup runtime (FESFT method with 15 minutes temporal resolution). Red dots is associated with MSCI method runs with different temporal resolutions, Blue dots represents the FESFT method run and black dot stands for the ESFT method.

4.3 Conclusions and recommendations

A new radiation solver for the scattering and absorption of the radiation by gases (H_2O, CO_2, O_3) was implemented. The new solver based on a soft version of the Monte-Carlo Spectral Integration, that was originally written by Bodo Ritter in a private version, is now fully implemented and tested in the official release of COSMO. To use it one should choose the name list parameter itype_mcsi = 1 with a recommended radiation temporal resolution of 100 seconds (i.e. for a model time step of 20 seconds one should set nincrad = 5). Still, the default scheme using itype_mcsi = 0 with a 15 minutes temporal resolution (nincrad = 45 for the previous example) is still the recommend setup for an ideal combination between performance and runtime. This recommendation is valid for the COSMO-2.8km setup. It is recommended to evaluate the MSCI option for different spatial resolutions (i.e. LES) or different applications like climate models.

5 New parametrization for vertical microphysical profiles in shallow cumulus

(P. Khain, H. Muskatel, U. Blahak)

5.1 Overview

Shallow convection is a sub-grid process in cloud-resolving models for which their grid-box is larger than the size of small cumulus clouds (Cu). At the same time such Cu substantially affect radiation properties and thermodynamic parameters of the low atmosphere. The main microphysical parameters used for calculation of radiative properties of Cu in cloud resolving models are liquid water content (LWC), effective droplet radius (r_e) and cloud fraction (CF). In this study, these parameters of fields of small warm Cu are calculated using large-eddy-simulations (LES). We performed it using the System for Atmospheric Modelling (SAM) with spectral bin microphysics. Despite the complexity of microphysical processes, two fundamental properties of Cu were found. First, is that despite of the high variability of LWC and droplet concentration (N_d) within clouds and between different clouds, the volume mean and effective radii per specific level vary only slightly; Second is that the values of r_e are close to those forming during adiabatic ascent of air parcels from cloud base. These findings allow characterizing a cloud field by a specific vertical profiles of r_e and of mean LWC, which can be calculated using the theoretical profile of adiabatic LWC and N_d at cloud base. Using the results of these LES, a simple parametrization of cloud-field averaged vertical profiles of r_e and of LWC is proposed for different aerosol and thermodynamic conditions. These profiles parametrization is implemented in COSMO to be used for calculation of radiation properties of subgrid Cu fields. For more details, the reader is referred to (Khain et al., 2019).

5.2 Theoretical background

5.2.1 Calculation of shallow cumulus LWC and R_e in NWP models

Large–scale models with grid spacing of tens of kilometres do not resolve clouds and require the use of convective parametrization schemes. The values of r_e and LWC that are usually prescribed in such models, inevitably leads to errors in calculation of related quantities.

The treatment of clouds in meso-scale cloud-resolving models (CRM) with grid spacing of a few kilometres is complicated since only the largest, grid scale, clouds are resolved in such models. Small clouds and especially shallow warm Cu, with a typical size smaller or similar to the grid spacing of CRM remain a sub-grid phenomena.

In CRM calculations of effective drop radii at resolvable scales are performed when the relative humidity (RH) in the grid point exceeds 100%. When the grid spacing is larger than the size of shallow Cu, the conditions for small clouds formation can be suitable even when the calculated mean grid relative humidity (RH) is lower than 100%. These clouds may, however, affect the radiative budget substantially, and the knowledge on r_e, LWC and CF values is necessary for such calculations.

In the limited area NWP r_e of unresolved clouds is a tuning parameter. For instance, in COSMO r_e=5 μm by default. Since on average over the grid box there is sub-saturation, the LWC in these shallow cumuli is crudely parametrized as a function of temperature (reduces with a decrease in temperature), mimicking the reduction of available water vapour for condensation with height. Recently, a new cloud radiation scheme was developed for COSMO (Blahak and Ritter, 2013), and is currently under evaluation. Among other developments, r_e of unresolved clouds is calculated in this scheme from the ratio of LWC and N_d. While LWC is evaluated using the parametrization described above, N_d is determined using the assumed aerosol concentration and the effective (unresolved) vertical velocity at cloud base. The large uncertainty in LWC causes r_e to be highly uncertain as well. As a result, such parametrizations may lead to significant errors in evaluation of effects of shallow convection on radiation and on other thermodynamic atmospheric properties.

5.2.2 Utilization of LES for simulation of small Cu

Large Eddy Simulations (LES) is an efficient method to simulate fields of small Cu and investigate Cu dynamics and microphysics, or to develop new parametrizations for those. To simulate cloud microphysical processes we use the detailed microphysical approach of the bin microphysics, which solves the microphysical equations for determining the droplet size distributions (DSD). In LES simulations the bin-microphysical approach is often used for investigation of thermodynamic factors and aerosols on the parameters of droplet size distributions, drizzle formation and on cloud dynamics (e.g., Jiang et al., 2008). Such parameters as LWC, N_d and $\mathrm{r_e}$ are determined directly from the calculated DSD. In addition to simulation of cloud fields, LES are used to develop parametrization schemes for the large scale models. In the present study we use LES results to investigate the behaviour of microphysical properties of non-precipitating and slightly precipitating shallow Cu fields under different aerosol conditions. The goal of the study is twofold. First, we will check the variability of $\mathrm{r_e}$ in clouds of different sizes and the robustness of utilization of one mean vertical profile of $\overline{r_e}(z)$ to characterize all the clouds within the field. We explore the reasons for the comparatively low horizontal variability of $\mathrm{r_e}$ despite of the high variability of LWC both within each cloud and between different clouds. Second, using the results of the LES we propose a simple parametrization of the mean vertical profiles of $\mathrm{r_e}$ and LWC that uses adiabatic LWC profile and N_d at cloud base. This parametrization is implemented in COSMO model to be used for calculation of radiation properties of subgrid Cu fields.

5.3 LES set-up

In this study LES were performed using System for Atmospheric Modelling (SAM) (Khairoutdinov and Randall, 2003) with Spectral Bin Microphysics (SBM, Khain at al. 2004, 2013) (for

details see: http://rossby.msrc.sunysb.edu/~marat/SAM.html). SAM is a non-hydrostatic, inelastic model with cyclic boundary conditions in the horizontal direction. The SBM is based on solving kinetic equations for size distribution functions of water drops and Aerosol Particles (AP). Aerosols and droplet size distribution functions are defined on the doubling mass grids containing 33 bins. The drops radii range between 2 μm and 3.2 mm. The size of AP serving as cloud condensation nuclei (CCN) ranges between 0.005 μm and 2 μm. Using the values of supersaturation with respect to water, the critical CCN radius is calculated (using the Köhler theory) and APs larger than the critical size are nucleated to droplets as described by Khain et. al (2000). The rest of APs are advected with air motion. Diffusional growth and evaporation of droplets are calculated basing on the changes in the supersaturation during a model time step. The time steps are chosen to be smaller than drop relaxation time. This is the physical condition of accurate calculation of diffusion growth/evaporation. Collision-coalescence is solved by the stochastic collision equation using the accurate method of Bott (1998). The collision kernels were calculated using an exact method described by Pinsky et al. (2001). Drop sedimentation is calculated using fall velocities determined by Beard (1976). Fields of small trade Cu were simulated within a domain of 12.8 km x 12.8 km x 5.1 km using horizontal resolution of 100 m, and vertical resolution of 40 m with a dynamical time step of 1 s. As a case study, small Cu observed during BOMEX were chosen for simulation (Siebesma et al., 2003). The vertical profiles of temperature and dew point used in simulations are shown in Fig. 11. The original BOMEX profile is that with the inversion at 1500m, the other two profiles with the inversions at 1000 m and 2000 m were used for analysing the effect of the inversion height on the microphysical properties of simulated cloud fields.

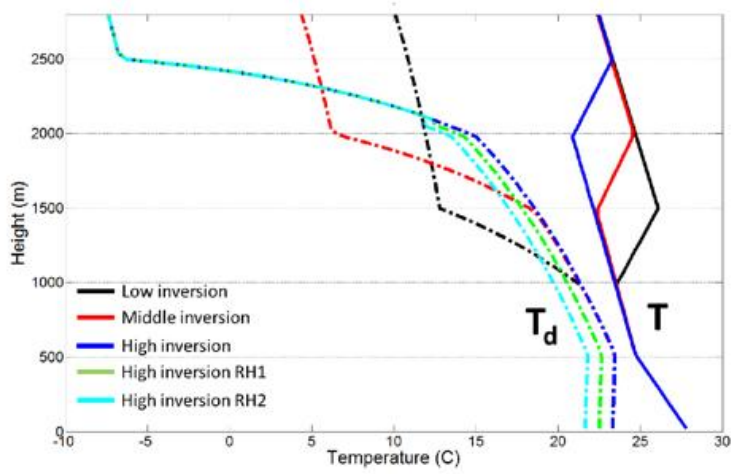

Figure 11: Initial vertical profiles of temperature (solid) and dew point (dashed) used in simulations: low inversion at 1000 m (black), high inversion at 2000 m (blue), middle inversion at 1500 m (red- the original BOMEX profile). Green and cyan profiles denote sensitivity tests with decreased relative humidity (by 5% and 10%, respectively) with respect to high inversion profile.

In the simulations we used concentrations of CN within the range from 500 cm^{-3} to 5000 cm^{-3} which lead to mean N_d at cloud base of $\sim 50\ cm^{-3}$ to $\sim 500\ cm^{-3}$. According to the accepted definition, this range of N_d includes three cloud types: clean (maritime), intermediate (clean continental) and polluted (continental) (Ghan et al. 2011). Note that comparatively small mean cloud N_d at cloud base at such CN concentration is determined by low vertical velocities at cloud base and by prescribed initial CN size distributions containing large fraction of

small CN, which cannot be activated at such vertical velocities. We do not consider clouds developing in the extremely clean atmosphere, and producing drizzle immediately after their formation. We will refer the simulations according to the CN concentration and inversion height: H-high, M-medium and L-low, e.g. E5000H, where E denotes "experiment" and 5000 shows CCN concentration. The list of simulations is presented in Table 2.

Name of experiment	Height of inversion (m)	Aerosol concentration (cm^{-3})	Main results				
			total CF (%)	STD of total CF (%)	<N_d> (cm^{-3})	<CWC> max (gm^{-3})	<r_e> max (μm)
E5000L	1000	5000	20.1	1.8	403	0.52	7.7
E5000M	1500	5000	17.9	1.0	371	0.54	8.2
E5000H	2000	5000	19.7	1.6	372	0.47	8.4
E3000L	1000	3000	20.5	1.6	248	0.58	9.4
E3000M	1500	3000	18.7	1.7	222	0.52	9.8
E3000H	2000	3000	20.4	1.7	221	0.47	10.2
E2000L	1000	2000	20.8	1.1	164	0.58	10.7
E2000M	1500	2000	18.8	1.1	149	0.51	11.3
E2000H	2000	2000	20.6	1.5	148	0.48	12
E1000L	1000	1000	21.9	1.0	81	0.55	13.6
E1000M	1500	1000	19.4	1.3	82	0.49	14.9
E1000H	2000	1000	21.7	1.6	83	0.42	15.5
E500L	1000	500	24.2	1.8	47	0.43	16.7
E500M	1500	500	21.5	1.3	49	0.37	18.2
E500H	2000	500	23.1	1.8	48	0.32	18.3

Table 2: List of simulations. Notations: "total CF" – time averaged total cloud fraction, "STD of total CF" – standard deviation of total CF, "<N_d>" – time and space averaged N_d, "<CWC> max" – maximum (over height) value of the mean profile of CWC, "<r_e> max" – maximum (over height) value of the mean profile of r_e.

In addition to simulations listed in Table 2 three supplemental simulations were performed. The simulation E2000H-50 is similar to E2000H but has horizontal grid spacing of 50 m. It was performed to analyse effects of model resolution on cloud thermodynamics and microphysics. Two other simulations E2000H-RH1 and E2000H-RH2 have air relative humidity within the layer from the surface to the inversion base by 5% and 10% lower than in E2000H, respectively. The profiles of Td(z) in these simulations are shown in Fig. 11. These simulations aim to investigate effects of environment humidity on cloud properties and to check universality of the parametrization proposed (see below) under different thermodynamic characteristics of the boundary layer. Convection is triggered by random temperature perturbations at the beginning of the simulations. For isolating the aerosol effect on the thermodynamic conditions, the radiative effects (as included in the large scale forcing) as well as the surface fluxes were prescribed in all simulations (see Dagan et al., 2016 for detail). The surface fluxes and the large scale forcing of BOMEX have been used for this study following Siebesma et al. (2003). All simulations were performed for 8.3 hours.

5.4 Results

In order to give an idea of how the cloud field simulated by SAM looks like which can simplify further interpretation of the results, we present in Fig. 12 3D snapshots of the LWC, Nd and r_e in E5000H. In this particular case rain water content is negligible, so LWC is equal to cloud water content (CWC), determined by cloud droplets with radii below 25 μm. This is the approximate maximum drop radius that can be reached by diffusion growth and non-intense collisions between small cloud droplets (Pinsky and Khain, 2002). The cloud field consists of clouds of different sizes and shapes. The smallest clouds rapidly evaporate by mixing with surrounding, while few largest clouds penetrate the inversion layer. The largest clouds contain cores with high CWC. As expected, the CWC increases with height, reaching its maximum near the cloud top, while Nd is nearly constant with height. Hence, the drop size r_e is increasing with height, as can be seen in Fig. 12c. It is possible to see that r_e changes in horizontal direction within the range 9-11 μm in the upper parts of clouds, i.e. the relative changes of r_e are much lower than those of CWC and N_d.

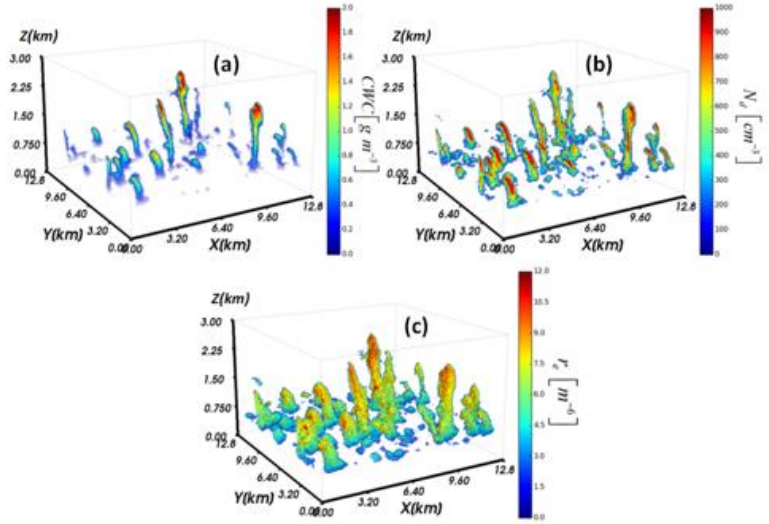

Figure 12: A snapshot of (a) CWC, (b) N_d, and (c) r_e fields for E5000H experiment: inversion is at 2 km, the CN concentration is 5000 cm^{-3}, t = 208 min. The impression of "noodle" shape clouds and not the usual "cotton balls" shape, are just due to the difference between the horizontal and vertical scales.

For more details regarding the performed simulation results the reader is referred to Khain et al., 2019. Here we continue with analysing r_e profile. The volume mean (r_v) and effective droplet (r_e) radii are among the most important microphysical characteristics of clouds. In several studies the mean volume and effective radii are related as $r_e \approx k r_v$. According to our simulations $k \approx 1.15 - 1.17$. The lowest values of coefficient k take place for polluted clouds in which DSD are the narrowest. Accordingly, the largest values of k take place for clean clouds, where DSD width is largest, and the existence of large cloud droplets increases r_e. Main properties of r_e in cloud field of small Cu can be derived from Fig. 13 showing height vs. re scattering diagrams for selected simulations with different inversion layer heights and different aerosol concentrations. These simulations reflect the basic properties of r_e. Purple lines in Fig. 13 denote the profiles of "adiabatic" effective radius of cloud droplets r_{e_ad}, which could be observed in adiabatically ascending cloud volume with droplet concentration N_{d_ad} calculated at cloud base. In Fig. 13 r_{e_ad} is calculated as:

$$r_{e_ad}(z) = 1.15 \cdot r_v = 1.15 \cdot \left(\frac{LWC_{ad}(z)}{\frac{4}{3}\pi \rho_w N_{d_ad}} \right)^{1/3} \tag{15}$$

where $LWC_{ad}(z)$ is adiabatic LWC that can be calculated as described, for example, by Pontikis (1996) or Pinsky et al. (2012). The adiabatic cloud number concentration N_{d_ad} is the concentration in an adiabatic cloud core. The cloud cores are adiabatic only at the first few hundreds of meters above the cloud base. Hence, in these levels $r_e(z)$ in the cloud cores should be equal to $r_{e_ad}(z)$. We have chosen N_{d_ad} so that $r_{e_ad}(z)$ will nearly coincide with $r_e(z)$ in the cloud cores. N_{d_ad} can be calculated in large scale models using, for instance, lookup tables as a function of aerosol concentration and cloud base vertical velocities (Segal and Khain, 2006) as it is done in COSMO, theoretical formulas (Pinsky et al. 2012) or other approaches (Ghan et al. 2011). The cloud base vertical velocities in the COSMO model are calculated as a sum of gridscale updraft, vertical component of turbulent fluctuations using turbulent kinetic energy (with isotropy assumption), radiative cooling effect (Khvorostyanov and Curry, 1999), and the convective velocity scale (Deardorff, 1970). Because of some uncertainties in evaluation of N_{d_ad}, we will refer r_{e_ad} to as "modelled" adiabatic effective radius. Although the Nd and LWC in cloud cores become smaller with height compared to N_{d_ad} and LWC_{ad}, but r_{e_ad} still represents well the effective radius in cloud cores. The advantage of r_{e_ad} is that it can be calculated in any model knowing the LCL (together with the cloud base temperature and pressure) and N_d at cloud base.

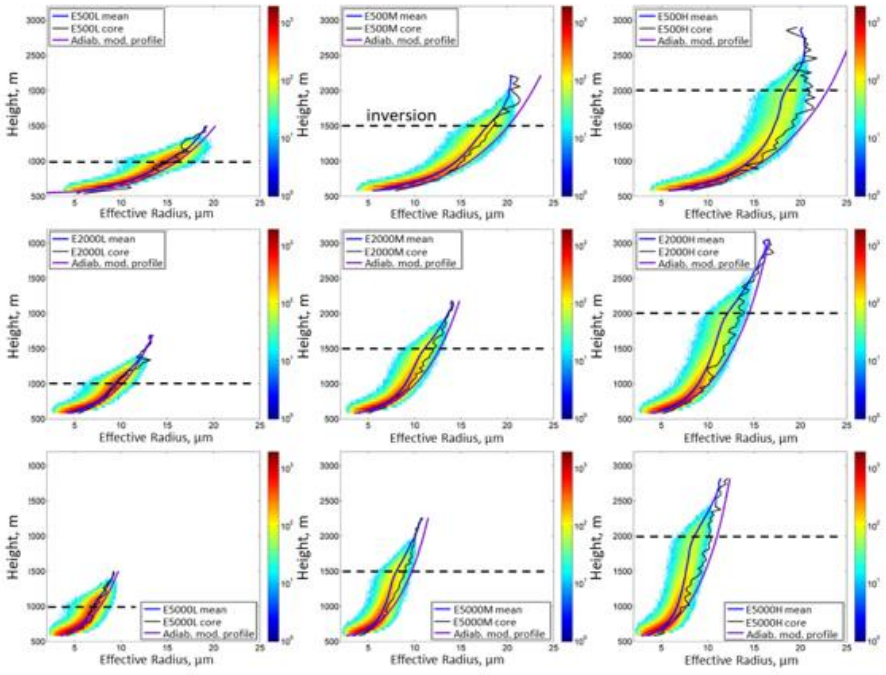

Figure 13: The height-r_e scattering diagrams for simulations with different CN concentrations. Left, middle and right columns show the cases with low (base at 1000m), middle (base at 1500m) and high (base at 2000m) inversion, respectively. Notations: The colour-scale reflects the number of cloudy grid points with specific r_e in logarithmic scale; black curves denote effective radii in clouds cores; purple curves denote the modelled approximation to adiabatic r_e profiles; blue curves denote profiles of horizontally averaged r_e; black dashed lines denote the inversion base heights.

An analysis of Fig. 13 shows several important features of r_e in clouds forming in cloud fields:

a. Strong effect of aerosols

A well-known effect is the faster r_e growth with height in case of low CCN concentrations. In case of clean environment, N_d is small, therefore the fewer droplets that form near cloud base have little competition on the available supersaturation (S_W) (Pinsky et al. 2012, 2014; Dagan et al. 2016). As a result, S_W remains relatively high and the droplets grow rapidly with height. At CN concentration of 5000 cm^{-3}, the maximum of the r_e remains below 13-15 μm, so these clouds do not produce neither raindrops nor drizzle. At CN concentration of 2000 cm^{-3}, the maximum r_e reaches 14-15 μm at z = 2000 m and light drizzle arises above this level (not shown here). In E500 the maximum of r_e exceeds 15 μm and raindrops arise (not shown here).

b. Low horizontal variability of effective radius

A fundamental property of r_e is low horizontal variability. This variability is much lower than that of LWC. Generally, the averaged (over all heights) relative variability varies between 10-15%. Our results show low variability of r_e. We partially attribute this insensitivity to the following. The mean volume radius is proportional to $(LWC/N_d)^{1/3}$. As the incloud nucleation leads to the formation of the smallest droplets, the LWC is defined by the first mode of droplets activated at cloud base. Because of the 1/3 power, the in-cloud nucleation cannot change N_d strongly enough to significantly affect the mean volume radius (as well as r_e). Low variability of r_e indicates that cloud field can be characterized by robust vertical profile of r_e that is close to the adiabatic one and depends on the aerosol loading.

c. The maximum effective radius is in cloud interior

The important feature is that the r_e is maximal in cloud interior (black lines), where LWC are maximum. In cloud cores the profiles of $r_e(z)$ almost coincide with the adiabatic values (purple lines) calculated according Eq. 15. This fact shows that cloud droplets reach maximum size in cloud cores, together with the maximum LWC and the maximum N_d.

d. Limiting value in case of raindrop formation

As seen in Fig. 13, r_e in cloud core in simulations with $CN = 500\ cm^{-3}$ is maximum in cloud cores and close to the adiabatic value. Formation of raindrops is seen by termination of the r_e growth with height. In case of rain drop formation, r_e determined within the range of cloud droplet radii ($< 25\ \mu m$) does not exceed about 22 μm and remains height independent (Figure 5.3, E500H). Such regime is known as rainout (Rosenfeld and Lensky, 1998). The reason of low dependence of r_e on height in case of raindrop formation is that raindrops collect cloud droplets of all sizes that leads to decrease in N_d, but does not change r_e of the cloud droplet mode.

According to the results, in case of rain formation, the maximum r_e of cloud droplets can be calculated as:

$$r_{e_{max}} = \min(22\mu m, r_{e_ad}) \tag{16}$$

Because of low variability of r_e, the values of r_e are concentrated around $\overline{r_e}$ which is slightly smaller than r_{e_ad}. The physical reasons of low variability of r_e were analysed by Pinsky et al. (2016b), Pinsky and Khain (2018a) and by Magaritz-Ronen et al. (2016b). Relative humidity in cloudy volumes, even well diluted ones, remains high which does not allow r_e to decrease anyhow significantly. Small decrease in r_e reflects the contribution of air volumes

newly penetrating clouds and located near cloud edges. In such volumes partial evaporation of drops penetrating from cloudy volumes leads to formation of DSD with lower effective radii. Rapid increase of relative humidity in such volumes with time leads to termination of evaporation of largest droplets penetrating from the cloudy volumes. As a result, the r_e in the volumes penetrating clouds rapidly reaches values typical of cloudy volumes, while LWC and N_d remain much lower than in the cloud core. The mixing with humid air, which entrains clouds, does not cause strong changes in drop sizes near cloud edge.

5.5 Parametrization of microphysical parameters of cloud ensembles

For practical goals, it is desirable to characterize cloud field by some mean vertical profile $\overline{r_e}(z)$. Analysis of results presented in Fig. 13 shows that $\overline{r_e}(z)$ is smaller than the maximum value $r_{e_ad}(z)$ only by ∼10-15%. The difference between $\overline{r_e}(z)$ and $r_{e_ad}(z)$ reaches its maximum at the inversion base level. This increase is related to the fact that cloud ensemble contains clouds of different size and clouds of lower width experience stronger effects of mixing because the interface zone affected by mixing in such clouds occupies a significant fraction of the cloud volume. Above the base of inversion the difference $r_{e_ad}(z)$-$\overline{r_e}(z)$ decreases again, since only largest clouds remain. This behaviour retards a simple approximation of $\overline{r_e}(z)$ via $r_{e_ad}(z)$. We will approximate dependence between these two quantities (as well as other approximation of averaged values) ignoring the upper part of clouds within inversion layer, for which the contribution to the optical depth of cloud layer is less than 5% (not shown). Within the layer below inversion base the cloud averaged r_e can be approximated as

$$\overline{r_e}\,(z) = \alpha(z) r_{e_ad}(z) \tag{17}$$

$$\alpha\,(z) = \ 0.95 - 1.2 \cdot 10^{-4}(z - z_{cb}) \tag{18}$$

Where z is in meters, z_{cb} is the cloud base level, determined by the minimal distance from the surface where supersaturation for the first time becomes positive and droplet nucleation takes place. In order to take into account the effect of raindrops, the values of $r_{e_{ad}}\,(z)$ in Eq. 17 were replaced by $r_{e,max}(z)$ calculated using Eq. 16. Vertical profiles of the cloud averaged r_e are calculated directly from LES and parametrized using Eqs. 15-17 are shown in Fig. 14.

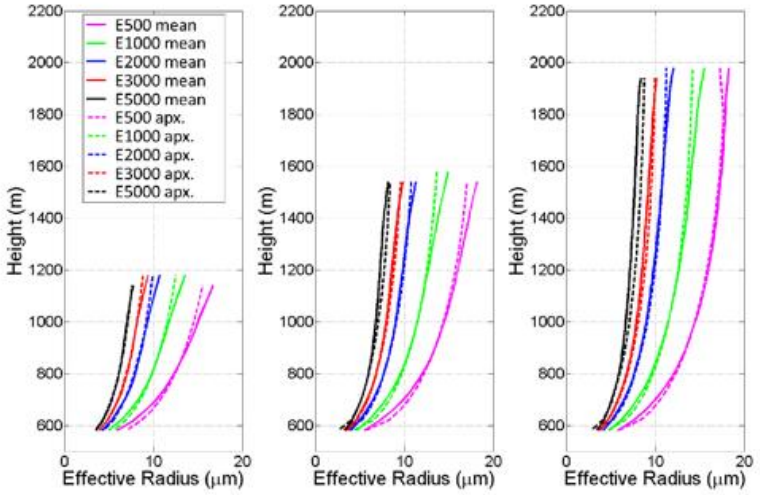

Figure 14: Vertical profiles of the cloud averaged r_e calculated directly from LES (solid lines) and parametrized using Eqs. 15-17 (dashed lines). Each panel is plotted for different inversion base height: low, medium and high, respectively.

One can see a good agreement of parametrized $\overline{r_e}(z)$ with those calculated directly in the LES within entire range of aerosol loadings and different levels of the inversion. The standard deviation is of 0.39 μm.

The next step is the parametrization of the mean droplet concentration as a function of N_d at cloud base. N_d, as was mentioned above, can be determined using different approaches in different kinds of atmospheric models, including NWP models. The concentration at cloud base can be referred to as adiabatic concentration N_{d_ad}, which being formed at cloud base does not change with height within ascending adiabatic parcels. In small Cu the changes of air density with height are small. Profiles of $\overline{N_d}(z)$ depend on whether clouds produce raindrops or not. In case of non-precipitating clouds $\overline{N_d}(z)$ and N_{d_ad} are equal to the maximum value N_{d_max}, which can be considered as constant with height. Analysis (not shown here) shows that the maximum N_d in clouds producing raindrops can be approximated as a constant till the level at which $r_{e_ad} = 12\ \mu m$ and linearly decreasing above this level. Statistical analysis shows that the profile of maximal N_d can be written in the form

$$N_{d_max}(z) = \begin{cases} N_{d_ad}, & z < z_{12}\ , \textit{where } r_{e_ad} = 12\ \mu m \\ N_{d_ad}\left[1-\gamma\,(z-z_{12})\right], & z > z_{12} \end{cases} \tag{19}$$

where $\gamma = 0.45 m^{-1}$ and z is in meters.

$$\overline{N_d}(z) \approx \beta N_{d_max}(z) \tag{20}$$

where on average (over all heights and simulations) $\beta = 0.38$ with standard deviation of 0.03. The parameters in expressions 17-19 are obtained minimizing the root mean square over all the simulations. Expressions 18 and 19 allow to calculate the averaged concentration profiles using N_d at cloud base and the height of the level where $r_{e_{ad}}$ reaches the precipitating threshold. Fig. 15 shows profiles of cloud averaged N_d obtained in LES and using expressions 19 and 20. One can see a good agreement between the approximations and profiles directly calculated using LES.

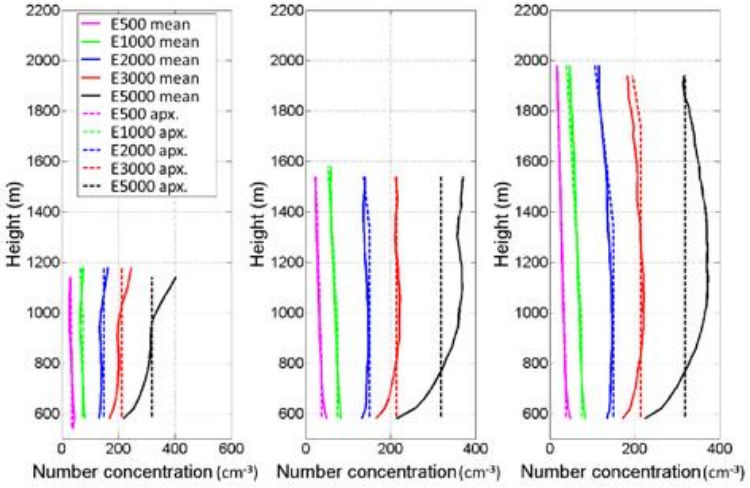

Figure 15: Profiles of cloud averaged N_d obtained in LES (solid lines) and using expressions 18 and 19 (dashed lines). Each panel is plotted for different inversion base height: low, medium and high, respectively.

In addition to $\overline{r_e}(z)$, the parametrizations of radiation transfer through unresolved cloudiness in many NWP and climatic models require a prognostic calculation of $\overline{LWC}(z)$. As mentioned in the introduction, the $\overline{LWC}(z)$ of unresolved clouds in the default version of the COSMO model is crudely parametrized as a function of the temperature. Now, using the parametrization of $\overline{r_e}(z)$ and $\overline{N_d}(z)$ as mentioned above, we are able to parametrize $\overline{LWC}(z)$ as well. Strictly speaking, the practically required values of $\overline{LWC}(z)$ should be determined as:

$$\overline{LWC}\,(z) = \overline{\frac{4}{3}\pi\rho_w N_d(z) {r_v}^3(z)} = \overline{\frac{4}{3}\pi\rho_w N_d(z)\left(\frac{r_e(z)}{1.15}\right)^3} \tag{21}$$

However, since variability of r_e is low, the last equality can be rewritten as:

$$\overline{LWC}\,(z) \approx \frac{4}{3}\pi\rho_w \overline{N_d}(z)\left(\frac{\overline{r_e}(z)}{1.15}\right)^3 \tag{22}$$

which is substantially simpler than Eq. 21. Fig. 16 presents the vertical profiles of $\overline{LWC}(z)$ calculated directly from the results of the LES simulations and the profiles of $\overline{LWC}(z)$ calculated using Eq. 22.

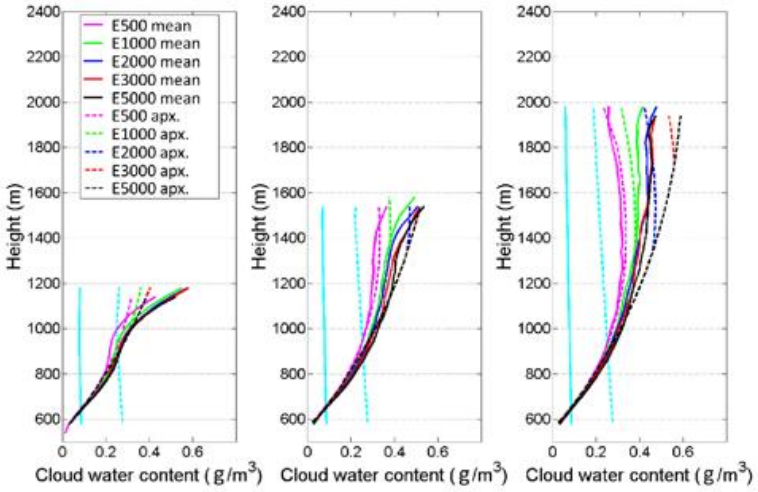

Figure 16: Vertical profiles of the cloud averaged CWC calculated directly from LES (solid lines) and approximation (Eq. 22) (dashed lines) for different aerosol loadings and for different inversion levels: low (left), medium (middle) and high (right). Cyan solid and dashed lines indicate the profiles obtained using different options within the default parametrization in COSMO.

One can see that Eq. 22 allows reproducing the LES profiles of $\overline{CWC}(z)$ quite accurately, especially in comparison with COSMO approximations (cyan solid and dashed lines). Deviations of CWC calculated using Eq. 22 from that calculated directly in LES seen at higher levels are not of high importance for calculation of radiation fluxes because CF of these clouds at such altitudes are low.

5.6 Implementation of the parametrization in the COSMO model

The new parametrization for $\overline{LWC}(z)$ and $\overline{r_e}(z)$ was implemented in COSMO for calculation of the optical properties of subgrid shallow cumulus. The main logical switch for activating the parametrization is luse_qc_adiab_for_reffc_sgs. Additional logical switch luse_qc_con_sgs allows calculating the subgrid scale LWC of shallow cumulus using either $\overline{LWC}(z)$ parametrization or the LWC(z) derived from the shallow convection parametrization (lconv = T). alpha1_adiab_rad and alpha1_adiab_rad parameters describe $\overline{r_e}(z)$ above cloud base z_{cb} according: $alpha1_{adiab_{rad}} - alpha2_{adiab_{rad}} * (z - z_{cb})$. The parameter beta_adiab_rad describes the ratio of cloud-average N_d of SGS shallow convection with respect to the cloud core value obtained by the Segal-Khain parametrization. The parameter gamma_adiab_rad describes the linear deviation with height ($r_e > 12$ μm level) of SGS shallow convection LWC from the "pseudo-adiabatic" value. The list of parameters of the new parametrization is presented in Fig. 17. It includes the meaning of each parameter, its type, default value, available range and recommended value.

Parameter	Meaning	Type	Def	Range	Recom
luse_qc_adiab_for_reffc_sgs	Use "adiabatic" parametrization for SGS shallow convection effective radius	LOG	F	T/F	T
luse_qc_con_sgs	Effective if luse_qc_adiab_for_reffc_sgs=F. F: use "adiabatic" parametrization for SGS shallow convection LWC. T: use LWC from shallow convection parametrization (if lconv=T)	LOG	F	T/F	T
alpha1_adiab_rad	Linear deviation with height (above cloud base) of SGS shallow convection effective radius from the adiabatic value alpha1_adiab_rad-alpha2_adiab_rad*(z-zcb). [-]	REAL	0.95	[0.7-1]	0.95
alpha2_adiab_rad	Linear deviation with height (above cloud base) of SGS shallow convection effective radius from the adiabatic value alpha1_adiab_rad-alpha2_adiab_rad*(z-zcb). [1/m]	REAL	1.2 E-4	[1-2] E-4	1.2 E-4
beta_adiab_rad	Ratio of cloud-average number concentration (of SGS shallow convection) with respect to the cloud core value (obtained from Segal-Khain)	REAL	0.38	[0.2-1]	0.38
gamma_adiab_rad	Linear deviation with height (above reff=12micron level) of SGS shallow conv. qc from the "pseudo-adiabatic" value. [1/km]	REAL	0.45	[0.2-0.7]	0.45

6 New shallow convection shutdown scheme

(P. Khain)

6.1 Overview

Global Numerical Weather Prediction (NWP) models use convection parametrization to describe both deep and shallow convection. Convection permitting models with grid spacing below ∼4 km usually describe deep convection on grid scale, but still parametrize the shallow convection, being sub-grid scale process. Many of these parametrizations are based on the mass-flux approach. The artificial combination of resolved and parametrized convection often negatively influences the model forecast skill and particularly precipitation. In this task we used COSMO 2.5 km resolution over the Eastern Mediterranean region to analyse the effect of the mass-flux shallow convection parametrization (SCP) on model forecasts. We show that SCP entrainment rate as well as restrictions on the shallow convection development height and maximum updraft speed have crucial effect on the forecasts of precipitation, temperature and moisture. Physically motivated tuning of these parameters can improve the model forecasts significantly. Finally, we estimate the climatic zones and seasons where SCP is expected to be particularly important for NWP.

6.2 COSMO shallow convection parametrization

COSMO mass flux Tiedtke type SCP (Tiedtke, 1989) calculates the grid scale feedback of subgrid-scale vertical fluxes of mass, heat, moisture and momentum in updrafts. The convective-scale eddy transports of dry static energy, moisture and momentum from cumulus updrafts are not described in terms of contributions from the individual ensemble components, but are represented by their average values using a one dimensional bulk cloud

model after Yanai et al. (1973). The updraft of the cloud ensemble is assumed to be in steady state, and the budget equations for mass, heat, moisture and momentum for the ascending air (the "updraft equations") are integrated. For their integration the possibility for shallow convection at a grid point is diagnosed. At the first model level above the surface an air parcel is defined with the grid-scale values of temperature (plus a small excess value representing subgrid scale perturbation), specific humidity and horizontal momentum. Lifting the parcel adiabatically allows to compute its condensation level. This level defines the cloud base or the level of free convection, if the parcel becomes buoyant with respect to the environment. The parcels values of temperature, mixing ratio, water content, and horizontal wind components at cloud base are then used as boundary conditions to integrate the updraft equations. In the updraft, entrainment is assumed to occur via turbulent exchange of mass and is parametrized as proportional to the updraft mass flux with a proportionality constant entr_{sc}. This constant is treated as a tuning parameter in the model with a default value of 0.0003 m^{-1}. The vertical integration of the updraft equations from cloud base to cloud top, where the parcel is no more buoyant, yields the values of the variables within the updraft. These values are then used to calculate the convective tendencies in the prognostic equations for the grid-scale variables of dry static energy (related to temperature), specific humidity and the horizontal wind components. During the ascent, the supersaturated parcel is assumed to condensate all the excess water vapour immediately. Since it is assumed that SCP should not produce precipitation, the resulting liquid water content is neglected by the model in autoconversion and other microphysical processes. This assumption may lead to an underestimation of light precipitation in the model. Besides, subgrid-scale vertical mixing by SCP tends to stabilize the CBL and thus to postpone or even cancel potential grid scale updrafts which produce precipitation. These drawbacks led to the necessity to limit the SCP in the model by turning it off. I.e. cancelling the subgrid-scale vertical mixing, in cases when the test parcel described above remains buoyant and rises too high in the atmosphere. Therefore, a second tuning parameter $thick_{sc}$ was introduced with a default value is 25000 Pa. This is the maximal pressure difference between the top and the bottom of the convection, and for higher values the scheme is turned off.

Fig. 18 schematically shows the typical options occurring at the model time step in SCP in case the test parcel is buoyant at the cloud base. In case 1 the entrainment entr_{sc} is chosen to be high, causing the parcel to stop being buoyant (top of the convection) already at level k2. In case 2 entr_{sc} is chosen to be lower, and the convection top occurs at level k3. In case 3 the parcel remains buoyant till the level k4 and the resulting convection vertical extent exceeds the threshold $thick_{sc}$. At that time step the SCP is turned off in the entire grid column, keeping the unstable profile unmixed and allowing grid scale updrafts to develop. In case 4 the SCP is turned off while the grid scale updrafts lead to grid scale supersaturation and activation of in-cloud microphysical processes and precipitation. This schematic picture shows that $thick_{sc}$ may have an influence in weakly unstable conditions, or unstable ones topped by an inversion. On contrast, during the peaks of the cyclones passage, the instability usually extends up to height of several kilometres. In these situations SCP is turned off and one would not expect any influence of $thick_{sc}$.

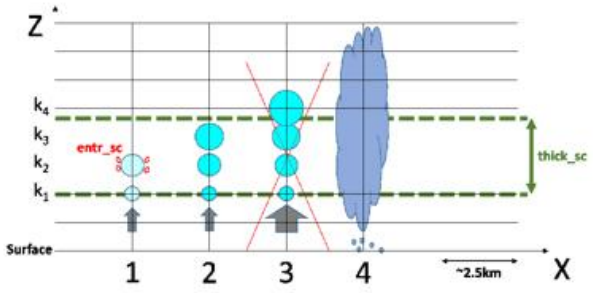

Figure 18: Schematic description of COSMO SCP. Case 1: $entr_{sc}$ is high, the top of the convection is at level k2. Case 2: $entr_{sc}$ is lower, the convection top occurs at level k3. Case 3: the convection vertical extent exceeds the threshold $thick_{sc}$. At that time step the SCP is turned off in the entire grid column. Case 4: the SCP is turned off, grid scale updrafts lead to grid scale supersaturation and activation of in-cloud microphysical processes and precipitation.

6.3 The effect of shallow convection parametrization on model forecast

At this section, cyclonic test case is used to explain the influence of the SCP on forecasts of precipitation. The selected test case occurred between December 30, 2015 and 2^{nd} of January, 2016. Fig. 19 presents the synoptic situation over the EM during these days using mean sea level pressure (MSLP) and geopotential height at 500 hPa from IFS analyses. One can see that the 500 hPa geopotential height over central Israel gradually drops from ∼5600 to ∼5500 m and then climbs back towards ∼5580 m.

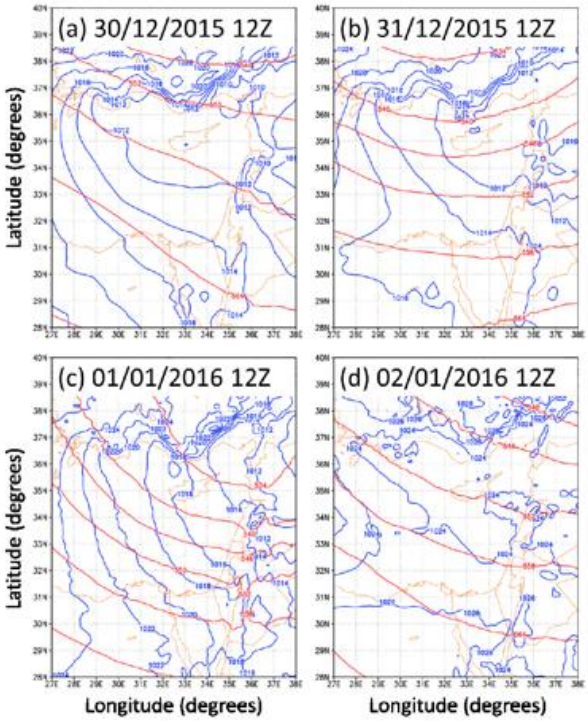

Figure 19: Cyclonic test case occurred during 30/12/2015-02/01/2016. The panels a-d show the IFS analyses of the mean sea-level pressure contours (blue lines) and the geopotential height (divided by 10) contours (red lines) for noon times (12Z) during the period.

It is a typical example of extratropical cyclones - the Cyprus Lows, which are responsible for most of the annual rainfall over the EM (Sharon and Kutiel, 1986; Alpert et al., 1990; Shay-El and Alpert, 1991; Ziv et al., 2006). The rain is formed within cold air masses of European origin that enter the region from the north-west. While moving over warmer Mediterranean waters, the air masses gain moisture and become conditionally unstable. The dynamics associated with the cyclone itself, together with that implied by the intersection of the westerly flow with the shoreline and, later on, with the mountain ridges, results in intensive rainfall over the Levant (Sharon and Kutiel, 1986). The concurrent upper-level system consists of a pronounced trough extending toward south-western Turkey. The upper trough over the EM induces cold advection aloft into the Cyprus Low region. Fig. 20 presents the initial (left panels) and the decay (right panels) stages of the cyclone evolution over the EM. The presented COSMO simulations were initiated on 30/12/2015 00 UTC (left panel) and on 01/01/2016 00 UTC (right panel).

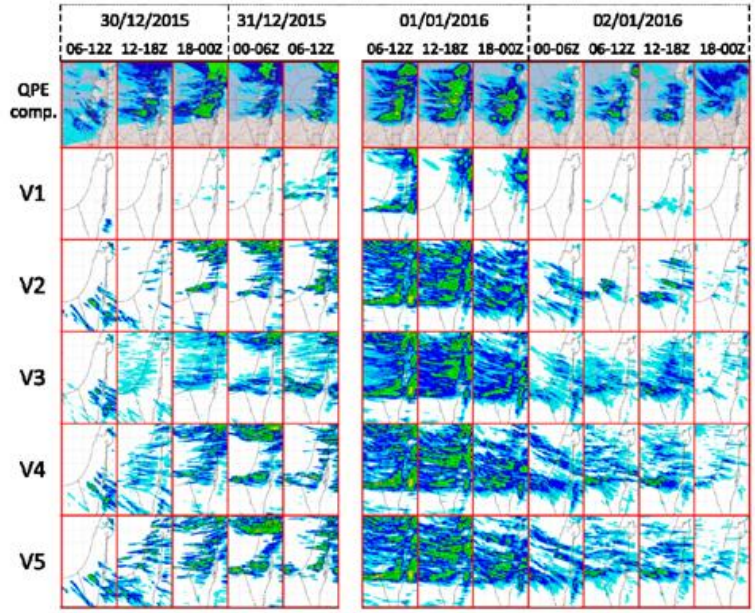

Figure 20: Initial (left panels) and the decay (right panels) stages of the Cyprus Low evolution over the EM (30/12/2015-02/01/2016). The QPE composite (first row) and five different COSMO SCP versions (see Table 3) forecasts are shown in 6hAP frames (rows 2-6). The peak of the cyclone evolution lasted for 18 hours during 31/12/2015 12Z – 01/01/2016 06Z and is not shown.

As explained in the previous section, the forecast for the peak of the cyclone evolution is not influenced by the SCP significantly. In this test case it lasted for 18 hours during 31/12/2015 12Z – 01/01/2016 06Z and is not shown. Fig. 20 (first row) presents the Quantitative Precipitation Estimation (QPE) composite evolution divided into 6 hourly accumulation periods (6hAPs). This QPE composite is compiled operationally at IMS using data from C-Band Doppler radar located in Bet Dagan and automatic rain gauges as described in Khain et al. (2020). The next five rows in Fig. 20 present 6hAP forecasts of the five COSMO versions (Table 3).

Version	$\boldsymbol{thick_{sc}}$ **[hPa]**	$\mathbf{entr_{sc}}$ **[m^{-1}]**	$\mathbf{W_{max}}$ **[m/s]**	**Rain strength**	**Rain Cover**
V1 (default)	25000	0.0003	-	Low	Low
V2	10000	0.0003	-	High	Low
V3	10000	0.003	-	Low	High
V4	10000	0.003	0.1	High	High
V4a	10000	0.003	0.3		
V4b	10000	0.003	0.15		
V4c	10000	0.003	0.05		
V5	SCP off	SCP off	SCP off	High	High

Table 3: Details of the five analysed versions of the COSMO SCP.

We begin the analysis of the five COSMO versions from comparing the "edge" versions V1 and V5, namely with very "active" SCP versus SCP turned off, respectively. Fig. 21 shows

the occurrence frequency of maximal over grid column wind speed and Convective Available Potential Energy (CAPE). The occurrence frequency was calculated for the period presented in Fig. 20 (30/12/2015-02/01/2016 without the 18 hours of the peak) over the sub domain 32-37E/29-34N.

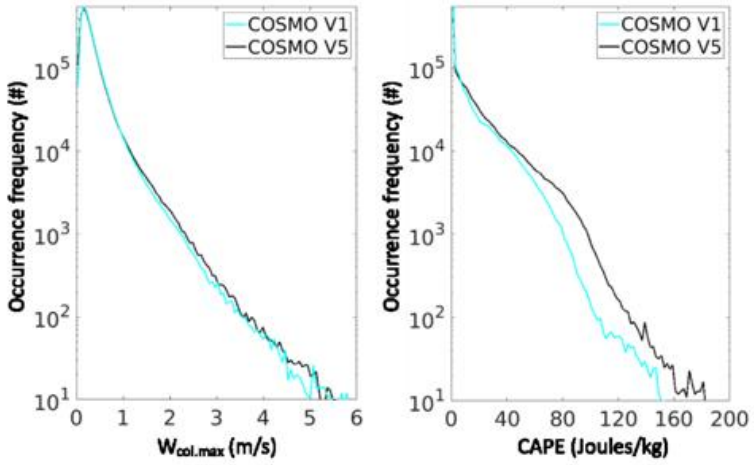

Figure 21: Occurrence frequency of (a) maximal over grid column wind speed and (b) CAPE. COSMO V1 (cyan) and V5 (black) are presented (see Table 3). The occurrence frequency was calculated for the period presented in Fig. 20 (30/12/2015-02/01/2016 without the 18 hours of the peak) over the sub domain 32-37E/29-34N. Note the logarithmic scale of y-axis.

As explained in the previous section, active SCP often weakens (or prevents) the evolution of grid scale convection and precipitation. Fig. 21 nicely shows that when the SCP is turned off, the updrafts are generally stronger and there are significantly more occurrences of high CAPE. As described in the previous section, COSMO SCP includes two tuning parameters. The first, $thick_{sc}$ (default value 25000 Pa), is the maximal vertical extent of the convection or the pressure difference between the top and the bottom, above which the scheme is automatically turned off. The second entr_{sc} (default value 3×10^{-4} m^{-1}) is the entrainment rate, which defines the mixing intensity of the rising parcel with the surrounding. As will be reasoned below, we added a third parameter, W_{max} (default value 0.1 m/s) which is the maximal grid scale updraft speed in a grid column above which the SCP is automatically turned off. Using the selected test case (see Fig. 6.3) we analyse five versions of the COSMO SCP (Table 3). Versions 1-3 differ by the values of $thick_{sc}$ and entr_{sc} parameters, while the effect of W_{max} is turned off. In version 4 we added changes in W_{max}. In version 5 we switch off the SCP so that convection may occur at grid scale only.

Spatial analysis of 6hAP precipitation which is presented in Fig. 20 (at the area covered by the radar) for QPE composite and precipitation forecast of various COSMO SCP versions yields the occurrence distributions (Fig. 22). The occurrence at each distribution bin, having width of 0.33 mm, reflects the average (over twelve 6hAP frames shown on Fig. 20) number of grid points which experienced 6hAP precipitation falling into that bin.

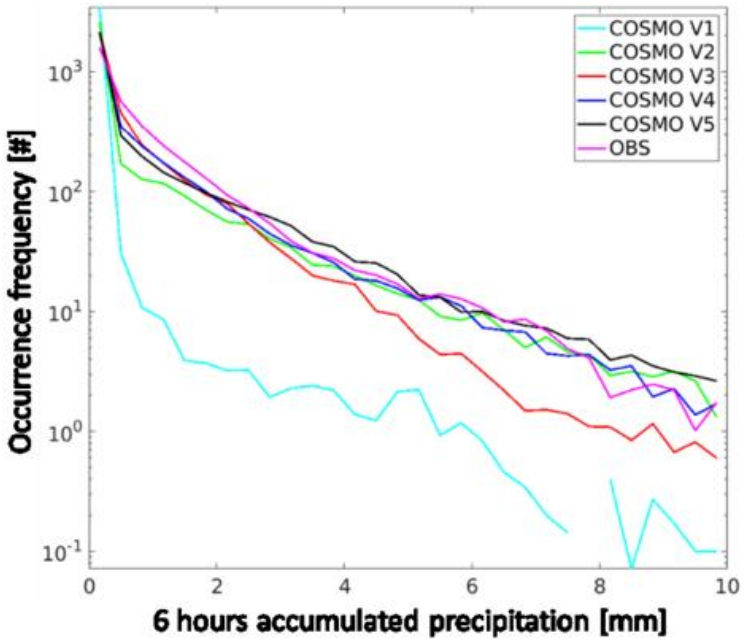

Figure 22: Occurrence distributions of precipitation over EM during a passage of Cyprus Low (30/12/2015-02/01/2016). The QPE composite (magenta) and five different COSMO SCP versions (see Table 3) forecasts are shown, respectively.

As can be seen from Fig. 20 and Fig. 22 (cyan compared to magenta), version 1 (see Table 3) strongly underestimates precipitation intensity and area. Having nearly adiabatic parcels and high permitted vertical extension (low entr_{sc} and high $thick_{sc}$, respectively), the SCP strongly mixes the lower atmosphere in vertical. This mixing ascends the water vapour from near the CBL top upwards into the free troposphere above the CBL. With less water vapour the grid-scale motions have lower potential producing grid-scale updrafts and precipitation.

Version 2 (V2) (green compared to magenta), performs better than V1, producing sufficiently strong precipitation. However, these strong precipitation spots are localized. Large areas still suffer from underestimation of weak precipitation. V2 differs from V1 by lower permitted vertical extension $thick_{sc}$. In strongly unstable areas the nearly adiabatic parcels (low entr_{sc}) can develop far above $thick_{sc}$. In these areas the SCP is turned off yielding proper grid scale updrafts and precipitation. In contrast, in weakly unstable areas the nearly adiabatic parcels do not reach the limit of $thick_{sc}$, the SCP is not turned off yielding strong vertical mixing and suppression of potential weak grid scale precipitation.

Version 3 (V3 - red compared to magenta), also shows positive results compared with V1, producing sufficiently wide precipitation cover. However it still suffers from underestimation of strong precipitation spots. V3 differs from V1 by lower permitted vertical extension $thick_{sc}$ and higher entrainment of the ascending parcels entr_{sc}. The physical motivation for increasing entr_{sc} and the choice of its value are explained in the next section. Similarly to V2, in weakly unstable areas the diluted parcels (high entr_{sc}) do not reach the limit of $thick_{sc}$ and the SCP is not turned off. However, here the vertical mixing is weak and the potential weak grid scale precipitation is not suppressed. Since SCP is rarely turned off, in strongly unstable areas these diluted parcels still cause significant vertical mixing partially suppressing potentially strong grid scale updrafts and precipitation.

Hence, in the framework of COSMO mass-flux SCP having two parameters for maximal

permitted vertical extension and the entrainment rate it seems impossible to reproduce the precipitation spatial distribution (magenta in Fig. 22) correctly. There is underestimation of either the cover by weak precipitation (version 2) or the strong precipitation values (version 3). Following the physical motivation behind version 3 (see Appendix), this version is chosen for further improvement. As mentioned above, in this version the SCP is rarely turned off even in strongly unstable situations. To solve this issue we added a third parameter (W_{max}, default value 0.1 m/s) which is the maximal grid scale updraft speed in a grid column above which the scheme is automatically turned off (version 4). The physical motivation is obvious – in grid column with sufficiently strong updraft, there is a potential for initiation of grid scale convection. In such column, switching off subgrid scale mixing by the SCP allows further CAPE development, followed by grid scale convection and precipitation. As can be seen from Fig. 20 (V4) and from Fig. 22 (blue compared to magenta), version 4 (Table 3) shows better results than versions 1-3, producing not only sufficiently wide precipitation cover but also sufficiently strong precipitation spots. The optimal value for W_{max} will be chosen following the tuning over ten test-cases (see next section).

A question arises, whether SCP is essential to the model, or it can be continuously turned off over the entire model domain. This test is conducted in version 5 (Table 3). As can be seen from Fig. 20 (V5) and from Fig. 22 (black compared to magenta), version 5 is of similar quality to version 4 producing sufficiently wide precipitation cover and sufficiently strong precipitation spots. However, SCP is essential in slightly unstable areas not covered by precipitation. In such areas lack of vertical mixing, which does occur at nature, may yield to concentration of heat and moisture at lower levels, causing wrong vertical profiles of temperature and humidity.

6.4 The entrainment rate parameter $entr_{sc}$

As explained in Sec. 6.2, the entrainment parameter entr_{sc} plays an important role in the SCP. Higher entr_{sc} values reduce both the intensity and the vertical extent of the mixing by the SCP. During the ascent, a parcel becomes saturated, yielding a condensation of water vapour to cloud water, resulting a profile of liquid water content LWC(z). This profile is closely related to entr_{sc}. For higher entr_{sc} values, the ascending parcel saturation is postponed, yielding smaller values of LWC. For entr_{sc}= 0 the parcel is raised adiabatically resulting in the highest possible value of LWC (hereafter, $\mathrm{LWC}_{ad}(z)$). Both $\mathrm{LWC}_{ad}(z)$ and the expected vertical profile of LWC in shallow Cu (hereafter, $\mathrm{LWC}_{cu}(z)$) are discussed in Khain et al., 2019. Obviously, COSMO mass flux SCP cannot reproduce the exact $\mathrm{LWC}_{cu}(z)$ produced by large-eddy-simulations and compared with observations. Still, comparison of LWC(z) with $\mathrm{LWC}_{cu}(z)$ may help setting up the correct value of entr_{sc}. For that purpose, we define LWC normalized adiabatic ratio averaged over height (z) above cloud base:

$$\mathrm{LWC}_{\mathrm{ratio}}=\overline{\frac{LWC\,(z)-LWC_{cu}(z)}{LWC_{ad}(z)-LWC_{cu}(z)}} \tag{23}$$

Positive (negative) values of $\mathrm{LWC}_{\mathrm{ratio}}$ indicate too large (small) LWC(z) and too small (large) entr_{sc}. The optimal value of entr_{sc} is obtained for $\mathrm{LWC}_{\mathrm{ratio}}\approx 0$. In order to estimate the optimal entr_{sc}, several values were selected: $3\cdot 10^{-6}$, $3\cdot 10^{-4}$, 10^{-3}, $3\cdot 10^{-3}$ and 10^{-2}. For each of these values, we have performed COSMO forecasts for two events, one in winter and one in summer, dominated by shallow convection. The first COSMO forecast was initiated on 23/02/2018 00 UTC, and the second – on 03/06/2018 00 UTC. For each 78 hours range forecast, all the grid columns with active shallow convection were analysed and the LWC(z) was plotted versus height above cloud base. Fig. 6.6 presents the vertically, horizontally and

time-averaged $\mathrm{LWC_{ratio}}$ versus entr_{sc} for winter case (red) and summer case (blue). One can see, that for negligible value of $\mathrm{entr}_{sc}=3\times10^{-6}\ m^{-1}$ $\mathrm{LWC_{ratio}}$ is close to one, meaning that COSMO shallow convection scheme describes adiabatically ascending parcels. For default COSMO value of $\mathrm{entr}_{sc}=3\times10^{-4}\ m^{-1}$, $\mathrm{LWC_{ratio}}$ is around 0.5, meaning strong overestimation of vertical mixing by the SCP. Note that for $\mathrm{entr}_{sc}=3\times10^{-3}\ m^{-1}$, $\mathrm{LWC_{ratio}}\approx0$, and therefore this value was chosen for further tuning of the SCP in Sec. 6.6.

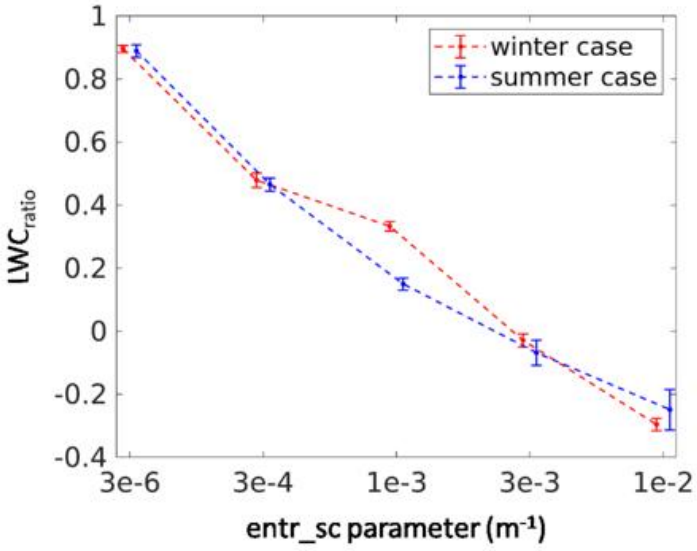

Figure 23: Vertically, horizontally and time-averaged LWC_{ratio} versus $entr_{sc}$ for winter case (23/2/2018 00 UTC run - red) and summer case (03/06/2018 00 UTC run - blue).

6.5 Evaluation of forecast quality

In order to analyse the forecasts quality two scores were chosen: precipitation verification score ΔFSS and temperature and humidity verification score T_RH_PROF.

6.5.1 Precipitation verification score ΔFSS

Due to the high variability of precipitation in space and time, it is common to verify it using Neighbourhood Methods. Here we use the Fractional Skill Score (FSS) (Roberts and Lean, 2008; Ebert, 2009; Mittermaier and Roberts, 2010). Besides FSS, additional neighbourhood methods of verification exist in the literature. These include extension of FSS to time dimension (Duc et al., 2013), scale-separation, object-based, and field deformation approaches (Davis et al. 2006a,b; Davis et al. 2009; Gilleland et al., 2009, 2010; Ben Bouallègue and Theis, 2014; Schwartz and Sobash, 2017). For each 6hAP forecasted and observed map, FSS was calculated for 30 km smoothing radius (see Khain et al. 2019 for the motivation) and for the thresholds of 0.01, 0.1, 0.5, 1, 2, 5, 10, 20 mm per 6h. The resulting FSSs were averaged over these thresholds, assuming double weight for the thresholds 0.5, 1, 2, 5 mm per 6h. The last are usually more important for the public than the negligible 0.01 and 0.1 mm per 6h and occur much more often than 10 and 20 mm per 6h. These averaged FSS were calculated both for COSMO and IFS and denoted as FSS_{COS} and FSS_{IFS}, respectively. Finally the precipitation verification score ΔFSS for each COSMO run was defined as:

$$\Delta FSS=\overline{FSS_{COS}-FSS_{IFS}} \tag{24}$$

where the average is over forecast ranges from +6h till +60h. ΔFSS varies in the range [-1,1], where ΔFSS>0 (ΔFSS<0) means COSMO precipitation forecasts are better (worse) than of IFS. As can be seen, IFS forecasts are of similar quality to those of COSMO, and it is convenient to use it as a reference.

6.5.2 Temperature and relative humidity score *T_RH_PROF*

The SCP is intended to vertically mix the CBL, and as such has a major influence on the temperature and relative humidity in the BL. In order to tune the scheme, we introduce the T_RH_PROF score which combines the verification of 2m-temperature and relative humidity versus stations measurements with the verification of the vertical profiles of temperature and mixing ratio versus radio-sounding data.

For each forecast initialized at 00 UTC the forecast ranges of +12h till +72h were verified at 12 hour steps. For 2-meter variables each forecast was verified versus 81 IMS stations over Israel, yielding RMSE for 2m-temperature and relative humidity (RMSET2m and RMSERH2m, respectively). For profiles verification we used the radio-sounding launched from Bet-Dagan (34.814E/32.007N) twice daily (at 00 and 12 UTC). Each model profile was interpolated on the radio-sounding measurements heights, and the RMSE was calculated giving five times larger weight to heights below 2 km above surface. The resulting RMSEs were averaged over the various forecast ranges yielding verification score for temperature profile (RMSETprof) and mixing ratio profile (RMSEQprof). These four scores were calculated for each COSMO (RMSET2m_cos, RMSERH2m_cos, RMSETprof_cos, RMSEQprof_cos) and IFS (RMSET2m_ifs, RMSERH2m_ifs, RMSETprof_ifs, RMSEQprof_ifs) forecast. Similarly to precipitation score described above, we normalize COSMO scores with respect to IFS and define $Skill_{field} \equiv 1-\frac{RMSE_{field_cos}}{RMSE_{field_ifs}}$, where $field$ can be T2m, TH2m, Tprof or Qprof. Finally, temperature and relative humidity verification score T_RH_PROF for each COSMO run is defined as:

$$T_RH_PROF=\frac{1}{4}\left(Skill_{T2m}+Skill_{RH2m}+Skill_{Tprof}+Skill_{Qprof}\right) \tag{25}$$

T_RH_PROF varies in the range $[-\infty,1]$, where $T_RH_{PROF} > 0$ ($T_RH_{PROF} < 0$) means COSMO precipitation forecasts are better (worse) than of IFS.

6.6 Tuning the shallow convection scheme

At this section we use ten typical rainy events first to show that turning off the SCP in cases of too strong grid scale updrafts (larger than W_{max}) improves the forecast, and second, to define the optimal W_{max}. Brief characteristics of the chosen events are summarized in Table 4. The chosen events are typical to rain season over EM. Usually during these 3-days long events significant parts of the simulation domain and the verification area are characterized by fair weather alongside unstable cyclonic areas. Therefore the following verification is not limited to rainy areas.

For each of the COSMO versions V1-V5 (see Table 3) a simulation was performed over the 10 chosen events (Table 4). In order to reveal the optimal W_{max}, three additional simulations V4a, V4b, V4c were performed using W_{max} values of 0.3, 0.15, 0.05 m/s, respectively. For

05-07/ 01/2018	05/01 00 UTC	66	05/01 12UTC	1001	3.6	5510	-22.3
18-20/ 01/2018	18/01 00 UTC	49	19/01 00UTC	1001	2.0	5420	-27.3
16-18/ 02/2018	16/02 00 UTC	66	17/02 12UTC	1007	3.0	5500	-25.3

Table 4: Characteristics of 10 selected rain events over EM. The columns from left to right represent: dates of each event; initiation time of COSMO run; maximum accumulated precipitation during the entire event at specific location; the time of sounding representing the peak of the event; Mean-sea-level pressure from the sounding; 850 hPa temperature from the sounding; 500 hPa geopotential height from the sounding; 500 hPa temperature from the sounding.

each simulation, the T-RH-PROF and ΔFSS scores were calculated. Fig. 24 presents ΔFSS (red dots) and T_RH_PROF (blue dots) for the various versions, calculated for the 10 chosen events. The dots were connected by straight lines to make the comparison of different versions more convenient.

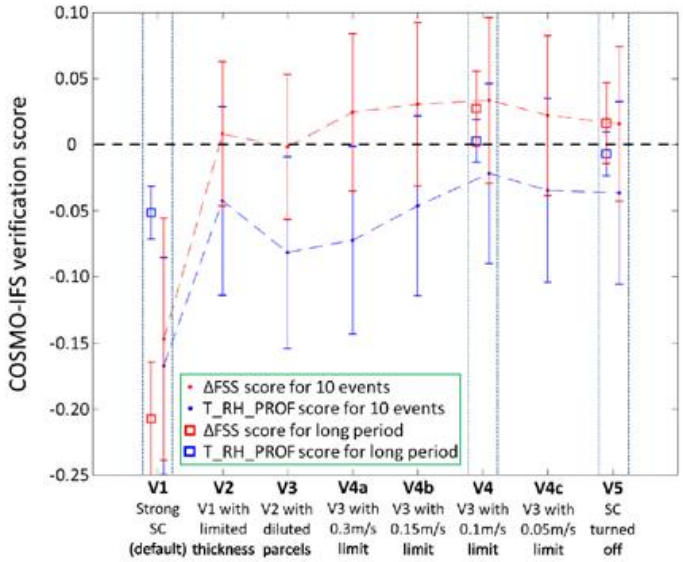

Figure 24: ΔFSS (red dots) and T_RH_PROF (blue dots) verification scores for the various versions (Table 3), calculated for the 10 chosen rain events (Table 4). The dots were connected by straight lines to make the comparison of different versions more convenient. The verification scores ΔFSS and T_RH_PROF for the entire winter season 01/11/2017-31/03/2018 are presented by red and blue squares, respectively.

One can see that reduction of the maximum allowed thickness for the shallow convection ($thick_{sc}$ parameter) significantly improves the forecast (V2 vs. V1). As mentioned above, this limitation is crucial as it allows the grid scale convection to develop. The increase of the entrainment rate (entr_{sc} parameter), which is physically motivated in the appendix, slightly worsens the forecast (V3 vs. V2). As discusses in the previous section (Figs. 20 and 22), V3 improves the weak precipitation coverage at the expense of deterioration of strong precipitation. Introduction of maximum allowed updraft (W_{max} parameter) for the shallow convection further improves the forecast. One can see a pronounced optimum at W_{max}= 0.1 m/s (version V4). At first glance, such low value seems too weak for realistic shallow convection. However, this grid scale value represents an averaged updraft over the model grid box of about $(2.5\ km)^2$. For higher horizontal resolutions W_{max} has to be retuned, and higher values are expected. Back to the current resolution, reduction of W_{max} towards 0.05 m/s (version V4c) slightly worsens the forecast. In this configuration the SCP switches off too frequently even in fair weather conditions, and is not replaced by grid scale vertical mixing. Such configuration mistakenly keeps the lower atmosphere unmixed, yielding in slight degradation of the verification scores. Finally, continuous switching off the SCP over the entire domain (V5) shows additional slight degradation of the performance.

At last, we show that the above tuning based on 10 rainy events indeed improves the wintertime forecasts over the EM. Versions V1 (default – strong SCP), V4 (optimum) and V5 (no SCP) were used to perform simulations over an entire winter season 01/11/2017-31/03/2018 (in total 151 72h-long simulations for each version). The verification scores T_RH_PROF

and ΔFSS were calculated for the entire period and are presented on Fig. 24 designated by blue and red squares, respectively. One can see that V4 is indeed optimal. However, the advantage over V5 (no SCP) is not significant. In rainy days switching off SCP might indeed be as good as V4 version, and definitely much better than activating the default SCP (version V1). On contrast, in fair weather days switching off SCP deteriorates the forecast. To prove it we performed similar analysis over all the fair weather forecasts, total of 75 cases, during the period 01/11/2017-31/03/2018. To isolate the main effect of the SCP, we focused on temperature verification part of 25 i.e. $T_PROF_T = \frac{1}{2}(Skill_{T2m} + Skill_{Tprof})$ during day times of each forecast (three 12 UTC values). It turns out that $\mathrm{T_{PROF_T}} = -0.0001 \pm 0.0204$ for version V4 (optimal) which is significantly better than $\mathrm{T_{PROF_T}} = -0.0472 \pm 0.0227$ for V5 (no SCP).

6.7 Discussion and conclusions

NWP models in convection permitting resolution often resolve deep convection but parametrize the shallow convection. This combination may have negative effect significantly influencing the model forecast. Majority of SCPs used in NWP convection permitting models are based on the mass-flux approach. In this work we analysed the effect of the widely used mass-flux SCP on COSMO model forecasts in convection permitting resolution of 2.5 km. On one side, the default configuration of the SCP turns out to be too active, causing decay of precipitation. On the other side, in fair weather without SCP the vertical mixing in the PBL is underestimated yielding degradation of temperature profiles. It turns out that even within the framework of regular mass-flux SCP, one can still find a delicate compromise by limiting the SCP activity. This compromise can be achieved by limiting the vertical extent, the entrainment rate and the updraft speed of the parametrized SC. The effect of each of the limitations thoroughly analysed using a test case of cyclone passage over the eastern Mediterranean (EM). Physically motivated tuning of the related parameters was performed using ten rainy events showing significant forecast improvement, which was validated based on entire rain season over the EM.

We now address the question whether SCP is important in other climatic zones except of EM. Although this question can be a topic of a different study, we provide a rough estimate below. As was shown, SCP significantly influences the forecast in unstable stratifications topped by an inversion around 800 to 500 hPa, as well as in weakly unstable situations. It is, however, not influencing severe situations with strongly unstable stratification reaching the upper troposphere. It is also not playing role in stable stratification dominated by stratiform precipitation. Although there are exceptions related to local climate, generally the central European climate is characterized by stratiform precipitation during wintertime and strongly convective during summertime. The Mediterranean climate is generally characterized by moderate convective precipitation during wintertime, strong convective events during autumn and spring, and dry summer. These weather types can be reasonably distinguished by CAPE values. In order to demonstrate these characteristics, we analysed the CAPE climatology in 8 sounding locations (Table 5) - 4 characterized by Mediterranean climate (hereafter “Mediterranean”) and 4 more characterized by central European climate (hereafter “European”).

For each location, twice daily (00 and 12 UTC) sounding data was retrieved for 20 years period 1/1/2000-31/12/2019 (www.weather.uwyo.edu/upperair/sounding.html). At each location at least 6000 available records exist allowing calculation of CAPE. Moreover, each of these stations provides 6 hourly precipitation measurements. In order to focus on rainy events, we selected only those CAPE values where there was non zero precipitation during

Sounding station	**Station number**	**Location**	**Latitude** (deg.)	**Longitude** (deg.)	**Climate**
Bet-Dagan	40179	Bet-Dagan (central Israel)	32.00	34.81	"Mediterranean"
LIRE Pratica di Mare	16245	Rome (central Italy)	41.65	12.43	"Mediterranean"
LIBR Brindisi	16320	Brindisi (south east Italy)	40.65	17.95	"Mediterranean"

Table 5: Sounding stations selected for CAPE analysis.

the last 6 hours. Fig. 25 shows the 90th percentile of monthly CAPE values at 4 "Mediterranean" locations (solid lines) and 4 "European" locations (dashed lines). Monthly CAPE values based on sample sizes below 30 were neglected.

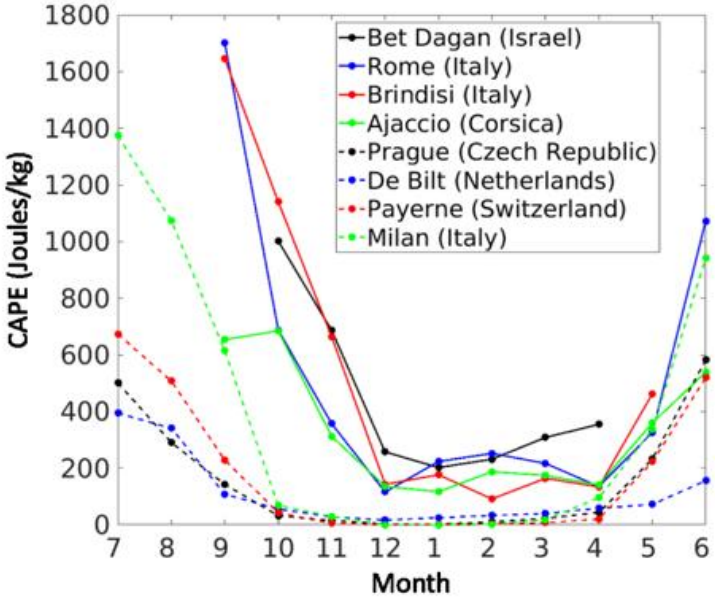

Figure 25: 90th percentile of monthly CAPE values at 4 "Mediterranean" locations (solid lines) and 4 "European" locations (dashed lines). The sample contains twice daily (00 and 12 UTC) sounding data for the period 1/1/2000-31/12/2019. Only CAPE values with non-zero precipitation during the last 6 hours were selected. Monthly CAPE values based on sample sizes below 30 were neglected.

As expected, during wintertime the "Mediterranean" locations are characterized by moderate CAPE around 100-300 J/kg. These are the values where SCP is expected to play an important role. However, wintertime at "European" locations is characterized by stratiform precipitation and hence negligible CAPE (below 50 J/kg). Consequently, we do not expect SCP to play an important role during European winter. Generally, the autumn and spring at the "Mediterranean" locations and summertime at the "European" locations are characterized by strong convective precipitation with high values of CAPE (300-1700 J/kg). SCP is automatically turned off in these cases and is not expected to influence the forecast. We do expect the SCP to influence the forecast during European autumn and spring where the CAPE values are moderate. The above statements are general and there are many exceptions. For example, De Bilt (Netherlands) shows moderate CAPE also during summer, so that SCP might be important there as well. Hence, in order to estimate whether and during which seasons the SCP is an important factor in NWP, one has to look at local climatology of CAPE.

To conclude, nowadays many weather forecasting centres run convection permitting NWP models, and often face difficulties obtaining satisfactory forecasts, particularly of precipitation. As mentioned, majority of these models resolve deep convection and use mass-flux approach to parametrize the shallow convection. This study shows that SCP configuration might be of crucial importance to the model forecasts. We believe that it sheds light on the numerical processes through which SCP affects the model forecasts, and most importantly, it provides a recipe to improve them.

7 Implementation of CAMS forecasted aerosols in COSMO radiation and microphysics schemes

(H. Muskatel, U. Blahak, P. Khain)

7.1 Introduction

Operational NWP models requires assessment of aerosols loads for both radiation transfer calculations (direct effect) and for microphysical parametrizations of liquid droplets activation and ice particles heterogeneous nucleation processes (indirect effect). Two approaches are often chosen for aerosols evaluation. First is using climatology values where yearly fixed values are chosen for each aerosol species as in Tanre climatology (Tanre et al., 1984, itype_aerosol = 1) or monthly means as in Tegen (Tegen et al., 1997, itype_aerosol = 2) and MACv2 (Kinne et al. 2013, itype_aerosol = 3) climatologies. All the three options mentioned above are available in the latest COSMO-CLOUDRAD version. In this approach the computational effort is minimal but air pollution events are neglected and sometimes severely degrade forecast skills (i.e. in dust outbreaks or volcanic eruptions events). The second approach is online-coupling of NWP models with aerosols and reactive trace gasses forecast. In these models (i.e. COSMO-ART and ICON-ART) the aerosols are treated as additional tracers and processes like emissions, wet and dry deposition, sedimentation and transport need to be explicitly calculated. This approach is usually expensive in terms of CPU consumption. As a result, it is operationally used as parallel modules to operational run with lower spatial resolution (i.e. ICON-ART-dust runs in DWD) or non-operationally upon demand (i.e. COSMO-ART). In this project we offered a third approach where the offline low resolution fully-coupled aerosols models forecast outputs are used as an input for the operational non-coupled LAM model. In this chapter we describe the use of CAMS-ECMWF forecasted aerosols as input for COSMO radiation and microphysics schemes while in chapter 8 we will discuss the use of ICON-ART-dust forecast. In this new approach the advantages compared to aerosols climatology is obvious since synoptic scale events including aerosols are included while being neglected in aerosols climatology approach. Since COSMO boundary and initial conditions are taken from global models (i.e. IFS or ICON), using the forecasted global aerosols based on these forecasting systems is a natural choice. The difference between interpolating atmospheric fields such as temperature and pressure from the driving model to the use of aerosols fields is that the data is updated in time, as for boundary conditions data, but for applied to the entire domain. The values of aerosols mixing ratios in 3D between two snapshots of aerosols fields are interpolated in space and time by INT2LM. The computational cost during runtime is minimal, since most calculations are performed in the pre-processing stage. Technically, INT2LM needs double run: once for the regular driving model and once for the aerosols. The initial and boundary files are later combined. The disadvantage of such method is that the aerosols are not coupled with COSMO dynamics but being advected, washed-out etc., only by the offline global aerosols model (i.e. CAMS). Differences in dynamics between the aerosols model and COSMO may lead to errors. Nevertheless, in the everlasting conflict between model realism and computational cost, we show that this is a fair compromise for operational NWP applications.

7.2 CAMS aerosols forecasting system

The Copernicus Atmosphere Monitoring Service (CAMS, formerly series of MACC projects) is an ECMWF project that provides near-real-time analysis and forecast of atmospheric

composition: aerosols, reactive gases, greenhouse gases, ozone, UV radiation and more. The aerosols 5-days ahead forecast is available twice a day with a 1-hour resolution. CAMS is based on IFS model with additional prognostic aerosols which are interactive with the dynamics and physics of the parent model (Morcrette et al. 2009). The processes treated are: emissions sources (some are updated in near-real-time), horizontal and vertical advection, dry and deposition, sedimentation and hygroscopicity. CAMS includes aerosols data assimilation using MODIS Terra and Aqua aerosols optical depth (AOD) and verified against AERONET AOD. The forecasted aerosols are mineral dust (MD) divided to three size bins, sea salt (SS) also with three size bins, black carbon (BC) and organic matter (OM) which both includes hydrophilic and hydrophobic species and Sulfate (SU). In Fig. 26 CAMS aerosols size limits, mode radius r_{mode} and geometric standard deviation σ of the log-normal distributions used to describe particle size distribution are presented. The mean volume particle masses of each species was numerically calculated using the formula:

Aerosol type	Size limits [μm]	r_{mode} [μm]	σ	modes weights	ρ [kg/m^3]	Particle mean mass [kg] at RH=80%	Soluble fraction
Sea salt	[0.03, 0.5]	0.1992, 1.992	1.9, 2.0	0.959, 0.041	1153	$7.80 \cdot 10^{-17}$	1
Sea salt	[0.5, 5]	0.1992, 1.992	1.9, 2.0	0.958, 0.042	1153	$3.33 \cdot 10^{-15}$	1
Sea salt	[5, 20]	0.1992, 1.992	1.9, 2.0	0.957, 0.043	1153	$9.34 \cdot 10^{-15}$	1
Dust	[0.03, 0.55]	0.29	2.00	1	2610	$2.87 \cdot 10^{-16}$	0.1
Dust	[0.55, 0.9]	0.29	2.00	1	2610	$4.73 \cdot 10^{-16}$	0.1
Dust	[0.9, 20]	0.29	2.00	1	2610	$1.56 \cdot 10^{-15}$	0.1
OM Hydrophilic	[0.005, 20]	0.0212	2.24	1	1800	$4.00 \cdot 10^{-18}$	0.59
OM Hydrophobic	[0.005, 20]	0.471, 0.0118	2.51, 2.0	$4.8 \cdot 10^{-6}$, 0.999952	2000, 1000	$4.91 \cdot 10^{-19}$	0
BC Hydrophilic	[0.005, 5]	0.0118	2.00	1	1000	$1.78 \cdot 10^{-19}$	1
BC Hydrophobic	[0.005, 5]	0.0118	2.00	1	1000	$5.98 \cdot 10^{-20}$	0
Sulfate	[0.005, 20]	0.0355	2.00	1	1760	$9.38 \cdot 10^{-18}$	1

Figure 26: CAMS aerosols size limits, mode radius r_{mode} and geometric standard deviation σ of the log-normal distributions used for particle size distribution. Sea salt and hydrophobic organic matter are described by a bimodal log-normal distributions with mode weights given in the third column from the right. ρ is the particle density. The particles mean masses were numerically calculated using Eq. 26.

$$\overline{m_v} = \frac{4\pi}{3}\rho \int_{r_{min}}^{r_{max}} r^3 \frac{1}{\sqrt{2\pi} ln\sigma \cdot r} \exp\left\{-\frac{1}{2}\left[\frac{\ln(r/r_{mode})}{ln\sigma}\right]^2\right\} dr \tag{26}$$

7.3 CAMS aerosols direct effect on radiation

7.3.1 CAMS aerosols optical properties

CAMS aerosols optical properties namely the extinction coefficient, the asymmetry factor and single scattering albedo, were originally calculated for IFS radiation RRTM scheme. This model has 16 wavelength intervals in the long-wave range (LW) and 14 intervals in the short wave (SW) range (A. Bozzo, private communication, 2016). In COSMO RG92 scheme there are only 5 intervals for LW and 3 intervals in the SW. Therefore, a special spectral averaging similar to the averaging procedure performed for ice particle as explained in Muskatel et al. (2021), was used to transfer the IFS high spectral resolution data to COSMO radiation scheme. The calculation includes weighting of the solar irradiance intensity at each wavelength according to Planck's function and layer thickness. The optical properties of the sea salt, sulfate and hydrophilic organic matter depend on relative humidity (RH) due to their growth factor in presence of water vapour. Larger RH usually results in

larger single-scattering albedo, extinction coefficient and asymmetry factor but these properties also depend on wavelength. An example for sea salt asymmetry factor for different RH for four COSMO spectral intervals are shown in Fig. 27. For the first time in COSMO radiation scheme, the optical properties of aerosols at each grid point is RH dependent.

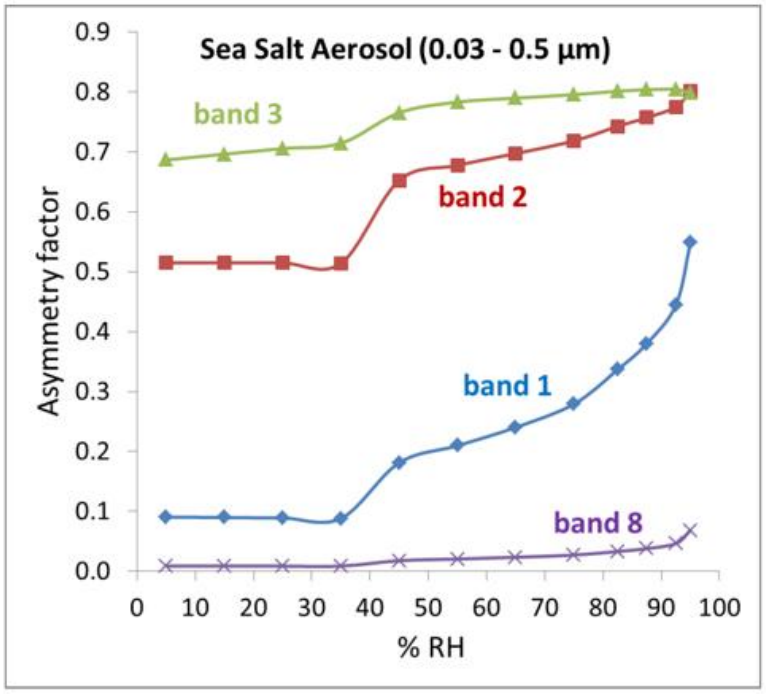

Figure 27: An example for CAMS aerosols asymmetry factor values of sea salt as function of relative humidity for COSMO bands 1 ($1.53\ \mu m - 4.64\ \mu m$), 2 ($0.7\ \mu m - 1.53\ \mu m$), 3 ($0.25\ \mu m - 0.7\ \mu m$), 8 ($4.64\ \mu m - 8.33\ \mu m$) data adapted from IFS RRTM radiation scheme (A. Bozzo, private communication, 2016) to COSMO RG92.

7.3.2 Testing the direct effect of CAMS aerosols on COSMO radiation

Direct effect of CAMS aerosols load in COSMO radiation scheme compared to other aerosols inputs were tested in several frameworks. The first is a using data from 10 selected radiation stations in Israel and two AERONET stations AOD measurements in Sede-Boker and Technion (see Fig. 28).

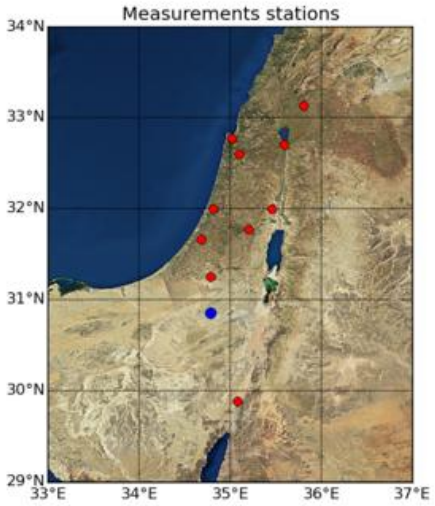

Figure 28: Israel satellite image with the locations of 10 IMS radiation (red dots) and 2 AERONET (blue dots) measurements stations. The data sets from these stations were used for the verification of COSMO aerosols inputs scenarios.

In the first verification, 29 selected test cases for mixed weather situations in the years 2015-2016 were chosen. The forecast range was either 30 or 42 hours using COSMO 5.0 version with spatial resolution of 2.8 km on IMS domain (see Fig. 37). Four versions were compared: the operational COSMO version with Tanre climatology, the new CLOUDRAD scheme with Tanre climatology, Tegen climatology and CAMS forecasted aerosols. The observational AOD data was taken from the AERONET station in Sede-Boker. In Fig. 29 one can see the models setup results for clear skies conditions. The cloudiness was defined by the model cloud cover. The points from all stations and hours of the day appear in one plot, model vs. observation. The 1:1 (black) line represents the ideal forecast. One can see that in both operational and the new CLOUDRAD versions, if Tanre climatology is used, the radiation is underestimated, which indicates an AOD overestimation. The negative bias almost disappears when using the new CLOUDRAD with both Tegen climatology or CAMS forecasted aerosols due to smaller error in AOD estimation (see Fig. 30). The AOD and global radiation bias and RMSE of climatology/model against 10 radiation stations and AERONET measurements in Sede-Boker for 7 test cases are presented in Fig. 30. The average RMSE and bias for these 7 clear skies cases and another 22 cloudy skies days are summarized in Fig. 26. The advantage of Tegen and CAMS over Tanre seems to vanish in cloudy skies condition probably due to the model tuning which was adapted to the operational setup.

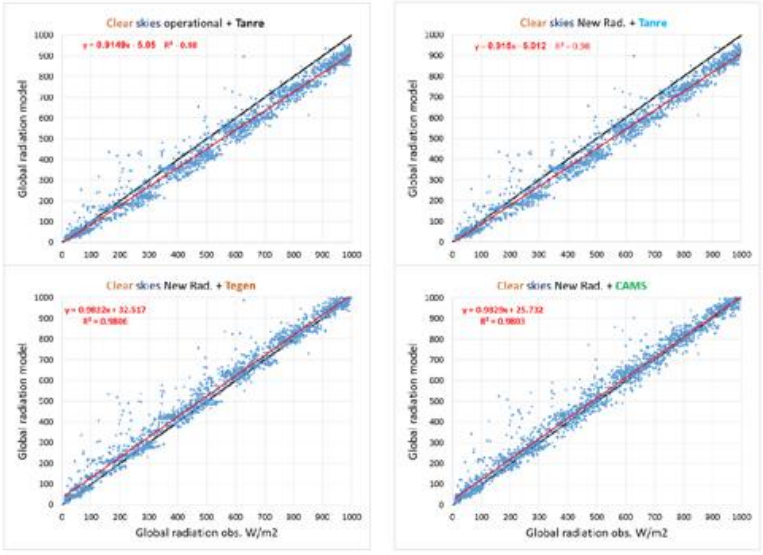

Figure 29: Clear skies conditions results for four radiation setups: operational COSMO version with Tanre climatology (upper left), new CLOUDRAD scheme with Tanre climatology (upper right), new CLOUDRAD with Tegen climatology (lower left) and new CLOUDRAD with CAMS forecasted aerosols (lower right) against measurements from 10 radiation stations in Israel. The 1:1 black line is the ideal match and red line is the linear fit between model and observation.

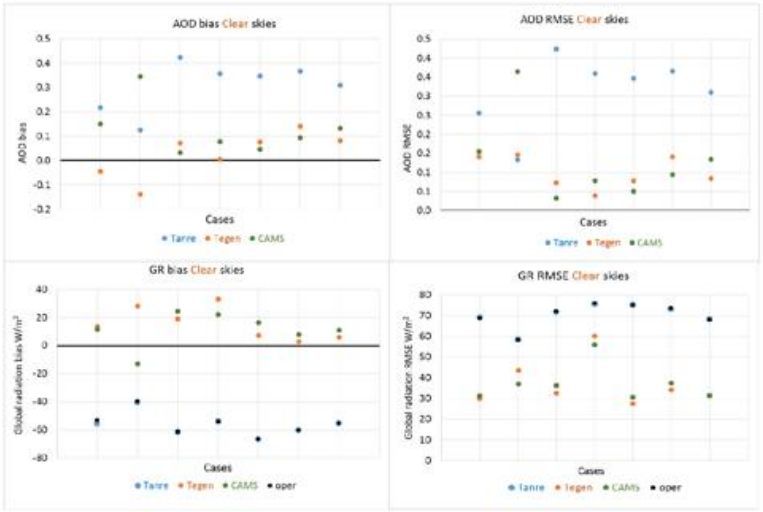

Figure 30: Clear skies conditions results for 7 test cases (17-18 May 2015, 14 and 26 February 2016, 18 April 2016, 19 and 24 June 2016) for four radiation setups: operational COSMO version with Tanre climatology (black), new CLOUDRAD scheme with Tanre climatology (Azure), new CLOUDRAD with Tegen climatology (orange) and new CLOUDRAD with CAMS forecasted aerosols (green). Upper panels show the AOD bias (left) and RMSE (right) climatology vs. measurement in AERONET station in Sede-Boker. Lower panels display the bias and RMSE of global radiation against measurements in 10 radiation stations in Israel.

Model	Clear skies (7 test cases)				Cloudy skies (22 test cases)			
	AOD		Global Radiation W/m^2		AOD		Global Radiation W/m^2	
	bias	RMSE	bias	RMSE	bias	RMSE	bias	RMSE
Tanre	0.31	0.31	-56.2	70.1	0.20	0.28	-11.1	131.5
Tegen	0.03	0.10	15.6	37.0	-0.12	0.17	54.2	140.5
CAMS	0.12	0.13	11.4	37.1	0.11	0.14	40.7	140.4

Figure 31: Clear skies (7 test cases) and cloudy (22 test cases) conditions results for three aerosols models input for COSMO-CLOUDRAD radiation scheme. AOD bias and RMSE calculated against AERONET data in Sede-Boker. Global radiation bias and RMSE are against measurements in 10 radiation stations in Israel (see Fig. 28).

Proper tuning of the CLOUDRAD version improves the scores even for cloudy skies conditions as can be seen in Fig. 32. In this Fig. the global radiation results for three models are presented: ECMWF-IFS with CAMS climatology (red), COSMO operational scheme with Tanre climatology and CLOUDRAD with CAMS forecasted aerosols. The period is July-August 2019 in IMS operational domain and verified against 17 ground based stations. Cloudy/clear skies definition was made by using CMSAF cloud cover product (https://www.cmsaf.eu) where clear/cloudy skies situations are defined when all models and satellite observation CLC is lower/larger than 5/95 % respectively. The RMSE for CLOUDRAD-CAMS version is the lowest compared to IFS and operational COSMO-Tanre version which has the largest RMSE for the entire period (Fig. 32 Upper-left). In the upper-right panel of Fig. 32 we see that the occurrences of errors larger than 50 W/m^2 (fiascos) in global radiation forecast is smallest in CLOUDRAD-CAMS compared to other models. Nevertheless, the mean bias of CLOUDRAD-CAMS is comparable to IFS in cloudy conditions (lower-left) and slightly higher than IFS. The bias of operational COSMO-Tanre is in the order of $\sim$50 W/m^2 in both cloudy and clear skies. COUDRAD-CAMS improved the bias also in cloudy skies conditions, indicates that the tuning procedure (see Sec. 10) significantly improved model skill.

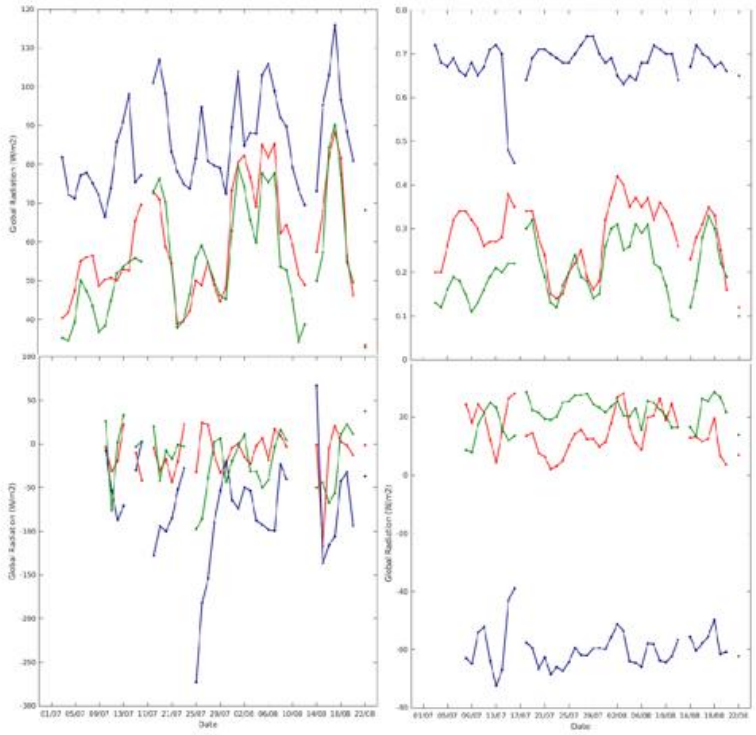

Figure 32: Global radiation results for three models: ECMWF-IFS with CAMS climatology (red), COSMO operational scheme with Tanre climatology (blue) and CLOUDRAD with CAMS forecasted aerosols (green). For the period July-August 2019 in IMS operational domain and is verified against 17 ground based stations in Israel. Upper left: global radiation RMSE [W/m^2], upper right: occurrences of fiascos where model error was larger than 50 W/m^2, lower left/right: cloudy/clear skies global radiation bias [W/m^2].

7.4 CAMS aerosols indirect effect on radiation

7.4.1 Water droplets number concentration and effective radius

The effective size and number concentration of water droplets significantly affect the cloud optical thickness. Fig. 4a shows that for the same total water path, changing droplets number concentration (tuning parameter cloud_num_rad) from 500 cm^{-3} ($R_{eff} \approx 4\ \mu m$) to 50 cm^{-3} ($R_{eff} \approx 9\ \mu m$) can change the global radiation on the surface from ~300 W/m^2 to ~450 W/m^2. In the operational radiation scheme (iradpar_cloud = 1) the effective size is defined by the formula: $\mathrm{R}_{eff} = \mathrm{c}_7 + \mathrm{c}_8 LWC$ (Ritter and Geleyn 1992) without an explicit dependency on number concentration. The effective radius in the new CLOUDRAD scheme (iradpar_cloud = 4) is calculated from the number concentration following the formula:

$$\mathrm{R}_{eff} = \mathrm{c}_1 \left(\frac{LWC}{\mathrm{n}_c} \right)^{\mathrm{c}_2} \tag{27}$$

Where n_c is the cloud droplets number concentration and $\mathrm{c}_{1,2}$ are coefficients related to the particle size distribution used by the microphysical scheme.

Formula 27 is used for grid scale clouds. For sub-grid scale (SGS) clouds, LWC is by definition zero. In the default radiation scheme, a tuning parameter (luse_reff_ini_x_as_reffx_sgs) is used

to define a fixed effective radius for SGS clouds and the tuning parameter for this background effective radius is reff_ini_c (default 5 μm). In the new CLOUDRAD scheme we added the option of calculating SGS effective radius in the same way done by grid scale clouds by setting luse_reff_ini_x_as_reffx_sgs=.FALSE.. In this case, formula 27 will be used with a special treatment to LWC as was discussed in Sec. 5.

Unlike the default radiation scheme where the chosen value for cloud_num_rad is effective at each cloudy grid box (default value 200 cm^{-3}), the new CLOUDRAD scheme (iradpar_cloud = 4, cloud_num_type_rad = 1) the number concentration is defined by setting cloud_num_rad as the value for cloud base and decreasing according to the vertical profile formula:

$$\mathrm{n}_c = \mathrm{n}_{c0} \cdot exp\left(-\frac{z - z_0}{\Delta z_{1/e}}\right) \tag{28}$$

Where z_0 is the cloud base height (tuning parameter zref_cloud_num_rad, default value 2000 m) and $1/\Delta z_{1/e}$ is the rate constant (tuning parameter dz_oe_cloud_num_rad , default 6000 m). n_{c0} is defined by the tuning parameter cloud_num_rad.

7.4.2 Water droplets activation using Segal and Khain (2006) scheme

In numerous studies it was shown that cloud droplets number concentration depends on aerosols concentrations (Segal and Khain, 2006, SK2006 hereafter) since the aerosols serve as condensation nuclei according to Kohler theory. In pristine atmosphere (i.e. in the Pacific Ocean) the aerosols number concentration is relatively small hence the cloud droplets number concentration is small and the cloud droplets effective radius is large. In a polluted atmosphere, cloud number concentration is higher. The limited humidity is spread on more particles resulting smaller droplets and optically thicker clouds. Using a simplistic estimations of cloud number concentrations based on fixed values at cloud base is unrealistic in most cases. In the new CLOUDRAD scheme we added the SK2006 activation scheme for cloud formation parametrization even in the 1-moment microphysical scheme (cloud_num_type_rad = 2). Segal and Khain (2006) used LES simulations with 2000-bin microphysics to parametrize cloud number concentrations as function of both vertical velocity at cloud base and aerosols size distribution. SK2006 is suitable for both stratiform and cumulus clouds in maritime, continental or extreme continental environments. They showed that the aerosols soluble concentration is the dominant factor in the resulted CCN concentrations. the realization of SK2006 in COSMO is by using 4D LUT to define n_c at cloud base using 4 parameters:

$$\mathrm{n}_{c,CB} = \mathrm{f}(\mathrm{N}_{CN,CB},\ log\sigma_{CN},\ r_{CN},\ w_{CB}^{eff}) \tag{29}$$

where σ_{CN} and r_{CN} are the geometric standard deviation and mode radius of the aerosols lognormal distribution (see Eq. 26), N_{CN} is the aerosols number concentration at cloud base which can be taken from CAMS (itype_aerosol = 4) or Tegen climatology (itype_aerosol = 2). w_{CB}^{eff} is the effective updraft speed for nucleation at cloud base.

When Tegen aerosols are used, the lognormal distribution parameters are fixed to the values $\sigma_{CN} = 0.3$ and $r_{CN} = 0.0335\ \mu m$. Aerosols number concentration for each of the species in Tegen climatology (dust, organic matter, sulfate and sea salt) are computed from optical depth assuming vertical exponential profile confined in the space between COSMO topography and 12 km height (the original Tegen topography is unavailable). The total N_{CN} is a summation over all species but with the soluble fraction consideration where dust soluble fraction is 0.9 and organic matter 0.9. Sulfate and sea salt are considered 100% soluble.

If CAMS aerosols are chosen as input for SK2006 activation scheme (cloud_num_type_rad = 2; itype_aerosol = 4), effective parameters for the lognormal distributions for the mixture of aerosols need to be calculated at each grid point. Weighted soluble particles number concentration $\overline{N}$, effective mode radius $\overline{r}$ and standard deviation $\overline{\sigma_g}$ are calculated according the formulas:

$$\overline{N_{CN}} = \sum_i N_i s_i \tag{30}$$

$$\overline{r} = \frac{1}{\overline{N}} \sum_i N_i s_i r_i \tag{31}$$

$$\overline{\sigma_g} = \sqrt{\frac{1}{\overline{N}} \sum_i N_i s_i \left[\sigma_{g,i}^2 + (r_i/\overline{r})^2\right]} \tag{32}$$

where r_i, $\sigma_{g,i}$, s_i are the mode radius, geometric standard deviation and the soluble fraction of each aerosol specie i detailed in Table 26. N_i are the number concentrations at each grid point for each species which are calculated from the 3D mixing ratios, $w_{a,i}$ $[kg{\cdot}kg^{-1}]$, provided by CAMS for each time step and each grid point:

$$(7.8) N_i(x,y,z) = w_{a,i}(x,y,z) \cdot \rho_{air}(x,y,z)/\overline{m_{v,i}}$$

where $\overline{m_{v,i}}$ are the mean (volume) particle masses of each aerosol tracer (see Eq. 26 and Table 26).

The appropriate vertical velocity for aerosol activation should be representative of adiabatic and diabatic cooling within updraft regions to parametrize supersaturation build-up during cloud condensation:

$$w_{eff} = \overline{w} + 0.7\sqrt{\frac{2TKE}{6}} - \frac{c_p}{g}\frac{\partial T}{\partial t} \tag{33}$$

Where $\overline{w}$ is the vertical velocity at cloud base, the middle term is the turbulence term and the third is the equivalent adiabatic updraft speed from radiative cooling.

For convective clouds, the option for imposing surface-based convective velocity scale as a lower limit diagnosed from convective cloud cover and theta-profile is implemented (name list parameter lincl_wstar_in_weff = .true.):

$$w_{CB}^{eff} = \max(\mathrm{w}_{eff}, \quad w^*) \tag{34}$$

$$w^* = \left(-g z_{topcon} \frac{\overline{w'\Theta'_{v,s}}}{\overline{\Theta'_{v,s}}}\right)^{1/3} \tag{35}$$

where z_{topcon} is the upper boundary of the convective PBL, Θ is the virtual potential temperature at PBL height (Deardorff, 1970).

As mentioned before, the cloud droplets number concentration is calculated at cloud base height which is diagnosed by scanning each column from bottom to top for first grid box with positive LWC or positive convective cloud cover. From this point and higher an exponential

profile decay is imposed using formula 28. If the effective updraft above cloud base is larger than the updraft calculated at cloud base (not a common situation), in-cloud nucleation is considered and the procedure detailed above is repeated but imposing the profile from half height between the cloud base and the actual height.

7.4.3 Using Segal and Khain (2006) scheme in the 1-moment microphysics

So far we discussed the direct and indirect effects of aerosols on radiation. In reality, the first and most important impact of aerosols is on cloud nucleation and dynamics. Clouds are the first factor effecting the radiation fluxes in the atmosphere covering roughly half of earth's surface. On the other hand, the very existence of clouds depends on the presence of aerosols. In pristine environments the cloud number concentration is usually low and the droplets are large. This will allow precipitation in the early stages of the cloud life which may suppress further development of the clouds to sever thunderstorms. In such situations, stratiform precipitation is expected and in cold temperatures, snow. In polluted environments higher cloud number concentrations are expected. In a humid environment, the droplets will grow slowly and can delay cloud formation and allow energy build up with stronger updrafts at later stages of cloud life (Rosenfeld et al., 2008). As a result, thunderstorms can develop with liquid and ice (graupel and hail) precipitation is possible. Nevertheless, extremely polluted environments results very high cloud number concentrations results in very small droplets which evaporate hence cloud formation is prevented (Rosenfeld et al., 2008).

In COSMO 1-moment microphysical scheme a size distribution is assumed and the mass fraction q^x can be predicted. The microphysical processes are determined by q^x. Cloud number concentration n_c is explicitly used only in the autoconversion rate parametrization (Seifert and Beheng ,2001)

$$S_{au} = \alpha \cdot q_c^4 / n_c^2 \tag{36}$$

$$\alpha = \frac{k_c}{20x^*} \frac{(\nu+2)(\nu+4)}{(k_c+1)^2} \tag{37}$$

Where S_{au} is the transfer rate due to autoconversion of cloud water, x^* is the separating mass between cloud and rain, k_c is the kernel coefficient for autoconversion and ν is the gamma exponent for cloud distribution. In the default COSMO 1-moment scheme n_c is a constant tuning parameter (default cloud_num = 500 cm^{-3}). In the new CLOUDRAD scheme n_c can be calculated as was described in details for the radiation in the previous section using the name list parameter icloud_num_type_gscp = 2. Here again, n_c will be calculated with SK2006 parametrization with Tegen climatology (itype_aerosol = 2) or CAMS forecasted aerosols (itype_aerosol = 4) as input aerosols for SK2006.

7.4.4 Case study - April 25-27, 2018

We examined the new CLOUDRAD radiation and microphysical scheme with CAMS aerosols and Segal & Khain droplet activation scheme using the event of 25-27/04/2018. In these three days of stormy weather in Israel, massive storm cells developed causing flush floods which caused the death of 14 people. Among them, 10 teenage hikers in the Eastern Negev on April 26, 2018. A low pressure system evolved in the Sinai Peninsula moving east (see

Fig. 33). Hot and humid air in lower layers along with cold air in the upper atmosphere caused extreme unstable atmosphere.

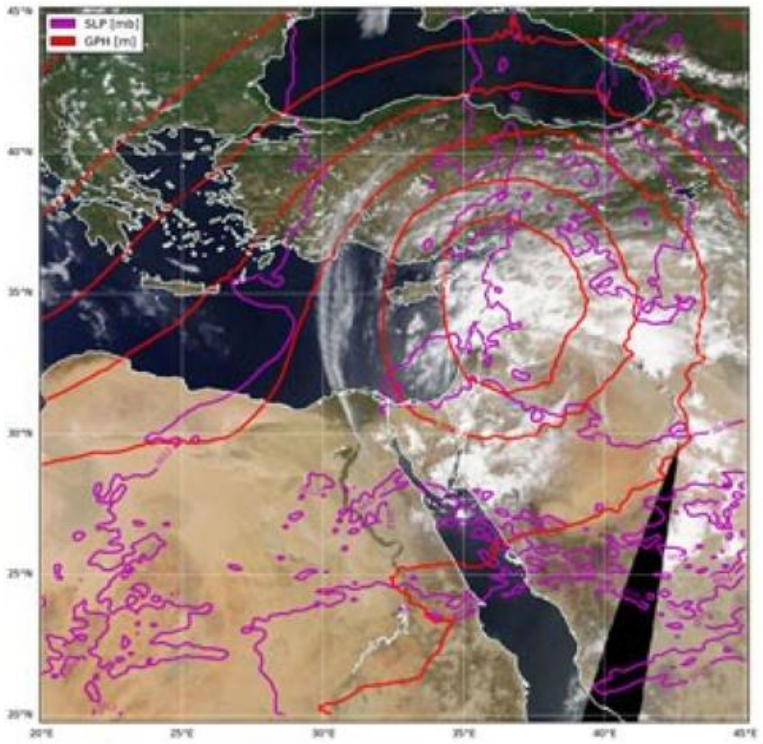

Figure 33: Synoptic analysis 26 April 2018 at 12:00 UTC, MODIS True Color RGB over Eastern Mediterranean. Red lines represents ECMWF analysis. Courtesy of Elyakom Vadislavsky.

The examination of CAMS aerosols cross sections for this highly convective event, reveals a diurnal cycle. The aerosols in all three days of the event are drifted upward by the convection at noon and descend at nights in a breath-like motion. A single snapshot of the event at April 25, at 14:00 UTC will be analysed here. Fig. 34 shows a cross section at 32N from 34E to 36 E from the Mediterranean Sea near Tel-Aviv to Amman in Jordan. The total hydrophobic aerosols concentration at cloud base heights (1000 m - 2000 m) reached 15000 cm^{-3} (Fig. 34 upper left panel) which is a typical number for polluted continental areas (Hess et al. 1998) especially in highly convective weather. Most of these hydrophobic aerosols are sulfate particles (lower right panel).

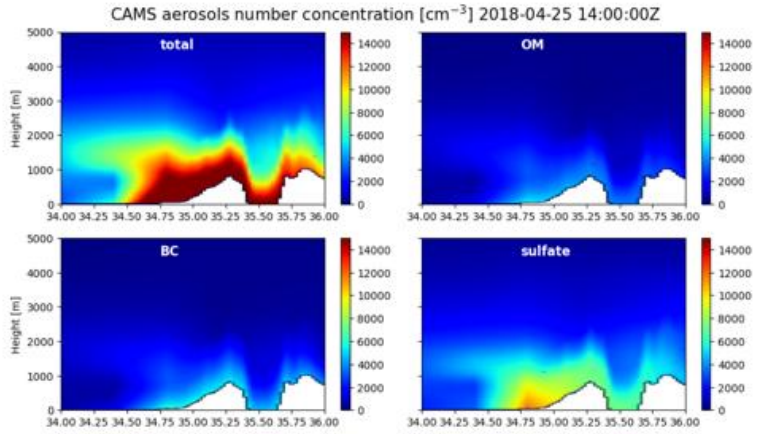

Figure 34: CAMS forecast for the 25^{th} of April 2018 at 14:00 UTC. A cross-section at 32N going from 34E to 36E. Top left: total hydrophilic CAMS aerosols number concentrations, top right: organic matter, bottom left: black carbon and bottom right: sulfate concentrations.

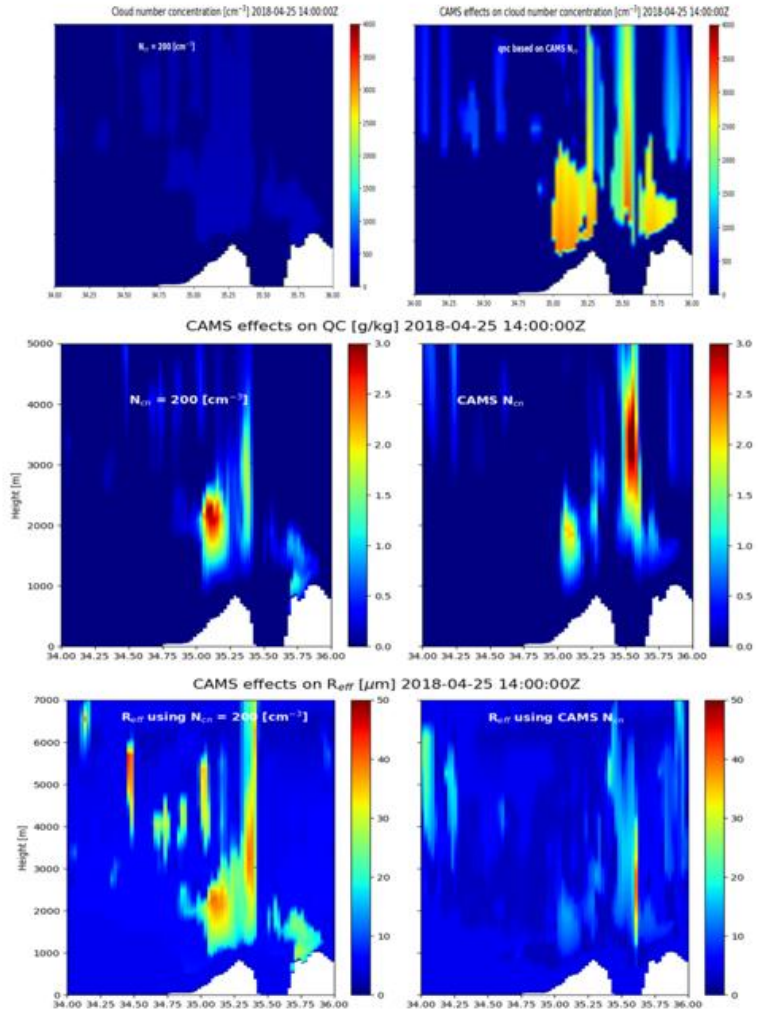

Figure 35: profiles for the 25^{th} of April 2018 at 14:00 UTC. Left panels: cloud number concentration using fixed value (cloud_num_rad = 2.0E+08) at cloud base and an assumed vertical profile. Right panels: CAMS forecast aerosols as input for Segal & Khain 2006 cloud activations scheme. Upper row: cloud number concentration profile $[cm^{-3}]$, midle row: LWC $[g/kg]$, lower row: droplets effective radius $[\mu m]$. The "noodle" shape of cloud is a result of the horizontal and vertical scales.

Fig. 35 shows the results for two model setups. The left panels represents the fixed number concentration at cloud base of 200 cm^{-3} and using a profile as described in formula 28 (cloud_num_type_rad = 1, cloud_num_rad = 2.0E+08). On the right panels SK2006 droplets activation scheme with CAMS aerosols are displayed (cloud_num_type_rad = 2; itype_aerosol = 4). The upper panels display cloud number concentrations profiles. One can see that the number concentrations of cloud droplets above Judea and Jordan mountains when using prognostic aerosols and SK2006 activation scheme are significantly higher than other areas and also compared to the default scheme (left panel). It is a result of both high aerosols densities at this hour and large updraft speeds due to deep convection and high instability of the atmosphere. The cloud number concentrations are diagnostic and are effective only at grid boxes with positive LWC. The middle panels of Fig. 35 show the LWC profiles for these two models. The clouds location and water load are significantly different. For example, the massive clouds above the Dead Sea at 36E are not present in the default scheme and can cause extreme flash floods in this area. Lower panels show results for the effective radius.

The prognostic scheme results in much smaller droplets.

The lower panels of Fig. 35 explain the immense effect of using forecasted aerosols and realistic cloud activation on the radiation. The clouds droplets are much smaller and with much larger densities which lead to a significant increase in cloud optical thickness (see Fig. 4). In Fig. 36 the results for the entire domain is presented. The colours indicates the points occurrences in the domain. The first row shown the cloud number concentration as a function of aerosols concentrations when SK2006 scheme is used in all grid points (left) and at cloud base (right). The cloud number concentrations can reach numbers as high as $3000\ cm^{-3}$ which may seem too large. Nevertheless, close inspection reveals that most points at cloud base have cloud number densities less than $1000\ cm^{-3}$ with an average of $621\ cm^{-3}$, a reasonable value for highly convective and polluted environments. As expected, the high $n_{c,CB}$ numbers are achieved when effective updraft speeds w_{nuc} are high as can be seen in the middle row of Fig. 36. The effective vertical wind speeds at cloud base can reach $\sim 3m/s$ (middle row right figure) while in the rest of the domain, at higher altitudes, the updraft can climb to much higher values (middle row, left panel).

The first two rows of Fig. 36 associate only with the CAMS and SK2006 configuration while the third raw shows the results of the two models setups described in Fig. 35. The effective radius as function of LWC is plotted enlightening the conclusion drafted from the lower panels of Fig. 35. We can clearly see that using forecasted aerosols combined with parametrized droplets activation can lead to more realistic droplet sizes of $\sim 7\mu m$ for continental clouds (see i.e. Fig. 6 in Reid et al. 1999) while using a fixed cloud number concentrations can cause large mistakes in cloud effective size and as a result, large errors in cloud optical thickness.

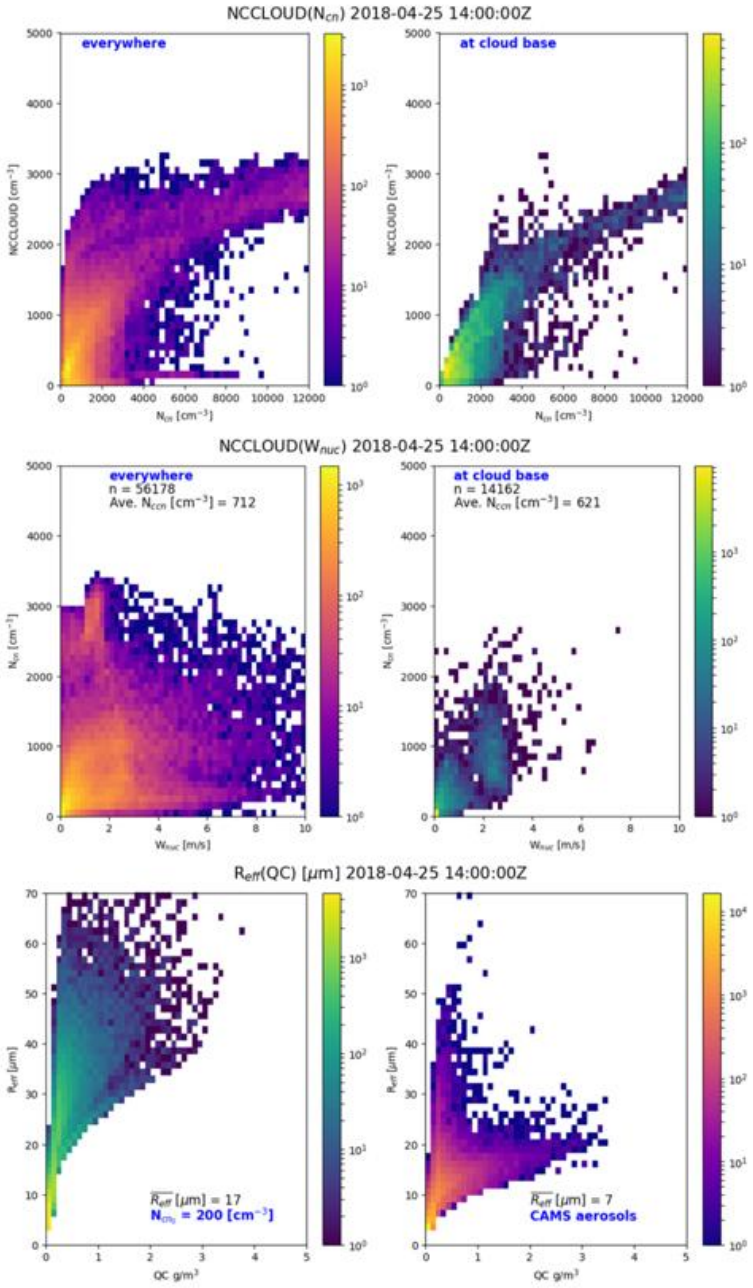

Figure 36: Upper row: droplet concentration as a function of aerosols number concentration $[cm^{-3}]$, middle row: droplet concentration as a function of effective updraft speed for nucleation $[m/s]$ (left: all points, right: at cloud base). Lower row: droplets effective radius $[\mu m]$ as a function of LWC [g/kg] (left: fixed droplet number concentration at cloud base, right: SK2006 activation scheme with CAMS forecasted aerosols.

In the previous sections we discussed the direct and indirect effects of the new SK2006 activation scheme radiation. While in Sec. 7.4.3 we discussed the influence of aerosols on the 1-moment microphysics scheme (on the auto-conversion rate). It can be done by using the name-list parameters icloud_num_type_rad/gscp in which setting each to the value of 2 will turn on the SK2006 activation scheme with the chosen aerosols input (Tegen or CAMS). The sensitivity of the model to each of these effects is presented in Fig. 37. For all four model configurations shown here, the aerosols input was CAMS (itype_aerosol =

4). The same test case was chosen but now the 11:00 UTC snapshot is taken to examine the effects on the maximum radiation at noon time. The upper four figures show incoming shortwave downward radiation on surface (global radiation) while the lower four show the 2m-Temperature. In each of these pair of four figures the upper left is for the new radiation scheme using fixed droplet number concentration (cloud_num_rad = 200 cm^{-3}) at cloud base icloud_num_type_rad/gscp = 1. In this configuration only the direct aerosols effect is activated. This setup will serve as a control run for which the absolute values are visualized. The other three figures shows the biases to the control run when we activate the indirect effects. Upper right panel represent the resulted bias due to turning SK2006 on but effective only in radiation (icloud_num_type_rad = 2). Lower left panel is the same but effective only in the microphysics (icloud_num_type_gscp = 2) and results when both effects are turned on icloud_num_type_rad/gscp = 2 are shown in lower right panel. The numbers on each of the three models are calculated over all model surface grid points compared to the control run in Wm^{-2} for the upper figures and K in the lower figures.

Analysis of these figures show that the indirect effect cloud droplets activation scheme on both radiation and microphysical schemes is significant. The biases of radiation/temperature can be as large as 300 Wm^{-2} / 3 K respectively. Although the RMSE and bias numbers appearing in each Fig. are a result of the average on all grid points where most of them are cloudless, these averages are unneglectable (bias ~ -7 Wm^{-2}, -0.04 K , RMSE $\sim$ 70 Wm^{-2}, 0.35 K). As expected, the use of CAMS aerosols which have larger number concentrations in this test case, reduced the droplet effective radius compared to the default scheme which in turns reduced the radiation on surface and the 2m-temperature. Surprisingly, the use of realistic aerosols and cloud activation scheme effected the microphysics (auto-conversion rate) in a way that caused significant changes in radiation but with smaller absolute values (RMSE $\sim$ 40 Wm^{-2}, 0.2 K). In this case, the radiation and temperature bias is almost zero since the effective radius of droplets was unaffected.

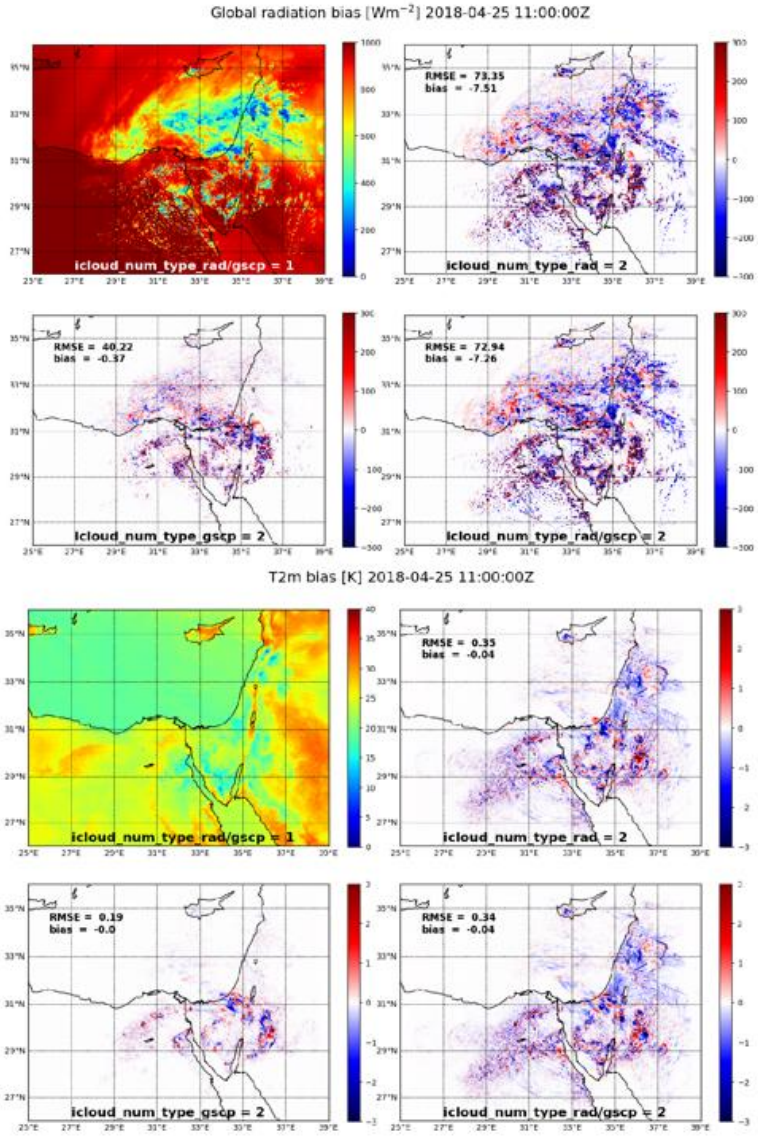

Figure 37: Global radiation (upper four figures) and Temperature (lower four figures) biases as a result of the indirect effects of SK2006 cloud activation scheme using CAMS forecasted aerosols. See text for details.

7.4.5 Ice nucleation scheme model inter-comparison using a case study

In Sec. 7.4.4, we showed the model results for the case study of 25-27-April-2020. In this chapter we will show the model sensitivity to the ice nucleation scenarios. The four models described in the previous section: the 1-moment scheme using Cooper (1986) parametrization (default), 1-moment microphysics using DeMott (2015) parametrization with CAMS dust forecasted fields, 2-moment microphysics with Phillips (2008) parametrization using fixed aerosols number concentrations and 2-moment scheme using CAMS 3D forecasted aerosols input. An example result of an atmospheric cross-section of IN concentrations for the 25-Apr-2020 14:00 UTC is presented in Fig. 38. We can see that the default Cooper (1986) scheme (upper left panel) underestimates IN concentrations compared with other models having no aerosols data as input. Fig. 39 presents the dust aerosols cross section for the same snapshot. The dust number concentration at ice cloud heights can reach a few tens

of dust particles per litter. As a result, high IN umber concentration can be seen in the DeMott (2015) parametrization (upper right) – the highest amongst all models. Since both ice supersaturation and the updraft speeds are not taken into account, high concentrations of ice cannot be seen in the cumulonimbus cloud formed at longitude 35°E. The 2-moment microphysics with Phillips (2008) ice nucleation scheme did simulate the formation of ice in this cloud at heights 4000-8000 meters where high vertical speeds and supersaturation values were found. Smaller number concentration were achieved using fixed aerosols concentration (lower left) compared to the forecasted CAMS input (lower right). The Phillips (2008) scheme also underestimated the IN concentration at cold temperatures (< 240K) compared to DeMott (2015) scheme. Fig. 40 displays the four models output of IN as a function of temperature for the same hour where brighter colours means higher occurrences in the domain for grid points with LWC $> 0.03\ g/m^3$. The numbers inserts are the domain averages. The DeMott parametrization result at this snapshot has an average IN concentration of 401 $[1/L]$ which is a factor of 4 larger than the default Cooper scheme and a factor of 7-10 larger than the averages of the Phillips (2008) nucleation scheme. The effect of the IN concentrations on the effective ice particle size can be seen in Fig. 41 where the average ice particle size for the DeMott scheme is $18\mu m$ while the default 1-mom scheme using Cooper is $24\mu m$, Phillips (2008) default 2-mom scheme resulted averaged size of $74\mu m$ and the same scheme using CAMS aerosols average is $56\mu m$. The effects on the IWC itself can be seen in Fig. 42.

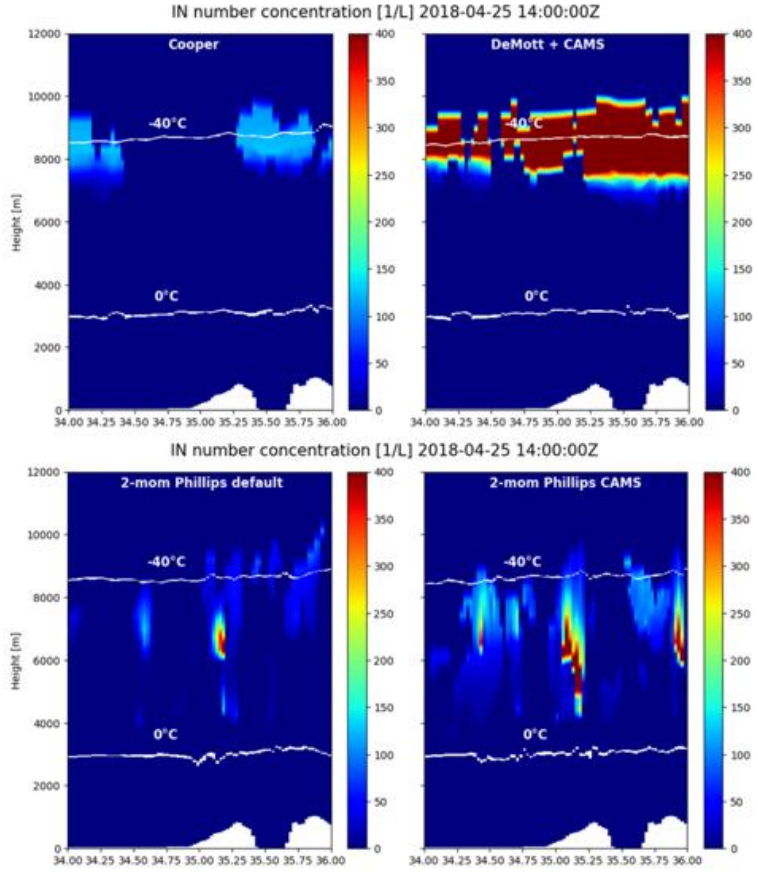

Figure 38: IN profiles in $[1/L]$ units for 1-moment microphysics using Cooper (1986) nucleation parametrization (upper left), 1-moment scheme using DeMott (2015) formulation using CAMS dust forecasted aerosols (upper right), 2-moment scheme using Phillips (2008) using default fixed aerosols number concentrations (lower left) and the same scheme using the 3D CAMS forecasted insoluble aerosols as input (lower right). The two white lines are the ice melting level and (roughly) the ice spontaneous freezing levels.

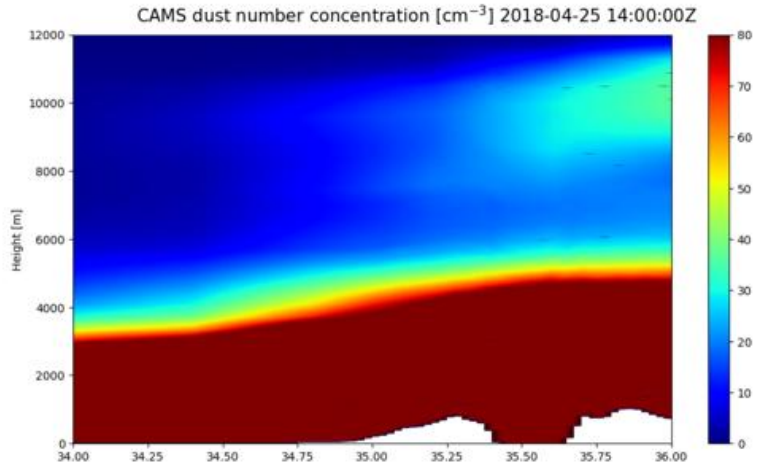

Figure 39: CAMS dust number concentration profiles forecasted for 25-04-2018 at 14:00. The scale was changed to emphasize the values at ice clouds heights (5000 m-10,000 m).

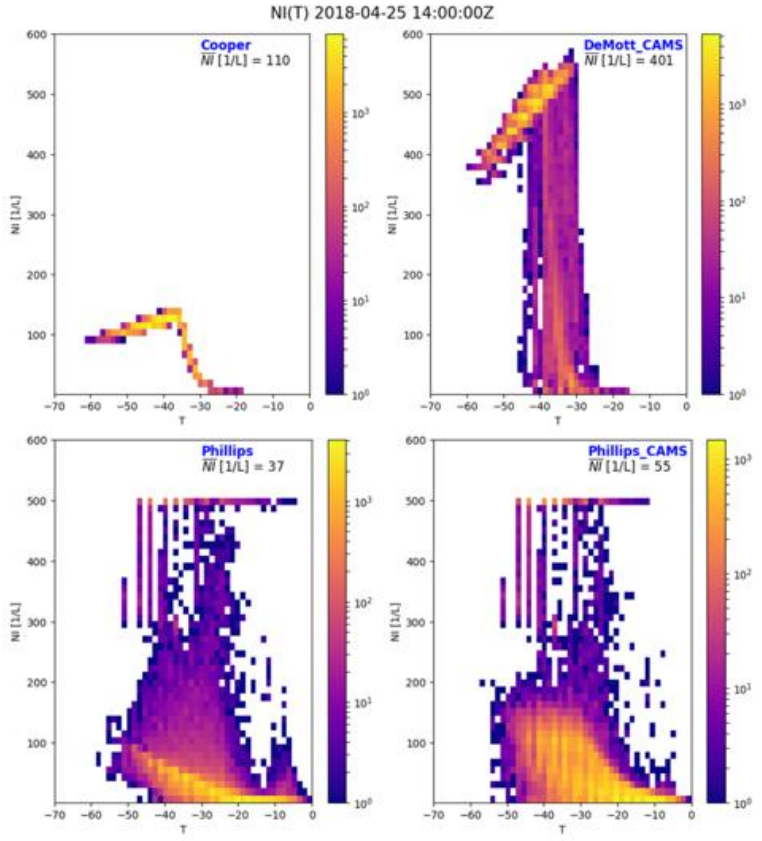

Figure 40: Occurrences plot for the IN concentration $[1/L]$ as a function of temperature for the same models described in Fig. 38. The number inside each panel represents the entire domain averages for grid point having non-zero ice content.

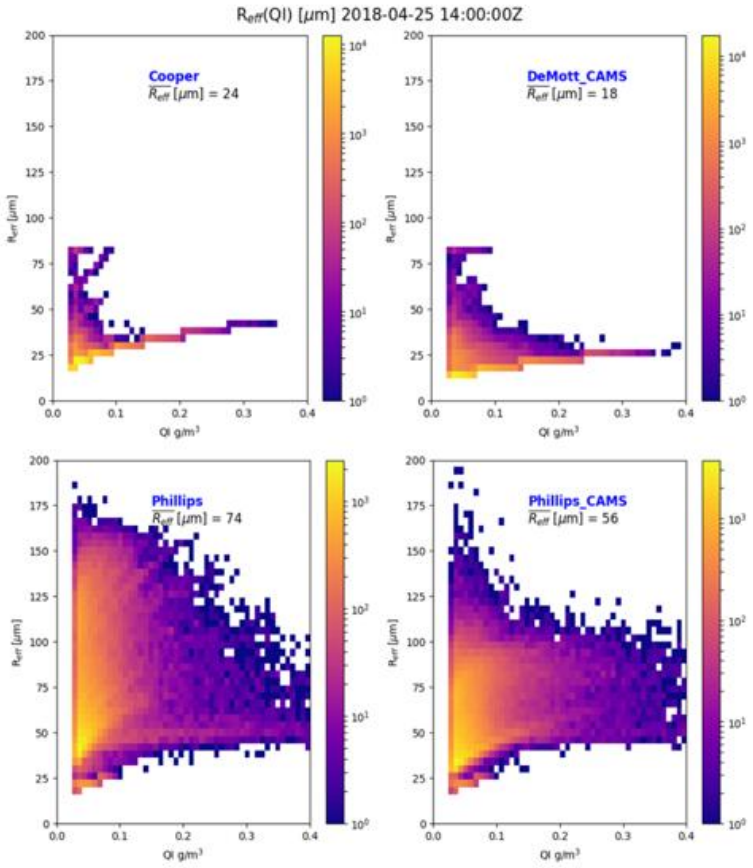

Figure 41: Occurrences plot for the IN concentration $[1/L]$ as a function of temperature for the same models described in Fig. 38. The number inside each panel represents the entire domain averages for grid point having non-zero ice content.

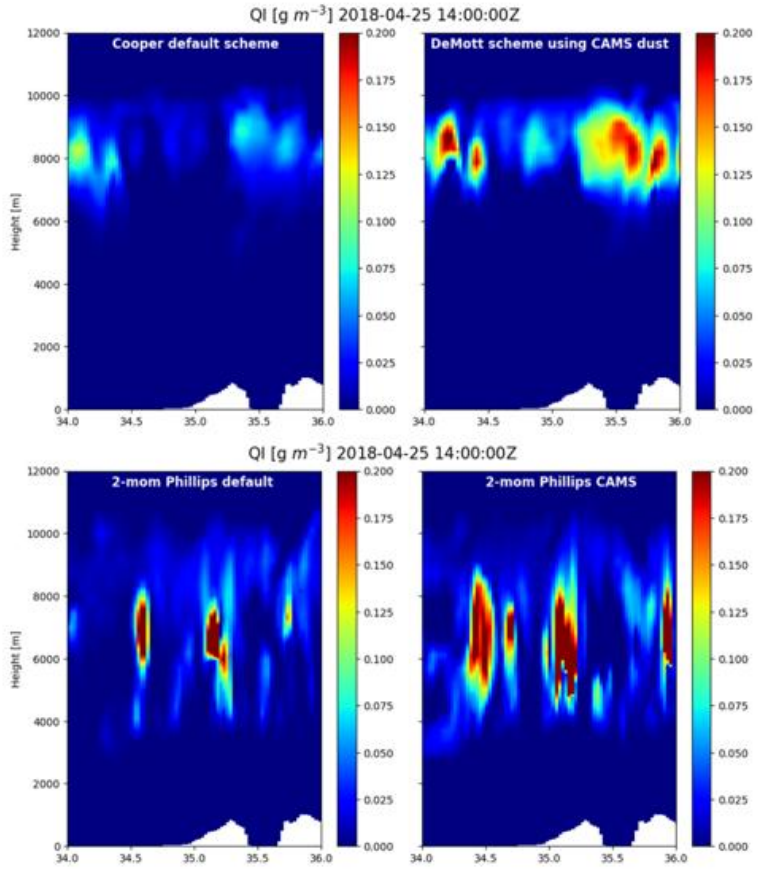

Figure 42: LWC profiles in [g/m^3] units for the same models described in Fig. 38.

7.4.6 DeMott (2015) ice nucleation scheme results vs. observational data

In order to statistically test the new DeMott (2015) ice nucleation scheme in COSMO using the CAMS forecasted dust field we performed 45 test cases runs in the IMS domain. The period chosen was in the October-November period and produced a 66-million points NI(T) plots as can be seen in Fig. 43. The upper left panel is for the default 1-moment COSMO microphysics using Cooper 1986 formula. In this plot of course, all points and the average (lime line) overlap. In the upper right panel the new DeMott & CAMS scheme results are presented. The scatter of points is due to the large divergence of dust particles densities. The averaged IN concentration for each temperature is in lime while point's colours visualize the occurrences in the domain. The same lime average line can be seen in the lower left panel but in a logarithmic vertical scale. The (schematic) blue line on this curve is copied on top of the plot in the lower right panel taken from Vergara-Temprado et al. (2018, with permission) which includes observational data from different locations around the globe. This shows that the new scheme implemented in COSMO fits the scattered points observed in terrestrial locations (red points).

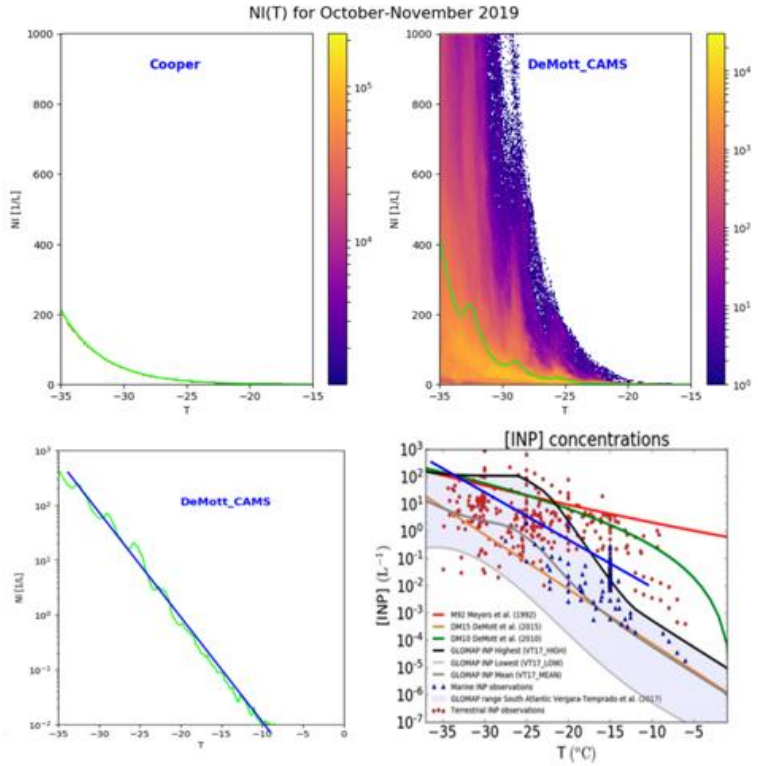

Figure 43: IN concentrations $[1/L]$ as a function of temperature for 45 test cases in the period of October-November 2019. Upper left: COSMO default ice nucleation scheme (Cooper, 1986), Upper right: COSMO new ice nucleation scheme using DeMott (2015) parametrization and CAMS forecasted dust concentrations, Lower left: the same but on a logarithmic scale, Lower right: observational data plot taken from Vergara-Temprado et al. (2018, with permission). See text for details.

8 Implementation of ICON-ART forecasted dust in COSMO radiation scheme

(H. Muskatel, D. Rieger, A. Shtivelman)

8.1 Introduction

ICON-ART is a global model system which online couples between ICON model (Zängl et al., 2015) and the ART modules for aerosols and reactive trace gases developed in KIT. The concentrations of the selected particles are calculated in every time step and synchronized with the NWP model dynamics.

COSMO model new CLOUDRAD radiation scheme has five options for aerosols input: Tanre climatology (Tanre et al., 1984, itype_aerosol = 1), Tegen climatology (Tegen et al., 1997, itype_aerosol = 2), MACv2 climatology (Kinne et al. 2013, itype_aerosol = 3), CAMS forecasted aerosols (Morcrette et al. 2009, itype_aerosol = 4) and now also ICON-ART-dust forecasted aerosols (itype_aerosol = 5). The details on ICON-ART model and especially dust forecast are discussed in Zängl et al. (2015), Schröter et al. (2018) and Gasch et al. (2017).

This semi-operational model, runs twice a day on global scale in DWD, currently including only three dust tracers but more aerosols species are planned for the future. As explained in the previous chapter regarding CAMS forecasted aerosols, the aerosols densities from the global aerosols model for every hour are interpolated in space and time by INT2LM over the whole domain. Since only dust forecast is available on a daily basis in ICON-ART, other four species of aerosols for the ICON-ART-dust option (itype_aerosol = 5) are taken from Tegen climatology (sea salt, organic matter, black carbon and sulfate).

8.2 ICON-ART dust aerosols direct effect on radiation

The direct effect of ICON-ART dust forecast on COSMO radiation was verified against ground-based measurements stations as detailed in Sec. 7 (see Fig. 28) and also 4 AERONET stations in Technion (Israel Institute of Technology in Haifa), Wiezmann Institute of Science (Rehovot), Sede-Boker and Elat. The time period selected was October-November 2018 and April-May 2019. These autumn and spring seasons in Israel region are very active in terms of dust outbreaks. The three COSMO-CLOUDRAD models aerosols inputs versions were: Tegen (1997) climatology, CAMS forecasted aerosols and ICON-ART-dust forecasted dust. The two variables which were evaluated were the downward shortwave radiation (global radiation) and the aerosols optical depth (AOD) at 500 nm. The global radiation in all skies conditions in all stations combined are presented in Fig. 44. The black 1:1 line represents the ideal model-observation match. The red/green lines are the linear fit to the model-observation scatter plot. Points located far from the black line means fiascos of radiation forecast and usually are due to cloud cover or cloud optical depth errors. Fig 45 is similar to Fig. 44 but for clear skies conditions. The clearness of the skies were defined as points for which all three models agreed on cloud cover less than 10%.

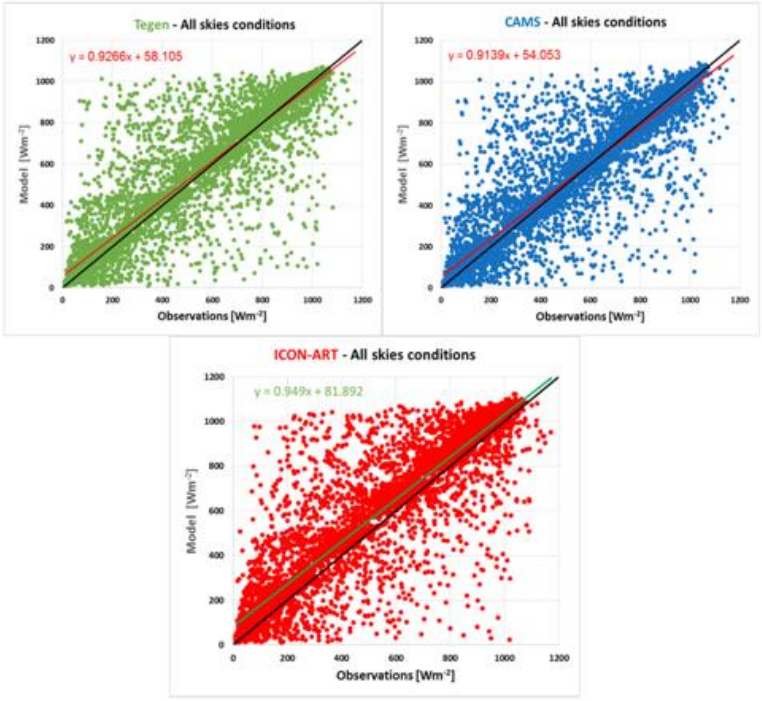

Figure 44: Global radiation model vs. observation for 10 ground based stations in Israel. For the period Oct-Nov-2018 & May-Apr-2019. All skies conditions at all grid-points and hourly snapshot time steps. Upper-left: CLOUDRAD scheme using Tegen climatology, upper right: CAMS forecasted aerosols, lower panel: ICON-ART-dust. Black line: 1:1 ideal match, red/green line: linear fit of the model-observation couples.

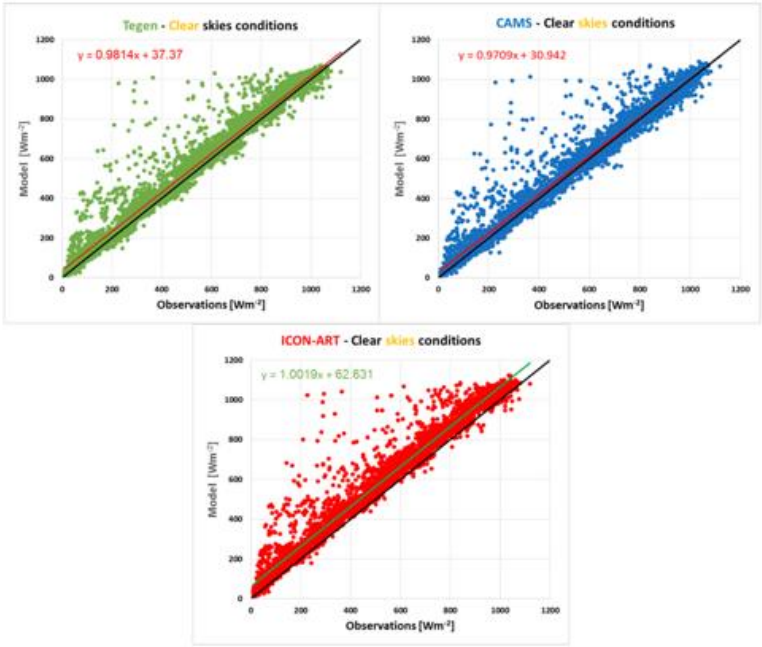

Figure 45: Same as in Fig. 44. For clear skies conditions defined for grid points in space and time for which at all models the total cloud cover was less than 10%.

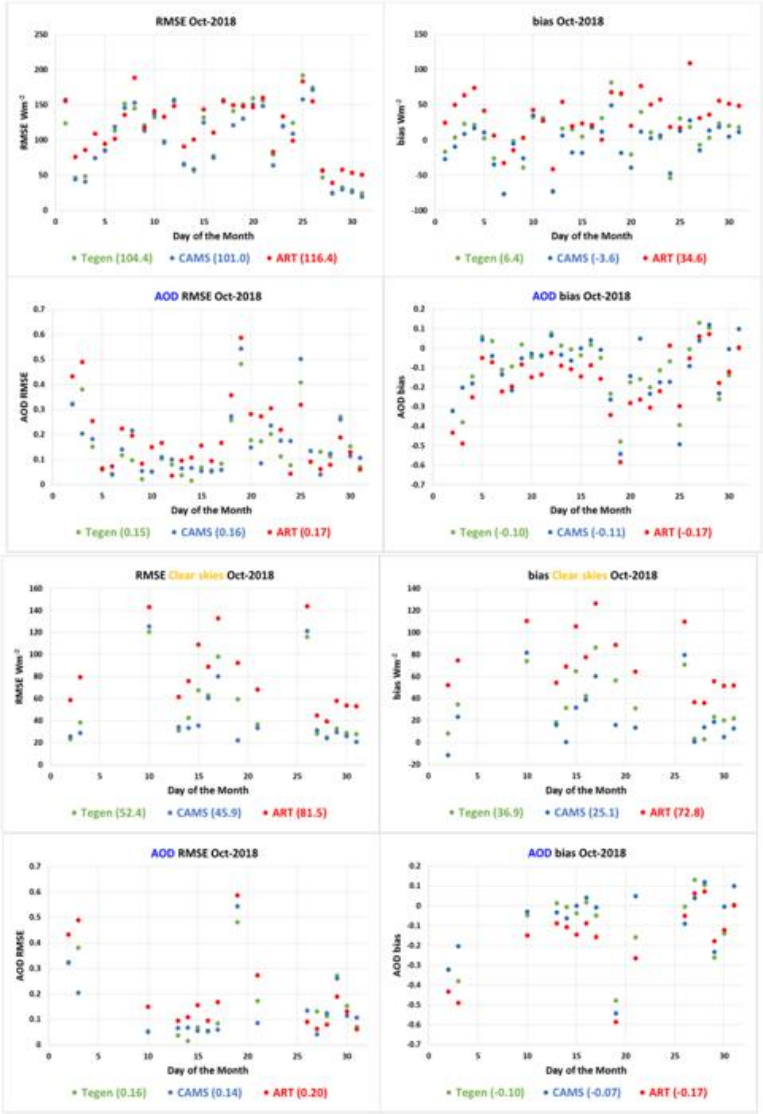

Figure 46: See text for details.

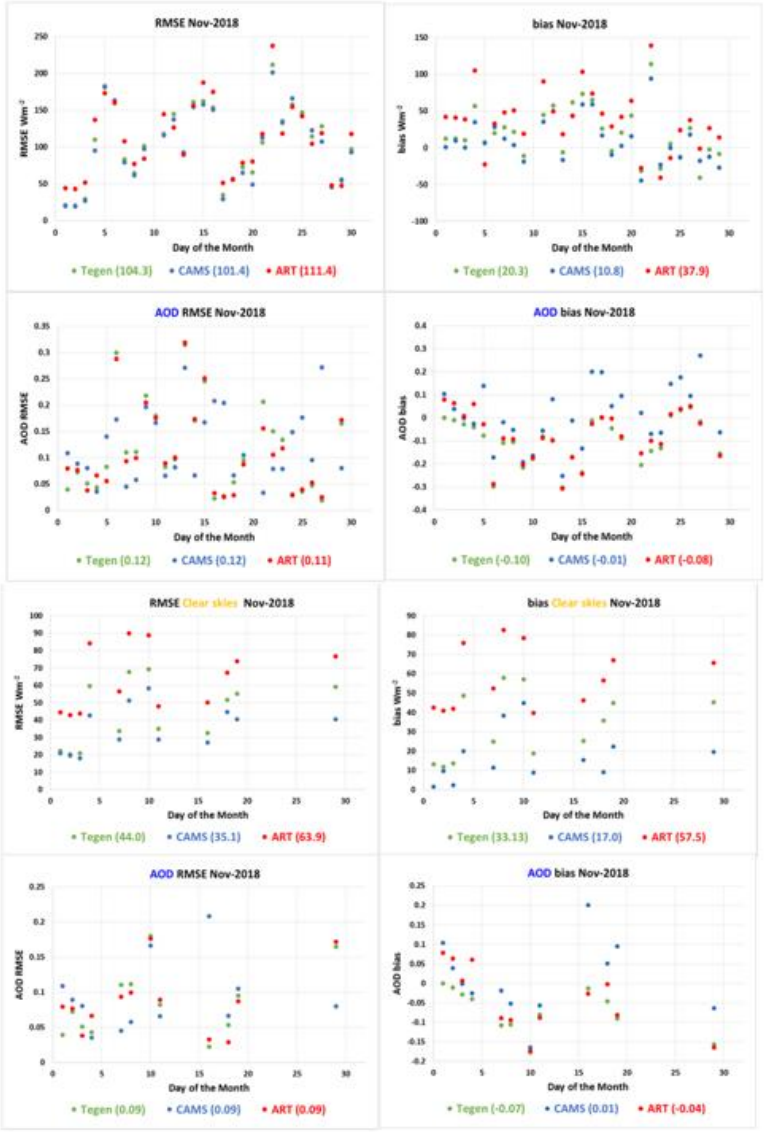

Figure 47: See text for details.

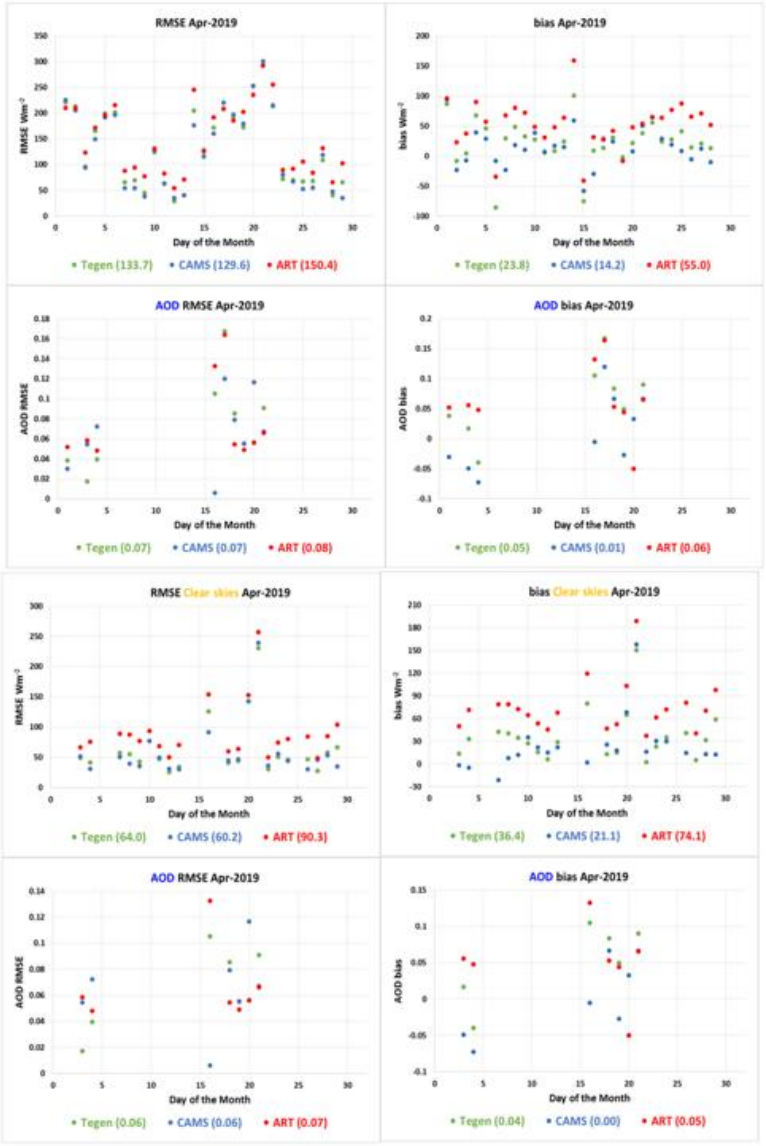

Figure 48: See text for details.

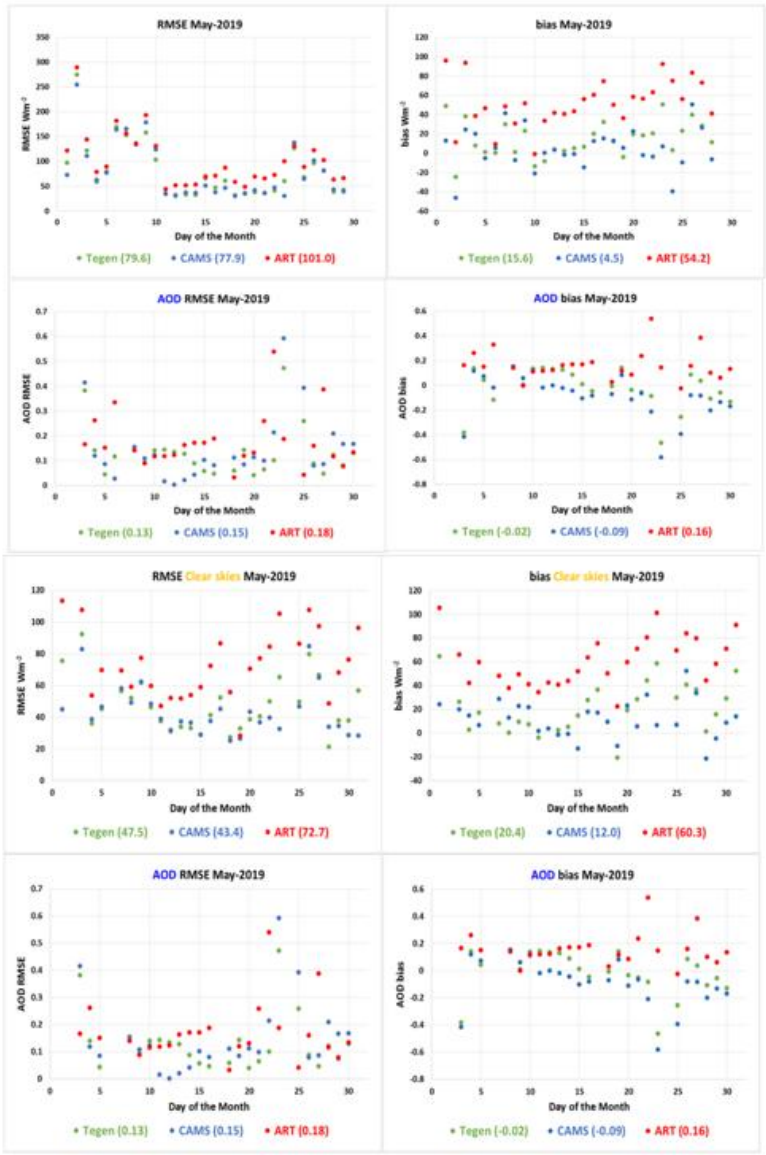

Figure 49: See text for details.

The results shown in Fig. 44 reveals the difficulty to forecast radiation fluxes without first having an accurate cloud cover estimation. Nevertheless, when observing the errors in 2-meter temperatures (not presented here) we see that usually the effect on surface temperature is in the order of 0.1 K. This is due to the fact that even when the cloud cover at a specific time step/grid point is wrong, the averaged fluxes over few minutes/hours are usually accurate when the overall synoptic situation is correctly forecasted. The clear-sky condition results shown in Fig. 45 reveals systematic errors in the models (apart from the outliers above the black line which are associated with clouded points not forecasted by the model). We can see that COSMO using Tegen climatology has a small radiative positive bias (negative AOD bias) which is more significant in the mornings and afternoons. CAMS forecasted aerosols linear fit red line almost overlaps the black line which means that the bias is very small during the whole day. On the other hand, ICON-ART-dust (with Tegen four other aerosols species) shows the poorest results with fixed positive bias which means that there is a negative bias in dust optical depth throughout the day. That may point to a systematic error in the dust forecast that may be a regional issue. Israel is in the midpoint between

two of the most significant dust emissions sources in the world – the Sahara Desert and the Arabian Peninsula. A systematic error due to a calculation error (code bug) is also a possibility which is being investigated.

Figs. 8.3 are subdivided into 4 pages, each page relates to a different month. In each page, the four upper plots represents the all-skies condition results and the four lower panels represents the clear-skies conditions points. Each point is a daily average value (over all stations and time steps of that day). For each 4-panels group, the upper-left/upper-right panels are the global radiation RMSE/bias averages and the lower-left/lower-right panels are for the AOD RMSE/biases. The monthly average values appear as coloured numbers under each plot. In October and November 2018, All models have a small negative AOD bias. Both radiation and AOD scores are very similar for both Tegen and CAMS forecast. CAMS results are slightly better with almost zero AOD bias in clear skies conditions. Unfortunately, the RMSE and bias is worsen when using ICON-ART-dust forecast. Although having similar AOD biases with Tegen, ICON-ART-dust has still much larger positive fluxes biases ($\sim$ 30 W/m^2) which needs further code investigation. In April 2019 all models showed an averaged positive AOD but still a positive radiation fluxes compared to the observations while in May 2019 only ICON-ART-dust showed a positive AOD bias. For these months as well, CAMS forecast had the best scores, second is Tegen climatology and third comes ICON-ART. The radiation RMSE are, as expected, larger for all-skies conditions ($\sim$100 W/m^2) compared with clear skies condition ($\sim$50 W/m^2) due to cloudiness but with much higher values for ICON-ART-dust compared with other models. This gap can be associated with the fixed positive bias in radiation when using the ICON-ART-dust aerosols. The RMSE for CAMS model is on the average $\sim$10-15 W/m^2 smaller compared to Tegen climatology RMSE due to the data assimilation and dynamical forecast of aerosols compared with the monthly mean values taken from Tegen (1997). We believe that in the future, such forecasted aerosols from ICON-ART or CAMS systems can be used also in the ICON model in both LAM or global modes of operations.

9 Verifications of the new COSMO radiation scheme in clear skies and cloudy skies conditions

(N. Chubarova, M. Shatunova, A. Poliukhov, A. Kirsanov, G. Rivin)

9.1 New MACv2 aerosol climatology and its verification in clear sky conditions

9.1.1 MACv2 aerosol climatology

The MACv2 climatology (Kinne, 2019) takes into account recent developments in aerosol modelling and experimental data and is a combination of the model ensemble data and ground-based aerosol measurements from AERONET dataset. It provides all necessary aerosol input parameters for the radiative computations in different spectral intervals for fine and coarse aerosol modes. It is also possible to retrieve an anthropogenic aerosol mode from this climatology. MACv2 aerosol climatology has monthly temporal resolution and provides 1°x1° spatial fields for wavelengths of 0.29, 0.32, 0.55, 0.87, 1.47, 2.0, and 2.6 μm in the solar spectrum and wavelengths 7, 8.85,9.75, 11.2 and 30 μm in the longwave range. An averaging procedure was performed to fit these wavelengths to COSMO 8-band radiative transfer model.

To include this aerosol climatology into the COSMO system we made the changes for the following blocks: EXTPAR, INT2LM and COSMO model. Unlike Tegen climatology (Tegen et al., 1997), receiving of all aerosol optical and radiation properties goes through EXTPAR, when using MACv2 climatology. Aerosol optical thickness (AOT), single scattering albedo (SSA) and asymmetry factor (ASI) values were normalized to the corresponding values at 550 nm and recorded in four-dimensional arrays: longitude, latitude, month and spectral interval.

9.1.2 Comparison with Tegen climatology and in-situ observations

We compared aerosol optical thickness (AOT), single scattering albedo (SSA) and asymmetry parameter (ASI) from the new MACv2 climatology as well from Tegen climatology with long-term measurements of AERONET at the Meteorological Observatory of the Moscow State University (further MSU MO or Moscow site) and AERONET/PFR data at the Lindenberg Observatory.

We used radiative measurements by Kipp & Zonen CNR-4 net radiometer at Moscow and by the BSRN (Baseline Surface Radiation Network) type of radiative instruments at Lindenberg. We focused mainly on the measurements of global solar irradiance. However, for obtaining surface albedo we also used reflected shortwave irradiance. Water vapour retrievals were also obtained using AERONET algorithm at 940 nm channel. In addition, we used upper – air soundings (temperature, water vapour) at both sites as well as Ozonesonde dataset - at Lindenberg. At Moscow air temperature measurements at 2 meters were analysed using routine observations and Vaisala automatic weather station. At Lindenberg the data from the automatic weather station were used. In order to reveal clear sky situations we used hourly visual observations at both sites.

AOT550 time series according to long-term measurements at the MSU MO (Abakumova et al., 2008, Chubarova et al., 2016) and MACv2 dataset are presented on Fig. 50. While AERONET data for Moscow site are available from 2002, AOT restored values from direct shortwave irradiance allowed to make comparison for the 30 years period. Increasing in AOT values are corresponded to eruptions of El-Chichon in 1982 and Pinatubo in 1991 and forest wildfires in 2002 and 2010. It is obvious that climatology does not take into account sharp random changes in AOT or other optical parameters. However, MACv2 data is in good agreement with point observations and demonstrates the same tendency in AOT decreasing during last 30 years.

MACv2 and Tegen climatologies overestimate AOT during most months at the both sites. SSA values from Tegen climatology practically do not vary throughout a year, while MACv2 SSA variations are closer to the observed values except winter when one can see noticeable overestimation for MACv2 data. Detailed comparison of MACv2, Tegen climatology data with in-situ observations for Moscow and Lindenberg sites presented in Chubarova et al., 2018 and Poliukhov et al., 2018.

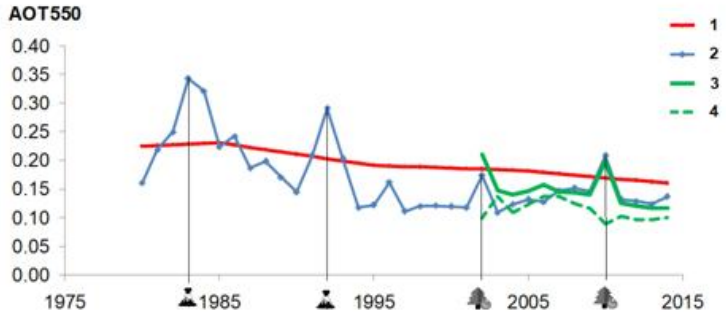

Figure 50: Comparison of aerosol optical thickness at 550 km from MACv2 climatology (1) with restored values from direct shortwave irradiance (2) and AERONET data mean (3) and median (4) values for MO MSU, Moscow.

In addition, the comparison for aerosol properties from Tegen and MACv2 climatologies against ground-based measurements over Israel in Eilat site with prevailing mineral type of aerosol, and over Arctic at the Tiksi Observatory in Russia have been performed. The results are described in Poliukhov et al., 2019.

9.1.3 Radiation fluxes assessment

To account the changes in all the aerosol properties (AOT, SSA, ASI) we chose global shortwave irradiance at ground as an aggregated characteristic. The comparisons between simulated and observed global solar irradiance datasets were fulfilled for different aerosol conditions and solar zenith angles for clear sky condition using accurate model simulations which were compared with solar measurements.

Using the obtained aerosol parameters from the climatologies and the observations we calculated global solar irradiance (Q) at ground and the corresponding difference $\Delta Q = Q_{climatology} - Q_{obs}$ (see Fig. 51). Radiative simulations were fulfilled using a modified CLIRAD radiative transfer code (Tarasova and Fomin, 2005) for noon conditions at the central day of a month. Results for Moscow (Fig. 51a) shows that Tegen climatology Q values were underestimated with a negative bias of 11-26 W/m^2 while for MACv2 Q bias varies from -23 to +4 W/m^2. The annual mean bias for the MACv2 climatology, -10.8 W/m^2, is closer to the observations compared with Tegen climatology having bias of -17.3 W/m^2. For Lindenberg site, both climatologies provide underestimation of global solar irradiance of about -10 W/m^2 for annual means compared with the Q values simulated with the aerosol input parameters taken from observations. Both of them have lower solar irradiance for almost all months mainly due to the overestimated AOT. At the same time, for the Tegen climatology in April and November in conditions with only small AOT overestimation (ΔAOT = 0.01-0.02) we observe even positive bias in solar irradiance (1-2 W/m^2) due to the large difference in SSA. For these months Tegen climatology provides much higher SSA values (0.92) compared with the observations (0.85). For Tegen climatology, 10-20 % of aerosol optical thickness over Europe relates to black carbon aerosol, which should significantly increase the absorption especially in visible spectrum. However, this is not enough to explain the lower SSA values observed at Moscow site, which probably occur due to smaller aerosol size.

A positive bias of AOT results in the underestimation by 2-3 % in global solar irradiance simulated by COSMO radiative algorithm for Moscow and Lindenberg sites (Chubarova et al., 2018; Poliukhov et al., 2018). Nevertheless, for some polluted cases the situation

may differ (Fig. 51). A sharp increase in the concentration of pollutants observed on 21 November 2014 in Moscow resulted in the difference between observed and simulated global radiation. AOT550 AERONET values reached 0.17-0.20, AOT055 according Tegen and MACv2 climatologies was similar – 0.17. However, there was a high concentration of NO2 (Fig. 51c) and possible additional absorption in visible region of spectrum due to this gas. In this case radiative transfer simulations made with Tegen and MACv2 data show large overestimation compare to observations. It is interesting that simulations with the former Tanre climatology (Tanre et al., 1984) show the best agreement with observations in this particular case.

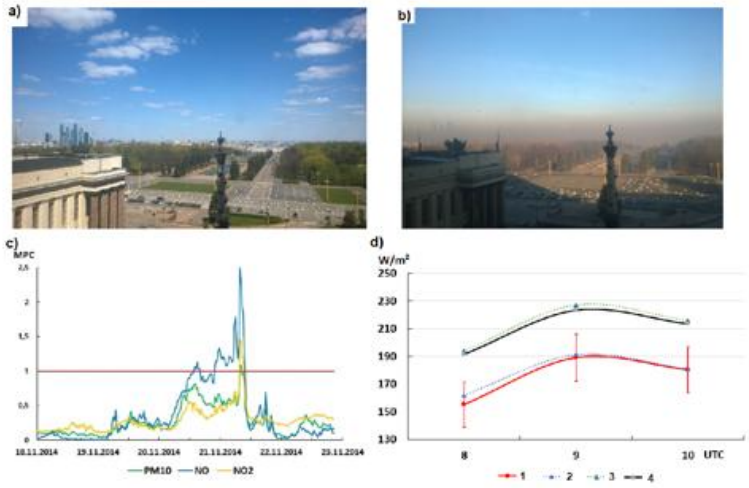

Figure 51: An example of polluted case: view over Moscow city on a) 17 November 2014 and b) 21 November 2014; c) observed level of pollutant concentration; d) observed (1) and simulated global radiation with Tanre (2), Tegen (3) and MACv2 (4) climatology data.

9.1.4 Temperature sensitivity to the changes in aerosol characteristics

The instant temperature effects of aerosol were analysed using different COSMO model runs with different aerosol climatologies and with zero aerosol conditions for the same clear sky days which are used in the analysis. Since aerosols over continental Europe are characterized by weak absorption in visible spectral range, it should provide the negative effect on temperature at ground level. To account the changes in all the aerosol properties (AOT, SSA and asymmetry factor) we chose net shortwave irradiance at ground as an aggregated characteristic. Net shortwave radiation is the difference in downwelling and upwelling shortwave irradiance and it also accounts for surface albedo effects, which play, however, minor role in our snow-less conditions. We analysed the dependence of difference in air temperature at 2 meters (ΔT) simulated in conditions with and without aerosols to the corresponding difference in net radiation (ΔB) to estimate the temperature sensitivity to aerosol. The negative values in net radiation at ground level due to aerosol provide negative effects on temperature difference. The difference in temperature should reach zero when ΔB=0 in conditions with zero AOT.

For Moscow and Lindenberg we obtained a pronounced statistically significant dependence which provides similar aerosol temperature effects. For Moscow, the effect is 0.8 $\pm$ 0.2 K per 100 W/m^2, which is in agreement with our previous estimates (Poliukhov et al. 2017). For Lindenberg the value is 1.0 $\pm$ 0.3 K per 100 W/m^2 with correlation coefficients r = 0.5,

0.6 respectively. The observed deviations may occur due to some slight variations in other parameters (water vapour, differences in profiles, etc.) in COSMO model runs.

Another testing was made using similar approach using comparisons with observations. In this case we should have much more deviations due to the influence of the uncertainty in actual atmospheric parameters which may differ from the simulated ones. We obtained the same tendency with the increase of positive temperature shift with positive bias in net radiation, which is mainly a function of aerosol loading. The gradients are similar to those obtained in the previous pure model experiment. These results confirm the pronounced temperature sensitivity to aerosol loading via its influence on net radiation at ground.

For estimating typical aerosol temperature effects for Moscow and Lindenberg, the changes in net radiation due to the changes in corresponding aerosol properties against aerosol–free conditions should be used. These temperature effects comprise about -0.2 K to -0.3 K for typical aerosol loads over these sites.

9.1.5 Temperature forecast sensitivity to aerosols

To estimate aerosol temperature effects we made simulation using COSMO for large domain (Europe – North Asia) with 13.3 km grid spacing for the central months of the seasons – January, April, July and October 2017. We performed simulations with Tanre climatology as a reference. Monthly averaged differences in T2m for July 2017 for simulations with Tegen and MACv2 aerosol climatologies as well as with CAMS reanalysis (see 7) are presented in Fig. 52.

T2m difference reaches 0.5 K (mostly on the regions with high probability of dust aerosol - North Africa, Meddle East, Central Asia) between simulations with old Tanre aerosol climatology and new one (MACv2) or CAMS. Significant positive T2m response up to 1 K appears in the North Africa and southern Europe in the case of MACv2 (Fig. 52b).

The assessment of temperature forecast considering MACv2 climatology and forecasted aerosol from CAMS compared to simulations with Tanre aerosol data was fulfilled using SYNOP and upper air sounding data. Simulation results with of MACv2 and CAMS show T2m RMSE decreases in southern Europe on 0.2-0.4 K (Fig. 53a,b). An effect of the new aerosol data implementation is neutral for the upper atmosphere.

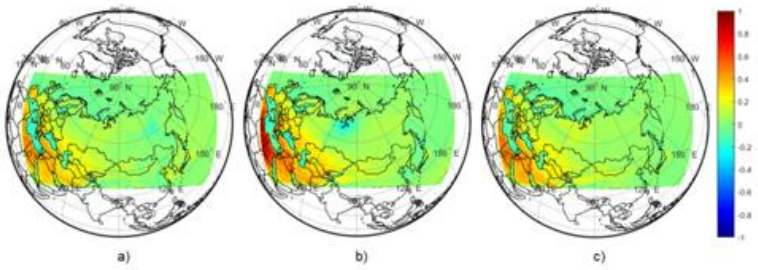

Figure 52: Monthly averaged differences in T2m for July 2017 for simulation with different aerosol setting compare to simulation with Tanre climatology: a) CAMS, b) MACv2, c) Tegen.

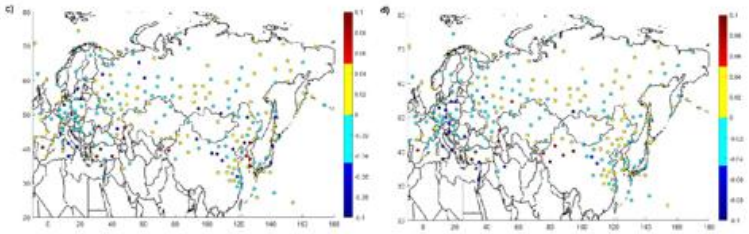

Figure 53: RMSE difference for T2m (a,b), T850 (c,d), T500 (e,f) forecasts between simulations with Tanre data and CAMS data (a,c,e) or MACv2 data (b,d,f).

9.2 Verifications in Cloudy skies conditions

9.2.1 Assessment of water vapour, liquid and ice water content in radiative scheme

To understand COSMO model behaviour in forecasting of the humidity characteristics we verified atmospheric water vapour content, cloud water and ice content, their vertical distribution and vertically integrated values using observations at Lindenberg observatory for the period March – October 2016. Appendix A contains the description of the experimental dataset.

All simulations were made with operational version of the model with 2.2 km grid spacing and 60 vertical levels for 550 x 600 km domain.

Results showed a correlation between errors in ice water content (QI) and water vapour content (QV) in the upper layers (6-12 km) (see Chubarova et al., 2018; Shatunova et al., 2019). An overestimation of QV values (see Fig. 2 in Chubarova et al., 2018) leads to overestimation of QI (Fig. 3 in Shatunova et al., 2019). In general, the model tends to overestimate total ice content. Model overestimate total water content (TQC) for rather small absolute values and underestimates TQC when its value is greater 0.1 kg/m^2.

9.2.2 Global radiation sensitivity to aerosol content

To investigate an impact of different aerosol setting on cloud optics and global radiation we made simulations with different set of concentration of cloud nuclei (CCN): fixed value characterized pure maritime, pollutant continental and intermediate clouds, and CCN calculated from Tegen aerosol climatology. Control runs were made with the default version of COSMO model without activation of the new COSMO radiation scheme (CLOUDRAD).

Simulations were performed with COSMO configuration with grid spacing 2.2 km for a domain covering Central Federal Region with Moscow located in the center of the domain for the warm period (April – October) of 2018. The data on global and direct radiation observed at the Meteorological observatory of Moscow State University were used to assess the quality of the obtained results.

Cloud optical thickness (OT) variation due to different CCN setting was investigated for the days with low cloud liquid water content. Cloud OT relative difference compare to control runs are presented in Fig. 54. Decreasing of cloud optical thickness within the lower 1.5

km layer of the atmosphere varies from 15% to 35 %. Smaller number concentration means larger water droplets and smaller OT (more transparent clouds).

The model setups tested (Figs 54, 55) were: the default radiation scheme (iradpar_cloud=1) as a control run, CCN calculated using SK2006 with Tegen aerosols as input (iradpar_cloud=4, cloud_num_type_rad = 2; itype_aerosol = 2), three setups with fixed number concentration at cloud base with exponential decay (iradpar_cloud=4, cloud_num_type_rad=1; itype_aerosol= 2, cloud_num_rad=100, 400, 1700) see Sec. 7 for details.

Comparison of global radiation simulated with default and CLOUDRAD schemes against observations is presented on Fig. 55. For the cases with optically thick clouds when the observed global radiation was less than 100 W/m^2 the errors of the predicted values do not exceed 50 W/m^2 and the old scheme showed here the best agreement. When observed global radiation is more than 250 W/m^2 which we can consider as optically thin cloud case, errors increase and difference between schemes become more evident. In overall, the results obtained with the new CLOUDRAD scheme have better agreement with observations (for details see Chubarova et al., 2018; Khlestova et al., 2019).

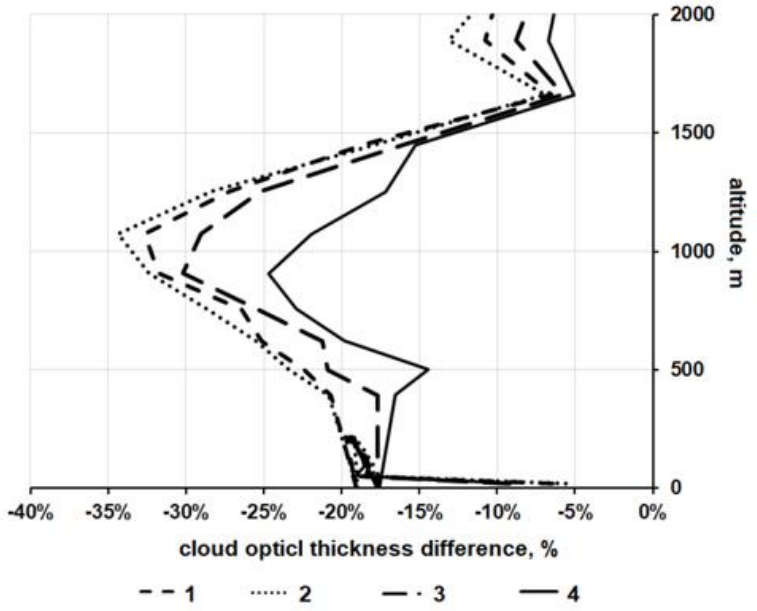

Figure 54: Cloud optical thickness relatively difference in dependence of CCN setting calculated with CLOUDRAD scheme compare to model version without CLOUDRAD. 1 – CCN from Tegen aerosol climatology, 2 – CCN = 100 cm^{-3}, 3 – CCN = 400 cm^{-3}, 4 – CCN = 1700 cm^{-3} see text for details of the setups.

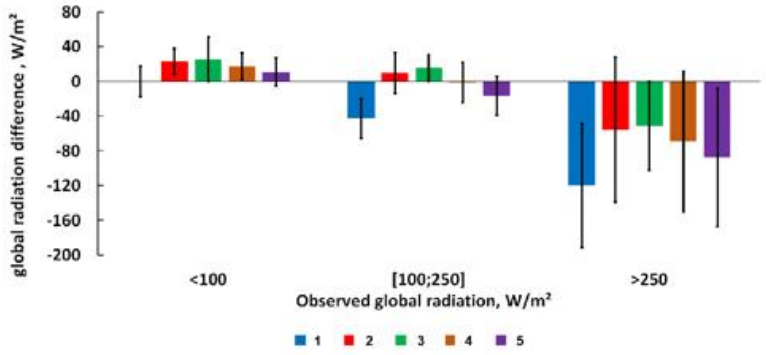

Figure 55: Verification of global radiation simulated with the old scheme (1) and the CLOUDRAD scheme with different aerosol setting (2 – CCN from Tegen aerosol climatology, 3 – CCN = 100 cm^{-3}, 4 – CCN = 400 cm^{-3}, 5 – CCN = 1700 cm^{-3}) against observations at Moscow State university observatory.

9.2.3 T2m forecast sensitivity

Taking into account the microphysical parameters of the cloud for evaluating its optical properties provide the increase in accuracy of both simulated global radiation, and air temperature forecast for the daytime. T2m forecast was verified against SYNOP observations (147 stations) for the period April-October 2018 for the Moscow region. Assessment shows that for the operational version (old scheme) RMSE equals 2.23 K and for the CLOUDRAD scheme RMSE is 2.04 K. The comparison of the scores for the two schemes is presented on Fig. 56. We should note that advantages of the old scheme within the first forecast hours is due to data assimilation system that was not applied for the simulations with CLOUDRAD.

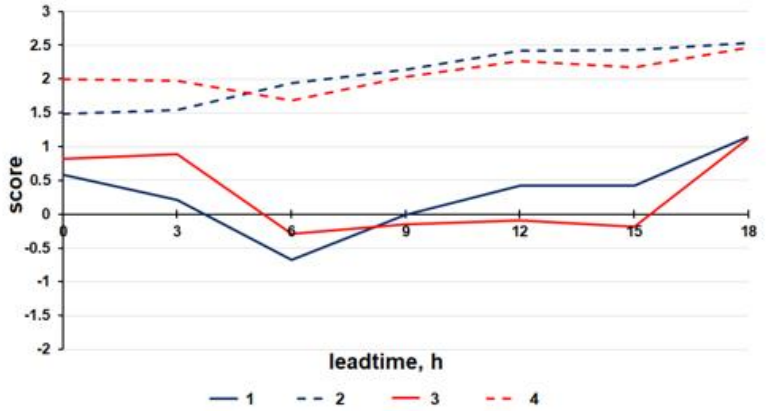

Figure 56: T2m forecast verification. Old scheme: 1 – Mean Error, 2 – RMSE; CLOUDRAD scheme: 3 –Mean Error, 4 – RMSE.

9.3 Conclusions

9.3.1 Clear sky case

MACv2 climatology provide better agreement with aerosol parameters for Moscow and Israel sites than Tegen climatology. The instant temperature sensitivity effects to aerosol loading is about 0.8-1.0 ±0.2°C per 100 W/m^2 in net radiation at ground. The application of a new MACv2 aerosol climatology provides a significant positive temperature (T2m) response of up to 1 K over Northern Africa and southern Europe in case of MACv2 compared with the results with the Tanre climatology application. Simulated results with MACv2 and CAMS demonstrate the T2m RMSE decrease in southern Europe on 0.2-0.4 K.

9.3.2 Cloudy case

Verification of COSMO model against ground-based measurements was made using the standard and CLOUDRAD cloud-radiation schemes with 2.2 km grid and 60 vertical levels for 550 x 600 km domain with start time at 00 UTC. In days with low cloud liquid water content, with solar irradiance above 250 W/m^2 we obtained a pronounced decrease in cloud optical thickness of 15-35%, when a new CLOUDRAD scheme was used. This change provides the increase in global irradiance at ground, which, in turn, leads to a better agreement with the observed global irradiance. In situations with optically thick cloudiness (with solar irradiance less 100 W/m^2) there is no difference between the two schemes.

Temperature T2m forecast sensitivity using the new CLOUDRAD scheme has been verified against SYNOP observations over Moscow region. The results demonstrated better agreement with the new CLOUDRAD scheme with decrease in RMSE from 2.23 (for the standard scheme) to 2.04 (CLOUDRAD scheme).

10 Testing and tuning of the new cloud-radiation scheme

(P. Khain)

10.1 Overview

The new cloud-radiation-coupling scheme includes revised sub-grid scale clouds effect on radiation, detailed optical properties for liquid and frozen particles of different sizes, more accurate representation of aerosol effects on cloud microphysics, etc. From algorithmical point of view, the new scheme contains many cloud-radiation dependencies which contribution is described by about thirty parameters. Besides, different options are activated using ten logical switches. This makes the tuning of the scheme a difficult problem. The idealized COSMO framework was previously used to determine the parameters having particularly high influence on the radiative fluxes in the model (Khain et al., 2016). Here we utilize an "objective" parameters tuning (Voudouri et al., 2017; Khain et al., 2017) via comparison of real model forecasts against global radiation from CM-SAF satellite data (Müller et al., 2015). The experiments were performed for several month during 2016 over COSMO-DE domain. We present parameters values of four subversions of COSMO-cloudrad, which optimize the global radiation over Offenbach, Lindenberg and Munich regions.

10.2 Calibrated COSMO-CLOUDRAD versions

The main features of the four calibrated versions, and the list of tuned parameters for each version are summarized in table 101. The four versions are: "Basic" version – Tegen aerosol climatology is assumed as well as constant cloud droplets number concentration and effective radius; "CAMS" version – Similar to "Basic" but assuming interpolated in time and space CAMS aerosol background; "SK basic" version – Tegen aerosol climatology is assumed, Segal-Khain parametrization is used for estimation of droplets number concentration and effective radius; "SK-SAM" version – similar to "SK basic" version with the use of "adiabatic" parametrization for droplets microphysics in convective SGS clouds (see chapter 5).

Key switches Tuned continuous parameters **Calibrated versions**

Parameter meaning	Parameter	Basic version	CAMS version	SK basic version	SK-SAM version
Tegen/CAMS CCN	itype_aerosol	2	4	2	2
Use Segal Khain parametrization for the droplets number concentration	icloud_num_type_rad	1	1	2	2
Use constant SGS droplets effective radius	luse_reff_ini_c_as_reffc_sgs	TRUE	TRUE	FALSE	FALSE
Use adiabatic profiles for droplets microphysics in convective SGS clouds	luse_qc_adiab_for_reffc_sgs	FALSE	FALSE	FALSE	TRUE
LWC reduction due to SGS variability	radqcfact [0.4 0.5 0.9]	X	X	X	X
IWC reduction due to SGS variability	radqifact [0.4 0.5 0.9]	X	X	X	X
SGS droplets effective radius	reff_ini_c [3 5 20]·10^{-6}	X	X		
SGS LWC scale factor	qvsatfact_sgscl_rad [0.005 0.01 0.02]	X	X	X	X
Droplets number concentration for radiation	cloud_num_rad [0.5 2 5]·10^{8}	X	X		
SGS droplets effective radius scale of adiabatic profile	reff_avg_fact [0.5 0.9 1]				X
SGS droplets concentration scale of adiabatic profile (clouds dilution)	qnc_avg_fact [0.1 0.38 1]				X

Figure 57: The main features of the four calibrated COSMO-cloudrad versions, and the list of tuned parameters for each version.

10.2 Global Radiation sensitivity

Before performing the calibration, we analyse the sensitivity of the global radiation to the change in the parameters (see Fig. 58). For every version and every parameter (X in Fig. 57) the averaged modelled (solid line) global radiation for 12Z is plotted against the parameter value (keeping other parameters in their default value) and is compared to the averaged observed value (dashed line).

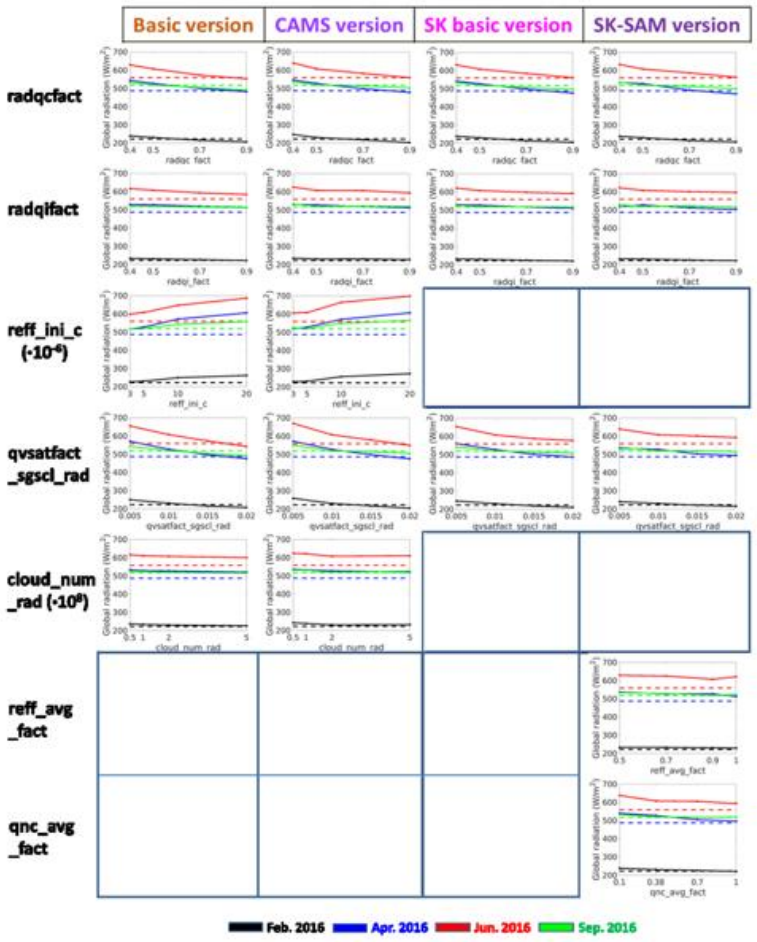

Figure 58: Sensitivity of the global radiation to the change in the parameters. For every version and every parameter (X in Fig. 57) the averaged modelled (solid line) global radiation (shortwave downward radiation on surface) for 12Z is plotted against the parameter value (keeping the other parameters default) and is compared to the averaged observed value (dashed line). February, April, June and September 2016 are denoted by black, blue, red and green lines, respectively.

Intermediate insights from Fig. 58:

1. Increase in radqcfact strongly reduces the global radiation due to increase grid scale and sub-grid scale clouds LWC.
2. radqifact, related to cloud ice water content, has weaker effect.
3. Increase in reff_ini_c, meaning higher SGS effective radius i.e. larger droplets, strongly increases the global radiation.
4. Larger qvsatfact_sgscl_rad, or larger SGS LWC, strongly reduces the global radiation.
5. Increasing cloud_num_rad (higher water droplets number concentration) slightly reduces the global radiation.
6. reff_avg_fact has two contradicting effects. A larger value increases the size of droplets in SGS cumulus making them more transparent. On the other hand, it increases clouds LWC which enlarge their optical depth.

7. Larger qnc_avg_fact slightly reduces the global radiation (because lower dilution leads to larger SGS LWC in cumulus. This parameter is more significant in convective seasons (i.e. April and June).

10.3 Calibration method

We have calibrated four COSMO-DE 2.8km 5.1 CLOUDRAD versions (Fig. 57) driven by ICON-EU analyses. For each version several continuous parameters are tuned (cyan in Fig. 57). The simulation and calibration domains are presented in Fig. 59.

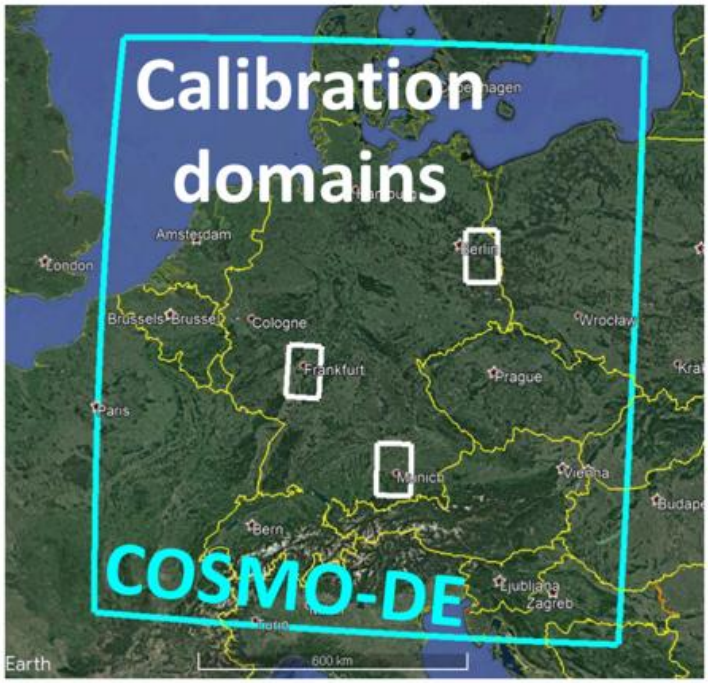

Figure 59: Simulation domain of COSMO-DE (cyan) and calibration domains (three white areas).

The calibration method is the following. First, several parameters combinations are chosen according to specific design (Voudouri et al. 2017). For each combination, COSMO runs are performed for February, April, June and September 2016. For every hour at every grid point, the forecast of global radiation is then interpolated in parameters space using 2^{nd} order polynomial with interaction terms. These interpolations yield a guess for the global radiation for any chosen parameters combination (Meta-Model). For optimization, the parameters space is then sampled by large number of parameter combinations. For each combination the Meta-Model is verified against CM-SAF hourly global radiation at 5km resolution. We look for the optimal parameters combination using a convergence algorithm (Khain et al. 2017). Finally the parameters combination which yields the optimal Meta-Model guess is defined.

10.4 Calibration results

	Basic version	CAMS version	SK basic version	SK-SAM version

Figure 60: Optimal parameters values for February, April, June and September 2016 (black, blue, red and green, respectively) averaged over the 3 regions. In parenthesis – uncertainty with respect to parameter range.

Fig. 60 presents the optimal parameters values for the four calibrated COSMO-cloudrad versions for each of the four selected month.

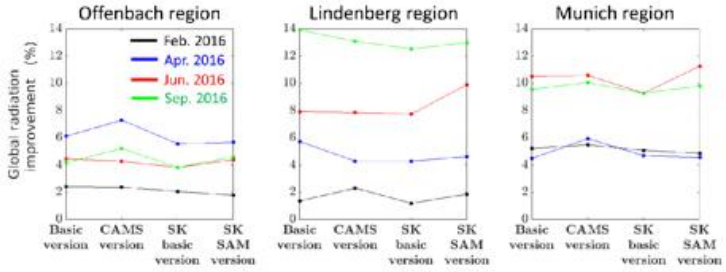

Figure 61: Global radiation estimated improvement (%) when using the optimal parameter combinations.

One can see that the global radiation forecast improvement by various COSMO-CLOUDRAD versions is similar. In summertime it reaches ∼10%. CAMS version has little effect with respect to the "Basic" because in that version the prognostic CCN plays role in the clear sky conditions only. The "SK-SAM" version improves the "SK basic" in summertime due to larger role of SGS cumulus clouds over Germany. Larger improvement from SK parametrization is expected when prognostic CCN is used for droplets activation but this experiment was not performed in this study.

11 Acknowledgements

We thank the following people: Qiang Fu for providing his codes for ice optics and for his many advices, Bodo Ritter for his original MCSI code, Paul J. DeMott for his advice on ice

nucleation processes, Alessio Bozzo for numerous discussions and for providing the aerosols optical properties data set used in ECMWF, Alexander Khain for fruitful discussions on cloud formation and aerosols and Theodore Andreadis for creating the COSMO cloud optics web-app.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

For any comments and questions, please contact the editor:

1 Introduction

1.1 Overview

The development, implementation and operational use of the original VERSUS package (2006-2009 PP project) satisfied most of the needs for traditional verification, but the constant increasing model resolution as well as the current and planned ensemble systems asked for more suitable information from verification activities. At the same time users of model forecasts asked for more information about the real quality of their model: this means a step towards user-specific verification information.

The extension of the VERSUS package to VERSUS2 has covered these items and has provided the COSMO community with a "state of the art" verification tool. The "System Architecture Design" (SAD) specification document was released in May 2009 and updated in January 2010 (www.cosmo-model.org/content/tasks/pastProjects/versus2/docs/versus2-SAD.pdf).

1.2 Motivations

The aim of the VERSUS-1 Priority Project, started at the end of 2006 and concluded in February 2009, with the official delivery of the package, was the development of a common and unified verification 'library' including a Conditional Verification (CV) tool. This library has been included in the public COSMO Software along with the new software from Priority Project VERSUS2. The package and all its main features have been planned and realised with the intention to be a useful and friendly tool for the entire COSMO community for operational as well as research activities to perform traditional and conditional verification (CV), based on conventional methods. As the typical approach to CV consist of a selection of one or several forecast products and one or several mask variables or conditions, which is used to define thresholds for the product verification, the flexible way to perform such a selection is to use an 'ad hoc database', planned and designed for this purpose. In this case the masks or filters can be simple or complex SQL statements. After the selection of the desired conditions, a classical verification tool to turn out statistical indexes can be used, along with a graphics package to plot the scores. The general VERSUS architecture is basically composed of a set of integrated tools:

- **Relational Data Base Management System** (RDBMS), to store observations (OBS) and forecast (FCS) data, Station Data, Configuration data to perform verification, Verification results, Scores and plots, and User permissions; the chosen data base is MySQL in case of the initial VERSUS version;
- **Front End loader** (FE), a "daemon" process to load data from different sources into the RDBMS (File system or another DB); among FE functionalities, and very useful for CV, it is possible to use a loader dedicated to the SRNWP Data Exchange Programme observations, consisting in good quality operational data from a limited set of well instrumented and high quality observation sites in Europe, in particular providing soil, surface and boundary layer data;
- **A process performing verifications** through specific requests (Integration into the "R" statistics package);
- **A web-based user interface** (server-client architecture).

The VERSUS1 project was divided into 10 tasks and most of them has been completed. The delivery of the complete package occurred during a Workshop/Tutorial in February 2009. In the course of the first VERSUS project development, most of the COSMO members moved towards higher resolution models as well as ensemble forecasting systems. The increasing resolution has, in general, the impact that objective scores for weather parameters can be worse for high resolution models than for low resolution models. Increased resolution, in fact, generally produces better defined mesoscale structures, greater amplitude features, and larger gradients, and inevitably leads to space and time errors. This is known as the "double penalty" problem. Nevertheless such a model can provide very useful information. The need for verification techniques that allow for some tolerance to reasonably small space and time errors is then clear, retaining the main feature to be capable to test the real quality of information provided by the high-resolution model and the possible connections between forecast deficiencies and specific weaknesses in the model formulation. At the same time, as COSMO model future plans were in the probabilistic and ensemble forecast direction, suitable verification methods had to be applied. In general there are three methods to evaluate this kind of forecasts (Casati et al., 2008):

- Verification of an ensemble distribution: methods used to verify ensemble distributions are rank histograms (Talagrand histograms), Continuous rank probability score and its related skill score (a measure for the difference between the cumulative distribution function of the forecasts and observation), and minimum spanning tree (a sort of multidimensional rank histogram, not so widely used);

- Verification measures for the probability density function (pdf) of a generic probability forecast: methods used are "linear probability" and the "ignorance score". Both the methods are local, evaluating the pdf at the observation value, and both rewards sharp distributions which are also accurate;

- Verification of the probability of an event: methods used are Brier Score (BS) and its decomposition, Brier Skill Score (BSS), reliability diagrams, ROC and the Rank Probability Score (RPS). It is useful to add to these methods also bootstrap confidence intervals to generalize score estimates over different sample sizes.

All the above verification techniques, and others specialised for extreme events and user needs, had been analysed and then included in the VERSUS package to have a common "state-of-the-art" tool for verification for the entire COSMO community. VERSUS is routinely used for the calculation of seasonal statistics over a common area according to the guidelines (http://www.cosmo-model.org/content/tasks/verification.priv) derived on an annual basis from WG5 for each participating model of COSMO consortium (Common Plots). VERSUS is also used in the framework of the NWP Test Suite, which is the software environment to perform carefully-controlled and rigorous testing with calculation of verification statistics for any COSMO model test version. For this aim VERSUS software has been also installed at the ECMWF on a dedicated virtual machine (an innovative solution for that time). The NWP Test Suite has been used over the years as benchmark for the major changes of the new COSMO model versions. These activities have been important for the software debug and continuous COSMO model development.

2 Tasks and achievements

2.1 Project presentation

The PP VERSUS2 has been approved in September 2009 during the 24th STC Meeting (07-08/09/2009) that took place in Offenbach, Germany and has been declared closed in September 2016, during the 38th STC Meeting (05-06/09/2016), in Offenbach as well, with the release of VERSUS 5.1 and VAST 1.4 packages (June-July 2016), which form the COSMO Common Verification Software (CVS). Further developments on the system have been carried out from the end of the project up to October 2018 and then reported here for completeness. VERSUS maintenance has been assured by the Italian Air Force Meteorological Service up to December 2018.

In a first phase (COSMO year 2009), a "User Requirements Specification" had been compiled, and has been implemented during the following phases of the project itself (COSMO years 2010-2016). Most of the single phases has been concluded in one COSMO year. Every year, based on the real deliverables produced, the plan has been updated accordingly to a quick review of the requirements of the next phase, and the new phase to be developed has been fully described (see COSMO GM presentations for details).

A concise account of the tasks and achievements developed during the project is thus chronologically presented in the next section.

2.2 Project phases and tasks

2.2.1 Phase 1. COSMO year 2009

It has been completed as planned in Cosmo year 2009 , with the delivery of System Design Overview Document (SDO, updated in July 2009 as requested by the STC) and System Architecture Design (SAD, approved by the STC). During this phase of the project the main activity consisted in the implementation of VERSUS system at every service within COSMO consortium, in particular through the realization of a multi-platform RDBMS version of the software and consequently the installation of multi-platform DB version of VERSUS at every service.

2.2.2 Phase 2. COSMO year 2010

This phase was composed of many different tasks: at level 0 the main goal was to provide assistance to all VERSUS users inside the consortium, through the Help Desk service, bugs fixing activities and the following VERSUS update patch release. The implementation of COSI (global Score Cosmo Index) was then carried out, through both the initial preparation of the technical reference document and the factual index implementation. Another important step was to implement the software features concerning conditional verification: VERSUS software modules and related web GUI updates were developed for the implementation of weather type dependent verification and conditional verification (WDV, CV). During this phase a detailed documentation of Fuzzy verification toolbox, necessary in order to perform verification on high resolution models, was produced, with the implementation realised via the VAST software. Another important achievement was the introduction of Feedback Files (FF from now) as input for the system, with the realisation of new loader modules to be integrated in VERSUS_FE; this type of file was useful for the management of

new observation data such as Airep, Amdar, Windprofiler, TEMP (non standard pressure level) and Radar wind data.

2.2.3 Phase 3. COSMO year 2011

In this phase continued the activity of Help Desk, bug-fixing and release of VERSUS updates, and in parallel was carried out the improvement of VERSUS security and "plug&play" installation and web pages: in detail new installation/patch update procedures and back-up functionalities for the DB were developed, as well as a review of web GUI search pages for improved functionality. The work for the final implementation of the Feedback Files capability was carried on, with the implementation of a loader module, the creation of new web GUI, conditional verification for data from FF and a stand-alone tool for FF creation for all partners ,with the related documentation. A dedicated test phase for FF tool implementation and FF functionalities in VERSUS was then realised. The attention of the developers was also focused in the improving of the probabilistic scores, necessary to the EPS verification, with the implementation of "R" package in VERSUS with the creation of new web pages for GUI and the production of the related documentation.

2.2.4 Phase 4. COSMO year 2012

In this year the aim of developers was focused on software usability: an improvement of the batch execution functionality, even with the possibility of using it for cross verification, and of the suspect observation menu were realised, as well as the addition of a data permanence process, able to delete observation and forecast older than a configurable time presence. The work on the FF processing modules, started the former year, continued. The use of Feedback Files (FF) was important to improve upper air verification and Conditional Verification activities, where large amounts of data must be manipulated. A feasibility study on how to proceed with the implementation of FF was created by the Project Leader (PL) team, reviewed by DWD in July 2010, and the new Database Structure for FF was then created. At the same time the importance of updating the system, according with the evolution of the standard meteorological message formats, was taken into account by the implementation of new BUFR format, for observation, and GRIB2, for forecast. The adoption by WMO of a new template for BUFR was the main reason for this task as well as the foreseen use of GRIB2 as output of COSMO models. The process consisted in updating the system for the upload functionality of new BUFR template and merge (in space and time) with the old format. The use of the new template has made verification more flexible for the cumulated precipitation. A document describing the activity was delivered and approved. The updating of the system for the treatment of produced forecasts coded in GRIB2 format was then carried out with the related documentation. At the same time continued the user support activity, the implementation of the FF modules and probabilistic scores within the R package.

2.2.5 Phase 5. COSMO year 2013

The goal of the year was to complete the most crucial developments define by participants of the last VERSUS user meeting that took place in Rome in April 2012. Concerning the Help Desk/bug-fixing activities and release of VERSUS updates new practices were introduced: a forum web page dedicated to help desk activity for the users was created and was stated that any new development of the software was followed by a documentation update

(User Manual and Technical Manual). Regarding the release process for the new patches, each new patch assumed the creation of a packet instalment. The patches were delivered to the users through the Italian Air Force Meteorological Service ftp server. Moreover the test of each new VERSUS release was followed by the related test procedure. Automation of processes/GUI adjustment were also carried out. In this task some generic improvements on GUI and VERSUS functionalities were carried on in order to improve friendliness and the operational use of the system; among these are cronjobs for running php scripts to compile verifications, automatic storage of figures with reasonable names for unambiguous identification, replication function for similar verification activities and inclusion of performance diagrams in VERSUS plots: an activity not connected to the automation, but with the need to include more statistical indexes for precipitation verification, in one graph. Inside the Probabilistic Scores area during this year the PL team finished the calculation and visualization of the ensemble and probabilistic scores in VERSUS, using as a reference the EPS documents edited by F. Gofa and A. Bundel. In the same year continued the implementation of the WMO BUFR standard for observations, with the creation of test procedures and following test phase, as well as the implementation of 1 and 3 hours period for cumulated precipitation and wind gusts.

2.2.6 Phase 6. COSMO year 2013-4

The purpose of this year was to complete some of the existing requirements and ensure the stability of the system. Beside the normal help desk and support activity this year the first VERSUS Course for Developers took place in Pratica di Mare (May 2013) for 3 days, with the aim to familiarize potential developers with the software architecture. Regarding the refinement of the system was realized a code adjustment for DB Partitioning and a definition of standard coding for precipitation parameter was set, thanks to the TAG and SCA collaboration and specification of WG5 requirements on the measures and verification activities to be performed with such data. The activity for the use of FF in Versus continued through the implementation of a dedicated loader module, a new web GUI and a specific test phase for FF tool implementation and FF functionalities. In the EPS products verification sector was carried on and concluded the development of the statistical indexes CRPS/CRPSS (Continuous Ranked Probabilistic Score/Skill Score) and the realization of the Spread/Skill relation plots. This allowed the beginning of the pre-operational phase, consisting in a series of test over a period of 2-3 months with a following comparison of VERSUS results with current operational EPS verification.

2.2.7 Phase 7. COSMO year 2014-5

This year the help desk activity was divided in two different support levels: the first one being managed by Russian colleagues for the basic requests. They involved the PL team in case of more technical problems and bug fixing. In addition VERSUS User Seminar was organized: it took place in Turin (May 2015) for 3 days with the aim to introduce the new functionalities; among these the concurrent use of VERSUS by more than one user: the system could now be used by more than one user simultaneously. The implementation of Feedback Files use in VERSUS was completed, with the development of a new versus library to read the Feedback File in NETCDF, the definitive implementation of Loader module for FF, the new web GUI and the improvement of the graphics for upper air verification. Another important step was executed in the process of implementation of VERSUS functionality to ingest and manage GRIB2. This process involved multiple tasks as the analysis and creation of new DB area, adjustment and upgrade of the Phoenix code, creation of new FE

in VERSUS, code/GUI adjustment and following functionalities test phase. The same year, with the aim of introducing additional statistical techniques compatible with VERSUS, a new activity was stated. This activity dealt with the introduction of new statistical techniques for high resolution forecast and observation data (neighbourhood methods). The COSMO Verification Community considered the use and adaptation of external packages or libraries for pre-processing of data for verification as one of its main priorities. For this reason the main goal of the activity was the integration or adaptation of pre-existing packages (e.g. Beth Ebert Fuzzy Verification Toolbox). Moreover this work was extended to the use of gridded precipitation data from composite sources (e.g. radar, raingauges) while a pre-processing tool capable of reading GRIB files (for forecast and/or observation) and producing data in suitable format for the VERSUS system itself was developed. To this purpose the PL coordinated the execution of the Project VAST, project funded by COSMO, started in June 2014 and ended in May 2015. The software allowed to produce spatial verification of the precipitation field (main goal), wind speed and total cloud cover. The argument is treated in detail in the COSMO Technical Report 33 (Vela, 2017).

2.2.8 Phase 8 / Extension Phase COSMO year 2015-2016

The phase 8 (or Extension Phase) has brought the project VERSUS2 to the final refinements. In particular with the release of patch 5.0 Version (December 2015) and 5.1 Version (July 2016) was solved the problem of loading multisteps files and implemented the total cloud cover verification. Regarding the software functionalities, for the GRIB2 ingest new front end were created, with update of VERSUS code and GUI, as well as the implementation of the connection with existing GRIB1 tables and following tests. After these processes various refinements activities have been carried out, such as a control on EPS score accuracy, a test phase on the XML file format ingestion and a report of the loading performances. In the end final tests on all system functionalities have been performed.

3 Further developments

In addition to the achievements of the VERSUS2 Priority Project other improvements have been developed during the period September 2016 - October 2018. We will present in this section a brief overview of the main innovations.

Patch 5.1.1: implementation of correct precipitation Performance Diagrams for ECMWF and COSMO 12UTC run.

Patch 5.1.2: problems with graphs of cumulative 24h precipitation 12UTC run solved; problems in the creation of cron directory for new VERSUS installations solved; upgrade of GUI menu list (problems with the former patch, RH was not visualised any more); improvement of batch execution menu (verifications already performed now have the label execution $\rightarrow$ yes).

Patch 5.1.3: Improvement of upper air verifications (creation of values at all levels); adjustment of the progressive verification number.

Patch 5.1.4: Included in 5.1.5 .

Patch 5.1.5: Management of a new buoy BUFR template which introduces a new descriptor for the buoy identifier; correct visualization of cross verification graphics.

Patch 5.1.6: Management of the new synop messages BUFR template, concerning cumulated/averaged fields defined by the time period descriptor (windgust, precipitation, etc).

4 Conclusions

The VERSUS2 Priority Project, as is visible looking at the chronology reported here, has brought a constant improvement of the original VERSUS software, in order to keep the pace with the development of new technologies and verification methods. Many innovations has been carried out in multiple fields: for example, in the direction of having a valid tool to verify the Ensemble Probabilistic System (EPS), a set of new statistical scores has been implemented (R package for EPS verification) as well as the new interface functionalities to manage it (GUI improvement); the database performances have also been improved in order to decrease the verifications execution time. Another fundamental activity inside the project has been the help desk support for all the Cosmo consortium members, consisting in solving practical issues and fixing the reported bugs with the relative releases of VERSUS software upgrades (patch). The team has also realised the implementation of Weather Type Dependent Verification and the improvement of Conditional Verification, the introduction in the system of the possibility to ingest new kind of data both in terms of type (Airep, Amdar, Windprofiler, TEMP and many more through the use of Feedback Files (FF)) and format (GRIB1 to GRIB2 management, ingestion of XML files of post-processed forecasts) and has worked over time to refine every aspect of the over-mentioned tasks.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

Abstract

For the calculation of soil surface temperatures and temperature profiles inside the soil a multi-layer version TERRA_LM shall replace the 'Extended Force Restore'(EFR) method. The multi-layer version is based on the numerical solution of the heat conduction equation (HCE method). The EFR method uses two soil layers only, however with soil-type dependent thicknesses. In the HCE method, the number of the layers as well as their thicknesses can be specified as the case requires.

The advantages of the HCE method over the EFR method are

(a) physical improvement:

As a consequence of the rather thick upper soil layer in the EFR method the treatment of freezing/melting of soil water/ice was not successful. Therefore, the freezing/melting process was not implemented in the operational soil routine TERRA. This process will be included in the updated version TERRA_LM.

(b) organisational simplifications:

In the thermal part of the soil model the thicknesses of the soil layers are no longer dependent on soil type.

The soil layers for the treatment of the soil water transport in the hydrological part of the soil model can be chosen identical to the soil layers for the heat transport.

In an additional chapter, a simplified version of the numerical treatment of melting of a snow cover is presented.

1. Background

The following short description of the 'Extended Force-Restore' method (EFR method) refers to Jacobsen and Heise (1982).

The method is based on the solution of two coupled linear differential equations for the mean temperatures T_1 and T_2 of two layers,

$$T_1 = \tfrac{1}{2}(T_s + T_m) \;, \qquad T_2 = \tfrac{1}{2}(T_m + T_u) \;,$$

where T_s is the soil surface temperature, T_m is the temperature at the lower boundary of the upper soil layer whose thickness is Δz_1, and T_u is the constant temperature (climate value) at the lower boundary of the second soil layer whose thickness is Δz_2.

The prognostic equations for the mean temperatures are

$$\frac{(\rho c \Delta z_1)}{2} \frac{\partial}{\partial t} T_1 \;=\; -(G_s - G_m) \;, \tag{1}$$

$$\frac{(\rho c \Delta z_2)}{2} \frac{\partial}{\partial t} T_2 \;=\; -(G_m - G_u) \;. \tag{2}$$

G_s is the soil heat flux at the surface represented by the atmospheric forcing (the sum of radiative fluxes and turbulent sensible and latent heat fluxes), G_m and G_u are the heat fluxes at the lower boundary of the first and the second soil layer, respectively, ρ is the density, and c is the specific heat which accounts for a constant mean water content (mean of air dryness point and pore volume). The thickness of the soil layers depends on the thermal characteristics of the soil. For the soil types used in LM/GME, the thickness of the upper layer Δz_1 varies for a rather dry soil between 0.07 m and 0.11 m, the thickness of the lower layer, Δz_2, varies between 0.25 m and 0.37 m. The thickness of the layers also depends on the water content that is time dependent. However, in operational implementation of the EFR method, the layer thicknesses are determined using a constant value of the water content that is used for the determination of c.

The hydrological part of the soil model is formulated as a multi-layer model already, the soil layer thicknesses being independent of soil type. Operationally we use two active layers with thicknesses of 0.1 m (upper layer) and 0.9 m (lower layer), which are different from those of the thermal part. Therefore, a simple treatment of the interaction between hydrological and thermal processes in the actual soil model TERRA is not possible.

This deficiency can be avoided by using the HCE method for the calculation of soil surface temperatures and temperature profiles in the soil.

The heat conduction equation reads

$$\frac{\partial T}{\partial t} \;=\; \frac{1}{(\rho c)} \frac{\partial}{\partial z} \left(\lambda \frac{\partial T}{\partial z} \right) \;. \tag{3}$$

At the upper boundary, the soil heat flux $G_s = -(\lambda \partial T/\partial z)_s$ is specified. At the lower boundary, a constant value T_u (climate value) is used. The volumetric heat capacity ρc is determined depending on the soil type and the actual water and ice contents. The heat conductivity λ is dependent on soil type and on soil water content.

For the solution of Eq. (3) the implicit finite differencing scheme is used which reads for the time index n

$$\frac{{T_k}^{n+1} - {T_k}^n}{\Delta t} = \frac{1}{(\rho c)_k} \frac{\partial}{\partial z} \left(\lambda \frac{\partial {T_k}^{n+1}}{\partial z} \right)_k . \tag{4}$$

The vertical discretisation at grid levels z_k results in a three-diagonal linear system

$$A_k \, T_{k-1}^{n+1} + B_k \, T_k^{n+1} + C_k \, T_{k+1}^{n+1} = D_k \tag{5}$$

which can be solved by an economic numerical procedure. To prevent high frequency oscillations the mean temperature of the uppermost soil layer is presently used as the soil surface temperature.

2. Comparison of EFR and HCE method

In this section, the reaction of the soil surface temperature on different forcing is shown for both the EFR and the HCE method. The results presented have been obtained by time integration to quasi-stationarity.

For harmonic forcing G_s, the temperatures T_s and T_m predicted by the EFR method agree with the respective analytical solution of the HCE. For this idealised condition of harmonic forcing, *Figure 1* shows the diurnal variation of soil surface temperature by the EFR method (t_EFR) in comparison to the analytical solution of the HCE equation (t_ANA) and to the two numerical solutions with the following vertical grid structures:

a) 100 layers of constant thickness of 0.005 m (t_100L),

b) 5 (active) layers with thicknesses 0.02, 0.02, 0.04, 0.08, 0.16 m (t_5L).

Figure 1 demonstrates that for the special case of harmonic forcing the differences in the results are small. The deviations between all temperature curves shown do not ecxeed 1 K at any time step. Apart from very small under- and overshooting, even the five layer version results (t_5L) cannot be distinguished from the other ones. These results confirm that for the case of harmonic forcing the numerical results of the EFR method and of the HCE method are equivalent.

As the next step, both methods are supplied with a modified forcing: harmonic forcing in the first half of the diurnal period, corresponding to the mean diurnal variation between 6 a.m. and 18 p.m. local time, and in the second half a constant forcing corresponding approximately to the mean situation between 18 p.m. and 6 a.m. To simulate more complex and realistic situations, this forcing is superimposed by a high frequency noise to test the

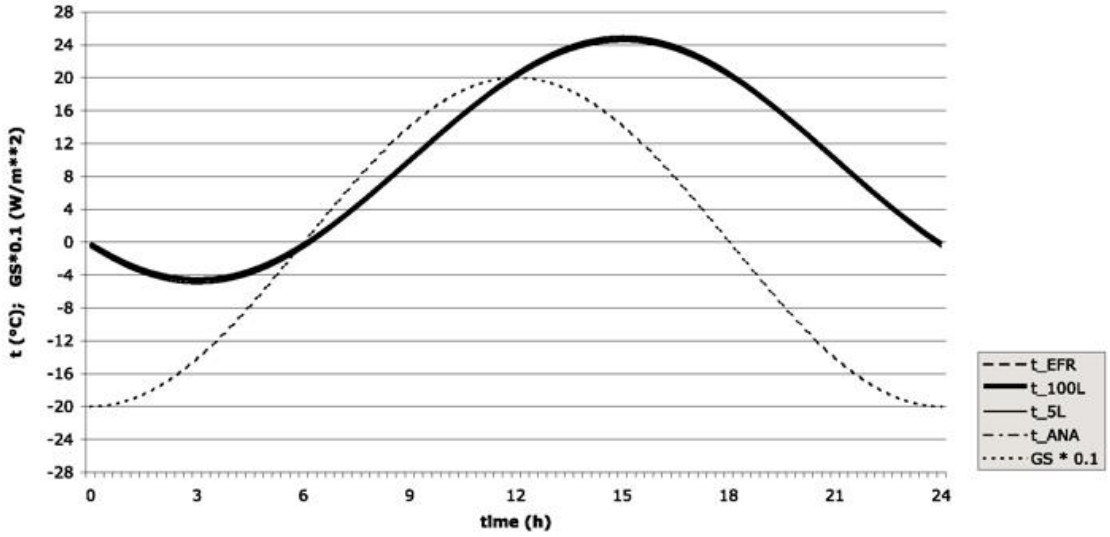

Figure 1: *Soil surface temperature using the EFR method (t_EFR) and the HCE method (t_XL) compared with the analytical HCE solution t_ANA (X=100: 100 layers, Δz = 0.005m; X = 5: 5 layers whose thicknesses increase with depth).*

ability of the different methods to provide a quick feedback in soil surface temperature. As no analytical solution is available now, the results of the HCE method with 100 layers are used as a reference. In *Figure 2*, the high frequency reaction to this type of forcing is shown. The results with the 5 layer version agree well with those of the 100 layer version.

This fast feedback of the soil surface temperature in the HCE method is caused by the choice of layers of small thickness close to the soil surface. On the contrary, the EFR method uses a thickness of the upper layer of about 0.1 m which results in a smooth feedback in the mean temperature of this layer and therefore also in the soil surface temperature. Again the EFR method agrees reasonably well with the 'true' simulation of the HCE method with 100 levels.

In a further test both methods are driven by a low frequency forcing with abrupt changes in three hour intervals to test the influence of a sudden but persistent change in solar radiation at the soil surface, caused for example by convective clouds. *Figure 3* shows that the EFR method simulates the temperature feedback with some delay especially at the points of extreme changes in the forcing at 9 a.m. and at 12 a.m. However, the results do not significantly differ in comparison to the results of the HCE method.

In summary these results demonstrate the quality of the EFR method operationally used in the DWD model suite. Indeed, if no freezing or melting processes inside the soil are considered, the EFR method is the most economic procedure to simulate the diurnal temperature variation with high quality.

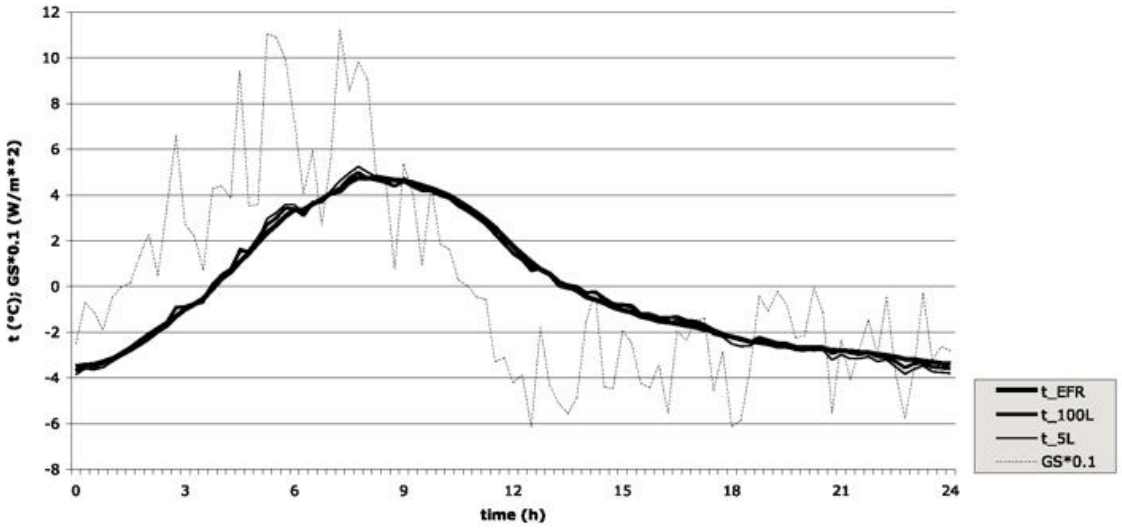

Figure 2: *Soil surface temperature calculated with the EFR method (t_EFR) and the HCE method(t_XL) for high frequent forcing GS (X=100: 100 layers, Δz = 0.005m; X= 4: 4 layers whose thicknesses increase with depth).*

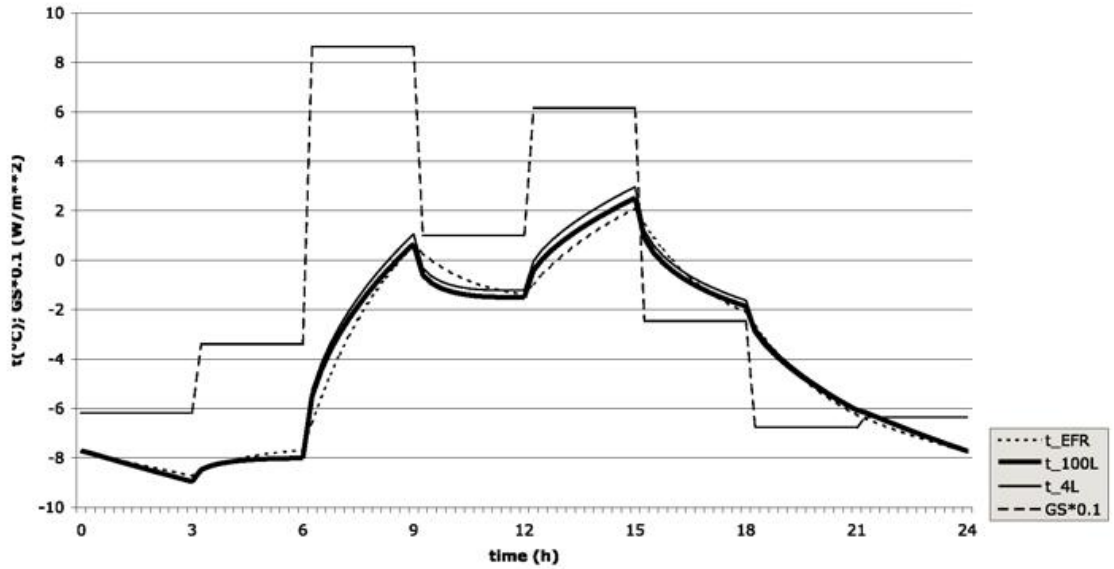

Figure 3: *Soil surface temperature calculated with the EFR method (t_EFR) and the HCE method(T_XL) for low frequent forcing GS (X=100: 100 layers, Δz = 0.005m; X= 4: 4 layers whose thicknesses increase with depth).*

3. The influence of freezing/melting of soil water/ice on soil surface temperatures

The process of freezing/melting of soil water/ice inside the soil is frontal in nature. Treating this process in discrete model layers results in averaging the front over the respective layer thickness. In the present operational models of DWD the upper layer in the hydrological part has a thickness of 0.1 m. The large amount of water/ice available in such a thick layer results in a remarkable suppression of temperature changes if phase transitions occur. In the worst case the diurnal cycle of the temperature can be totally suppressed for a period of several days.

This was the case for the Europa-Modell after it had become operational. Therefore, the freezing/melting process was switched off in that model. In the 4th generation model suite GME/LM the respective code was not included.

The neglection of freezing/melting processes also results in systematic errors. When crossing the melting point $t_0 = 273.15K$ the soil temperatures decrease/increase too rapidly. This leads to temperatures beeing too cold/warm for a considerable time.

Using the HCE method, the freezing/melting process can be included, and the deficiencies can be reduced by the use of high grid resolution, especially close to the soil surface. It will be shown, however, that for some short periods the temporal behaviour of soil temperature significantly depends on the grid resolution.

In section 3.1, the diurnal variation of the soil surface temperature is shown including freezing/melting of soil water/ice at t_0. A second approach (section 3.2) replaces t_0 by taking into account the influence of soil texture on the melting/freezing temperature as a function of soil water content.

3.1 The influence of the freezing/melting process at 273.15 K on the soil surface temperature

If the temperature T_{pre} resulting from the solution of the heat conduction equation (3) is crossing t_0 in any soil layer, a part of the existing soil water/ice will freeze/melt. The available energy for this phase change process is

$$\Delta E \;=\; (\rho c)\Delta z(T_{pre} - t_0)\;, \tag{6}$$

where $\Delta E < 0$ for freezing and $\Delta E > 0$ for melting.

The maximum possible change of liquid water $W_{l,max}$ and of ice $W_{i,max}$, respectively, can be calculated from

$$\Delta W_{l,max} \;=\; -\Delta W_{i,max} \;=\; \frac{\Delta E}{L_f \rho_w}\;. \tag{7}$$

L_f is the heat of fusion, ρ_w is the density of water. The actual change of ice content ΔW_i is given by

$$\Delta W_i = -MIN\{-\Delta W_{i,max}\ ; \quad W_i\} \quad if \ \Delta W_{i,max} < 0 \quad ,$$

$$\Delta W_i = \ MIN\{\ \Delta W_{i,max}\ ; W - W_i\} \quad if \ \Delta W_{i,max} > 0 \quad ,$$

where W is the actual total water content (sum of liquid water and ice) and W_i the ice content at the previous time step.

The effect on the temperature is included by using

$$T = t_0 + (\Delta W_i - \Delta W_{i,max})\frac{(L_f \rho_w)}{(\rho c \Delta z)} \tag{8}$$

to compute the final temperature T at the current time step.

For the whole period of melting or freezing inside a soil layer this procedure causes a final layer mean temperature of t_0 at the end of each time step. Additionally Eq. (8) considers the case that no phase transition occurs. In this case $\Delta W_i = 0$, and the energy ΔE will be completely used to change the soil temperature T.

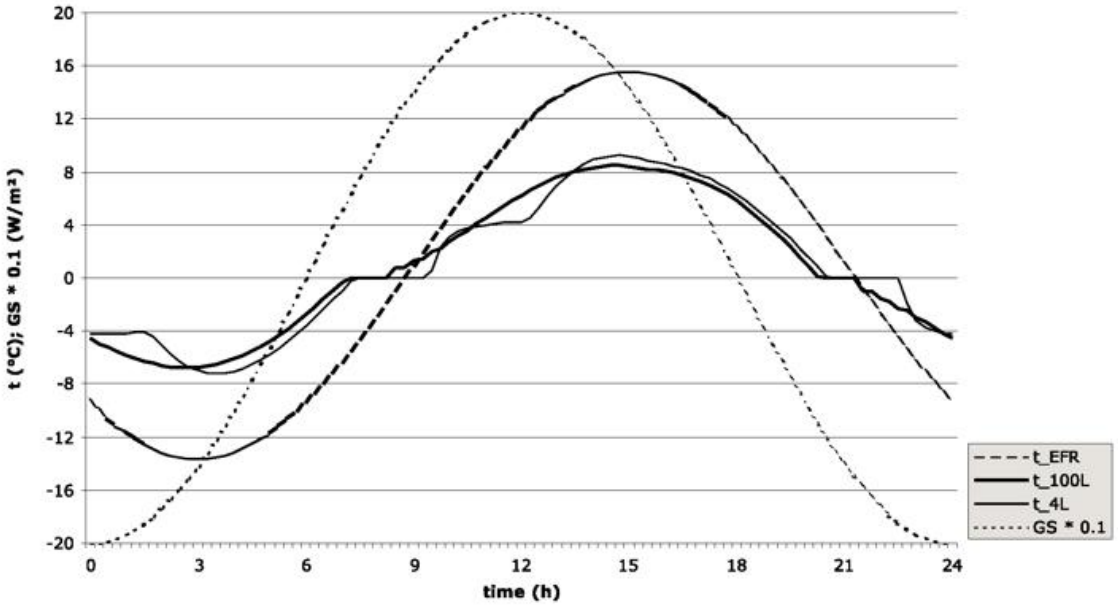

Figure 4: *Influence of soil freezing/melting at 273.15 K in the HCE method (t_XL) on the diurnal variation of soil surface temperature compared to the EFR method (t_EFR) without freezing/melting for harmonic forcing GS (X=100: 100 layers, Δz = 0.005m; X= 4: 4 layers whose thicknesses increase with depth).*

Figure 4 shows an example of the soil surface temperature behaviour with due regard for freezing/melting using the HCE method for two different grid resolutions. A comparison is made with the results using the EFR method, which, as already mentioned, is formulated with no regard for freezing/melting. Again the numerical solution of the 100-layer version of the heat conduction equation with constant layer thickness of 0.005 m is used as reference. Compared to the EFR method, the diurnal variation of the soil surface temperature is significantly damped. The extent of the effect is proportional to the amount of liquid water/ice available for freezing/melting.

The soil surface temperature behaviour for a version with only 4 active layers (layer thicknesses 0.02, 0.04, 0.08, 0.16 m) is also shown in *Figure 4*. Because of their greater thicknesses these four layers need more time to freeze/melt than the 0.005m layers of the 100-layer version. This is the reason for the pronounced step-like curve of the soil surface temperature in the 4-layer version compared to the 100 layer version. This effect can be minimized by using high grid resolution close to the soil surface. On the other hand, the lower limit of layer thickness is a function of the time step and has to take into account economic demands.

3.2 The soil type dependent melting/freezing and its influence on the soil surface temperature

Warrach (2000) uses a relation for the maximum of the volumetric water content $W_{l,max}$ in the soil based on a suggestion by Flerchinger and Saxton (1989). This relation reads

$$W_{l,max} = W_s \left[\frac{L_f (T - t_0)}{T g \Psi_s} \right]^{-1/b} . \tag{9}$$

W_s is the pore volume, T is the temperature, g is the gravitational acceleration, Ψ_s is the air entry potential at saturation, and b is the pore-size distribution index (Brooks and Corey, 1966).

After Cosby et al. (1984) the air entry potential Ψ_s and the pore-size distribution index b are determined by the soil type,

$$\Psi_s = \Psi_0 \cdot 10^{1.88 - 1.3 f_s} , \tag{10}$$

$$b = 2.91 + 15.9 f_c . \tag{11}$$

Ψ_0 is -0.01 m, and f_s and f_c are the fractions of sand and of clay in the soil, respectively. The following table shows for the soil types of the LM the fractions f_s and f_c (the remaining part of the soil fractions is assumed to be silt), the air entry potential Ψ_s calculated with Eq. (10) and the pore-size distribution index b calculated with Eq. (11).

	f_c	f_s	$\Psi_s(m)$	b
sand	0.90	0.05	- 0.0513	3.705
sandy loam	0.65	0.10	- 0.1084	4.50
loam	0.40	0.20	- 0.2291	6.09
loamy clay	0.35	0.35	- 0.2661	8.47
clay	0.15	0.70	- 0.4842	14.04

Eq. (9) can be transformed to calculate a freezing point temperature as function of the water content $W_{l,max}$ of the previous time step,

$$T_* \;=\; t_0 \left[1 - \frac{g\Psi_s}{L_f} \left(\frac{W_s}{W_{l,max}} \right)^b \right]^{-1} . \tag{12}$$

The temperature T_* is the equilibrium temperature where no freezing/melting is observed. If this equilibrium temperature in any soil layer is crossed by the solution T_{pre} of the HCE, freezing or melting occurs. As in section 3.1, the energy difference, that is proportional to the temperature difference T_{pre} - T_*, is used to melt ice or to freeze liquid water, that is

$$\Delta E \;=\; (\rho c)\Delta z (T_{pre} - T_*) \; . \tag{13}$$

Using modified formulations for ΔW_i,

$$\Delta W_i = -MIN\{-\Delta W_{i,max}; MIN(-(W - W_{l,max} - W_i), W_i)\} \quad if \;\; \Delta W_{i,max} < 0 \quad ,$$

$$\Delta W_i = \quad MIN\{\;\Delta W_{i,max}; MAX(\;(W - W_{l,max} - W_i),\; 0.)\} \quad if \;\; \Delta W_{i,max} > 0 \quad ,$$

the final temperature T can be calculated through the relation

$$T \;=\; T_* + (\Delta W_i - \Delta W_{i,max}) \frac{(L_f \rho_w)}{(\rho c \Delta z)} \tag{14}$$

that is analogous to Eq. (8).

The concept of a water content and soil type dependent freezing/melting temperature accounts for a more continuous behaviour of the soil temperature during freezing/melting. This is demonstrated in *Figure 5.* For the soil types (a) sand, (b) loam and (c) clay the quasi-stationary diurnal variation of the soil surface temperature (driven by a periodic harmonic forcing) for water content dependent freezing/melting (solid curve) is compared to freezing/melting at constant temperatures t_0 (dashed curve). The calculations are performed with a multi-layer version with layer thicknesses of 0.01, 0.03, 0.06, 0.12, 0.24, 0.48 m.

The total water content was set to 50% of the pore volume in each layer. For the soil type sand (a) the differences in the behaviour of temperatures are the smallest. With decreasing soil particle sizes lower temperatures are necessary to initiate freezing. Furthermore, for the soil type clay (c) even a water content of 50% of pore volume is not sufficient to allow any freezing at temperatures between 0°C and −10.5°C.

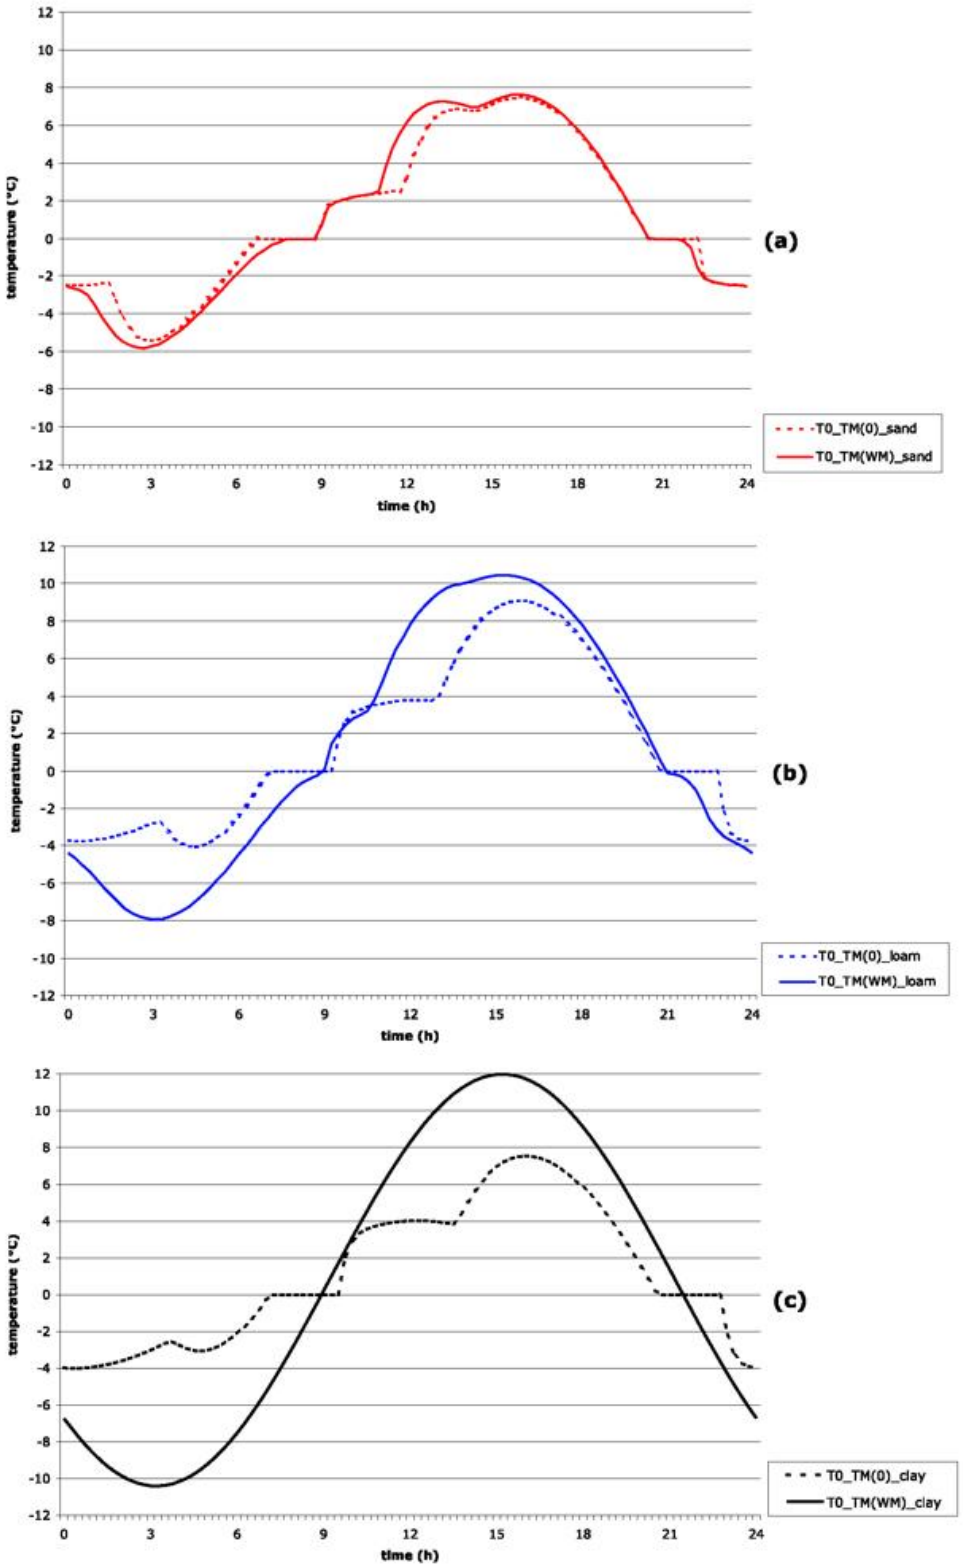

Figure 5: *Diurnal variation of the soil surface temperature for soil types (a) sand, (b) loam and (c) clay. Total water content: 50% of pore volume. $TO_TM(0)$: freezing/melting at $0°C$, $TO_TM(WM)$: freezing/melting as function of liquid water content.*

The local minimum of the soil surface temperature for the soil type sand in *Figure 5a* at 3 p.m. occurs because melting takes place in the layer between 4 and 10 cm which is supported by a downward directed heat flux causing a reduction of the soil surface temperature. However, when ice is completely melted the temperature in this layer can increase. This significantly reduces the downward directed flux and allows the soil surface temperature to increase again.

The method of simulation of the freezing/melting temperature described above produces results between the extrema of 'no freezing/melting', as in the EFR method, and of 'freezing/melting at t_0', as described in section 3.1.

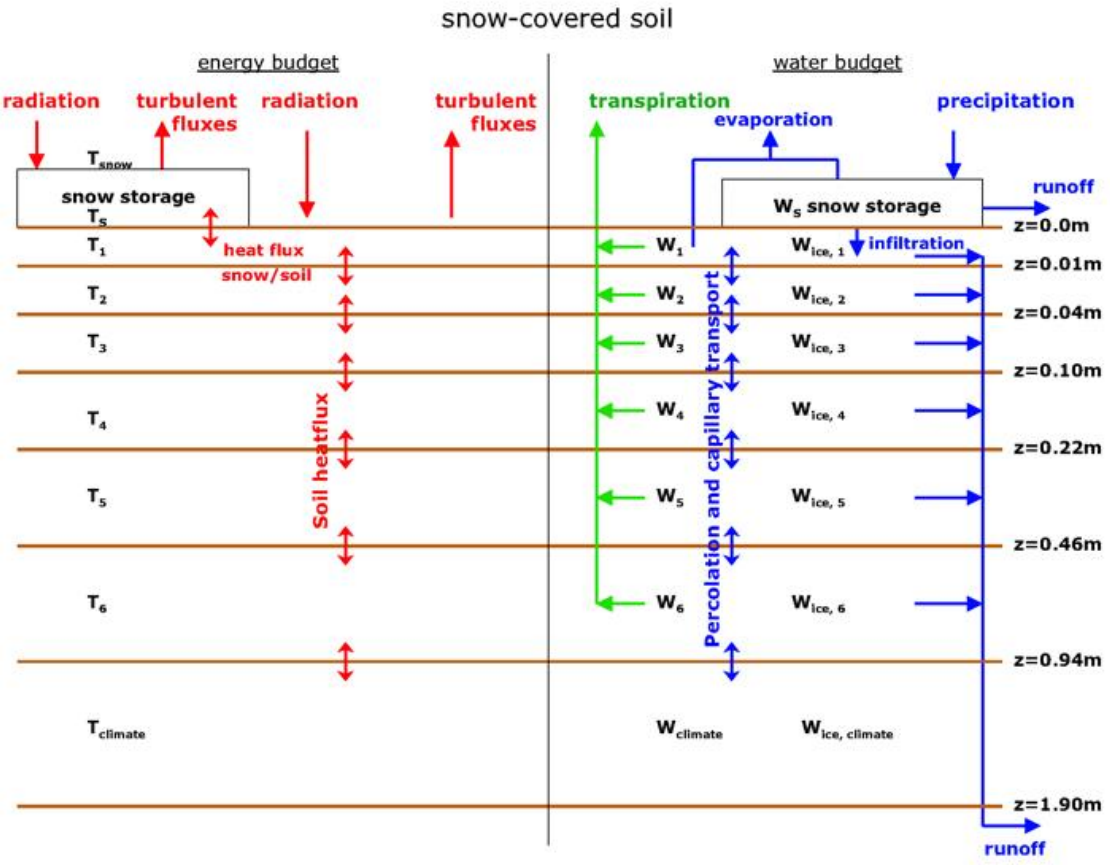

Figure 6: *The multi-layer grid of the soil model TERRA_LM: General structure and physical processes considered in case of a snow covered soil.*

4. A suggestion for fixing the vertical soil layer grid for the multi-layer HCE method

Because of computational limits, a maximum of six active soil layers can be afforded at present in the operational model LM. Experiments with different vertical layer distributions have shown that the uppermost layer should be of thickness of 0.01 m. Furthermore, the LM is nested in the Global Model GME with the lower boundary of the second hydrological layer in 1.0 m. For this reason, the following distribution of layer boundaries (layer bottom,

so-called half levels) for the thermal as well as for the hydrological part, is suggested:

$$z_k \;=\; 0.01\,,\; 0.04\,,\; 0.10\,,\; 0.22\,,\; 0.46\,,\; 0.94\,,\; 1.90\,m\,.$$

This distribution is built up by the formula

$$z_{k+1} \;=\; z_k + 0.03 \cdot 2^{(k-1)} \qquad \text{with} \qquad z_1 \;=\; 0.01\,m.$$

The layer limited by the half levels at 0.94 m and 1.90 m is the so called 'climate layer' with the values of temperature, liquid water content and ice content kept constant during a model run. Figure 6 shows an updated version of the layer structure published in COSMO Newsletter No. 1 (Doms and Schättler, 2001) for a snow covered soil.

Numerical experiments have shown that six active layers are sufficient for numerical weather prediction models. The results become useless if the the number of active layers in this distribution is reduced to less than four. Therefore, six soil layers are sufficient also for simulations over longer time periods with temperature waves penetrating deeper into the ground. Further experiments have shown that with additional layers close to the soil surface the results are not different remarkably, even if freezing and melting occurs.

5. An updated version for computation of melting of snow cover

The operational version for the treatment of melting snow required a rather complicated programming. In order to simplify this part of the model, the method was changed slightly (Heise and Schrodin, 2001). Now only two cases are distinguished:

Case (a)

The soil model calculates a preliminary temperature of the snow cover $T_{snow,p} > t_0$ and a preliminary soil surface temperature $T_{s,p} < t_0$. The reduction of $T_{snow,p}$ to $T_{snow} = t_0$ is simulated by redistribution of the heat content between the snowpack and the uppermost soil layer according to

$$\frac{T_{snow}+T_s}{2}(\rho c\Delta z)_{snow} + T_{so}(\rho c\Delta z)_{so} \;=\; \frac{T_{snow,p}+T_{s,p}}{2}(\rho c\Delta z)_{snow} + T_{so,p}(\rho c\Delta z)_{so} \qquad (15)$$

with $T_{snow} = t_0$ and the unknown temperatures T_s and T_{so}.

Additionally we assume

$$T_{so} - T_{so,p} \;=\; T_s - T_{s,p} \;=\; \Delta T_s\,. \qquad (16)$$

Combining (15) and (16) results in

$$\Delta T_s \;=\; [T_{snow,p} - t_0]\left[1 + \frac{2\cdot(\rho c\Delta z)_{so}}{(\rho c\Delta z)_{snow}}\right]^{-1}.$$

If T_s exceeds t_0, possible melting is postponed to the next time step.

Case (b)

If the preliminary temperature $T_{so,p}$ in the uppermost soil layer exceeds t_0, the redistribution of energy is simulated, now reducing T_{so} to t_0. Then Eq. (16) becomes

$$T_s \;=\; T_{s,p} - T_{so,p} + t_0 \;. \tag{17}$$

Replacing T_s in the budget equation (15) with T_s given by (17) results in

$$T_{snow} \;=\; T_{s,p} \,+\, T_{snow,p} \,-\, t_0 \,+\, 2[T_{s,p} - t_0]\frac{(\rho c \Delta z)_{so}}{(\rho c \Delta z)_{snow}} \;.$$

If $T_{snow} > t_o$, a melting step is performed. The energy available for melting is

$$E_{avail} \;=\; \frac{T_{snow} - t_o}{2}(\rho c \Delta z)_{snow} \;,$$

and the energy required for melting the whole snowpack is

$$E_{total} \;=\; L_f \rho_w W_s \;,$$

where W_s is the snow water equivalent. If $E_{avail} < E_{total}$, the melted fraction of snow ΔM_s is

$$\Delta M_s \;=\; \frac{E_{avail}}{E_{total}} W_s \;.$$

In case more energy is available than is required for melting the whole snowpack, we have $\Delta M_s = W_s$, and the soil surface temperature has to be recomputed through

$$T_s' \;=\; T_s \,+\, \frac{E_{avail} - E_{total}}{(\rho c \Delta z)_{so}} \;. \tag{18}$$

6. Conclusions and Outlook

Preliminary tests have shown that the HCE method is superior to EFR method if in the current soil model the freezing/melting process is to be included. The additional computational cost seems comperatively small. Furthermore, the HCE method can rapidly react to high frequency changes of the atmospheric forcing. A great advantage of the multi-layer version is the formulation of hydrological and thermal processes with exactly the same layer distribution. This simplifies the formulation of feedback processes between the thermal and hydrological parts as soil temperature and soil water interpolations are unnecessary.

The new multi-layer version of the soil model is currently implemented into the LM and a corresponding interface is written for the interpolation program GME2LM. Details on the implementation and on the evaluation of the scheme for real data cases will be published in a forthcomming issue. The new version is planned to become operational in winter/spring 2002.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *Consortium for Small-Scale Modelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (UGM, ARPA-SMR) and Switzerland (MeteoSwiss). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the Lokal-Modell (LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completition of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

The report series is also open for contributions from external users of the LM system at various universities and research institutes.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

1 Introduction

This report summarizes the work performed so far by Pavel Khain and Itzhak Carmona under the guidance of Antigoni Voudouri (head of the project) and Jean-Marie Bettems, and in collaboration with Euripides Avgoustoglou and Federico Grazzini. The CALMO project is based on the objective calibration method which was developed and implemented in regional climate model by Omar Bellprat and Christoph Schär (ETH). The purpose of the CALMO project is to implement the calibration method of (Bellprat et al., 2012) to NWP model COSMO. This report describes the implementation of the calibration method to COSMO-7km. In summary, the calibration method is the following:

a Define the parameters for calibration and their allowed ranges. In this work:

$$rlam_heat \in [0.1\ \mathbf{1}\ 10] \tag{1}$$

$$tkhmin \in [0\ \mathbf{1}\ 2] \tag{2}$$

$$tur_len \in [100\ \mathbf{500}\ 10000] \tag{3}$$

$$rat_sea \in [1\ \mathbf{20}\ 100] \tag{4}$$

b Define the forecast fields to be verified (in this work: maximum and minimum 2m-temperatures, 24h accumulated precipitation);

c Define the time periods for calibration (in this work: 3-20.01.2008 and 2-20.06.2008);

d Define the parameters (combinations) values for performing the COSMO simulations. In this work the combinations are: the default, maximum and minimum allowed values for each of the parameters (keeping the other 3 default), at least 1 pairwise interaction for every 2 parameters (for example maximum rlam_heat and minimum tur_len, keeping the other 2 default). The minimum number of simulations to be performed is $2N + 0.5N(N-1)+1$, where N is the number of calibrated parameters. **The simulations design, including initial and boundary conditions designs, the extensive scripting environment, and the simulations themselves were performed by Antigoni Voudouri.**

e After the simulations are performed, the Meta-Model is constructed (see Section 4), i.e. the forecasted fields are interpolated in parameters space via N-dimensional quadratic polynomial (for each field, for each region and each day, separately). These interpolation formulas (the Meta-Models) allow estimating the forecasted field value for arbitrary parameter values (for each region and each day) without performing real COSMO simulation.

f At the next stage, the parameters space is filled by a large number (in this work 10000) of parameters combinations. For each parameter combination, a forecast field time series is produced (using the Meta-Model), compared with the observations, and evaluated using a performance score (see Section 5).

g Finally, the parameters combination which obtained the best score is selected (see Sections 6 and 7).

h In principle, it is reasonable to perform a real COSMO simulation with the selected parameters combination, and verify whether the forecasts are indeed better (than with default parameters combination).

In order the calibration method to work, one first has to select the parameters which are the **most significant for the verified fields**. For example, for the maximum 2m-temperature we may need to focus on soil and radiation schemes parameters, while for precipitation, we may need to consider also microphysical parameters, etc. Therefore, in Sections 2 and 3 we first analyze the sensitivity of the verified fields to the chosen parameters. Generally, the sensitivity was found to be relatively small, meaning that at the next stage of the CALMO project we will have to extend the set of calibrated parameters and verified fields. In Sections 4-7 we will present the calibration procedure, following the steps e-g above.

As part of the next stage of the CALMO project, it is planned to calibrate parameters from the COSMO soil scheme Terra, for example the hydraulic soil conductivity. The plan is to run the Terra "standalone" (TSA) program (for the default soil parameters, and for any change of soil parameters) prior to running the COSMO model. Section 8 summarizes the work performed so far by the IMS team with the Terra "standalone".

2 The physically expected sensitivity to the tested parameters

2.1 tur_len

tur_len $[m]$ is l_∞ in Blackadar formula (Blackadar, 1962) for the turbulence length, which is present in the equations for the turbulent coefficients as described, for example, in the COSMO document part II §3.4 (see below).

"...in the present scheme we stipulate the following relation between horizontal and vertical diffusion coefficients in accordance with Schlünzen (1988) and Dunst (1980). The horizontal coefficients are determined from the vertical coefficients by use of an anisotropy factor considering the aspect ratio between horizontal and vertical mesh width:

$$K^H_{m,h} = r\frac{\sqrt{(a\cos\varphi\Delta\lambda)^2 + (a\Delta\varphi)^2}}{\Delta z}K^V_{m,h} \approx r\frac{\sqrt{2}\Delta}{\Delta z}K^V_{m,h} \tag{5}$$

Tentatively, we assume $r = 0.1$, and $\Delta \approx 2.8km$. In particular, we have assumed the ratio between horizontal and vertical coefficients to be independent of stability. To determine the horizontal from the vertical coefficients from this relation the vertical coefficient is specified after Prandtl and Kolmogorov as follows:

$$K^V_m = \phi_m l(\bar{e})^{1/2}, K^V_h = \phi_h l(\bar{e})^{1/2} \tag{6}$$

Here, the length scale l is adopted from Blackadar (1962) as a height-dependent scale of turbulence

$$l = \frac{\kappa z}{(1 + \frac{\kappa z}{l_\infty})} \tag{7}$$

Apart from the still undetermined factors ϕ_m and ϕ_h, which are thought to be stability-dependent, we need the determination of TKE

$$\bar{e} = \frac{1}{2}(\overline{u_i' u_i'}) \tag{8}$$

..."

Meaning: the higher is tur_len, the higher are the turbulent coefficients (both vertical and horizontal) in the middle-upper atmospheric levels, and consequently the higher are the turbulent fluxes (mixing) for all the variables and tracers. **Precipitation**: as a result of increasing tur_len, the low level mixing ratio (moisture) is transported upward, increasing mixing ratio on the upper levels, leading to larger cloud development and to the increase of precipitation (see for example Helmert et al. (2008)). We expect this precipitation enhancement to be pronounced mainly in **convective** conditions (typical in **summertime** over Switzerland and inland Europe), where increased tur_len will lead to increase of convective clouds development. In contrast, in stratiform conditions (more typical in **wintertime** over Switzerland and inland Europe), we expect this effect to be less pronounced. Important to mention, that in coastal areas, for example over Italy (close to relatively warm Mediterranean Sea), since the precipitation is highly convective in winter, we expect high precipitation sensitivity to tur_len also in wintertime (and not only in summertime, as in Switzerland). **Max/Min 2m-temperature**: since higher tur_len increases the middle-upper levels vertical mixing (of conservative variables, such as virtual temperature) as well as increases the convective circulation, the temperature profile tends to dry-adiabata, leading to **adiabatic heating in the lower atmosphere**, which in turn, is leading to the increase of 2m-temperature, both at day and night. **Important to note**:

a We would expect the mixing ratio (which is also conservative) to tend to be uniform with height (when increasing tur_len), i.e. increasing mixing ratio at upper levels, and decreasing them near surface. As part of the next stage of CALMO project, it is important to verify mixing ratio and the temperature profiles against **sounding** observations. That will prevent choosing wrong tur_len values which yield unrealistic profiles, although if improving 2m-temperature forecasts.

b Under stable conditions, for example during stable nights (fogs, frost on the ground, etc.), we expect that increasing tur_len will decrease the stability and eliminate these events.

2.2 tkhmin

Meaning: tkhmin $[m^2/s]$ and tkmmin $[m^2/s]$ determine the minimum limits for the turbulence coefficients. tkhmin presence is evident when the turbulent diffusion coefficients (then the mixing) are small, which occurs in **stable conditions**, at night near the surface, as well as at cold days near the surface (with snow cover for example). Increasing tkhmin will keep alive the turbulent kinetic energy at these stable conditions, increasing the mixing and **eliminating the strong inversions**. The expected effect at **stable nights**: increasing the 2m-temperature, i.e. the minimum temperature Tmin, as well as increasing the small convective cloudiness during these nights. Important to mention, that in order to increase the 2m-humidity during stable night and obtain fog, one should decrease tkhmin. The expected effect at **cold days near the surface**: slightly increasing the 2m-temperature, i.e. the maximum temperature Tmax (the last effect should be seen over Swiss plateau but not over Italy, because the proximity to the warm sea eliminates stable conditions during days). **Topography**: we expect this effect to be pronounced mainly in valleys and flat areas. It should not be important in mountains because the wind shears keep the turbulence alive (and the conditions are never very stable). **Season**: on **winter**, the stable conditions over Swiss plateau are common at nights but also during day time, so we expect the heating effect of tkhmin to be important. In contrast, during **summer**, the days are often unstable, and even the nights are not very stable, so we expect that heating effect of tkhmin is only slightly important (and only at nights). Fig. 1 (Cerenzia et al., 2014) presents an example

of the evolution of the near surface turbulent coefficient during a period of several days. One can see that it tends to drop below 1 m^2/s at nights and mornings. During these periods, tkhmin and tkmmin should play an important role.

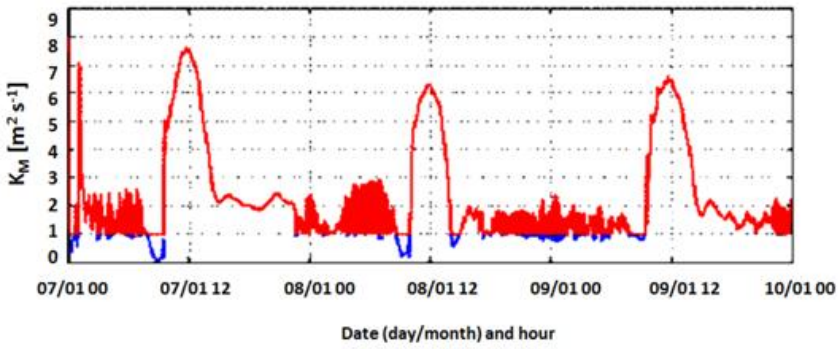

Figure 1: Time series of momentum diffusion coefficient at the lowest model level. Blue segments are the coefficients below the limit $K_M = 1m^2/s$.

Below we present a citation from Cerenzia et al. (2014) which describes tkhmin effect.

"...Nevertheless, some security limitations are active in order to prevent turbulence to decay. The most documented ones are the minimum limits for the vertical diffusion coefficients of momentum and scalars (namelist parameters tkmmin and tkhmin, see also COSMO User's Guide (2014)). In principle, they force the system to continue mixing also when the diffusion coefficients would drop below the prescribed minimum values. In the shear driven SBL case study simulated with COSMO Single-Column by Buzzi, the detrimental effect of this measure on the simulation of the SBL structures has been already underlined (Buzzi, 2008). In the same case study, it appears that the largest minimum limit of the diffusion coefficients not altering the SBL representation is $K_{min} = 0.1m^2/s$*, while in current operational setting it is* $K_{min} = 1m^2/s$ *(or* $0.4m^2/s$ *as recently suggested by DWD in order to avoid the detrimental effect on boundary layer clouds previously mentioned). In weak wind SBL, one can expect an even worse effect on the simulation, given that a stronger stratification should be established. In the case study considered here, the limitation to* $K_{min} = 1m^2/s$ *is frequently occurring (Fig. 1)..." "Another constraint acts on the sum of buoyancy and wind shear forcings in the TKE equation when the Richardson flux number (*$Ri_f = -f_h/f_m$ *) exceeds the critical value* Ri_c *(equal to 0.19 in operational setting), i.e. in very stable stratification. Essentially in this case the buoyancy term is excluded from the TKE calculation, so that the forcing sum depends only on mechanical forcing (positive definite), then the sum is prevented to become negative. Therefore, states of the system beyond* Ri_c *are not described by the TKE equation and are brought back to less stable conditions..." "According to our experience, these limits strongly effect the simulation of the very SBL..."*

Note: the parameter **pat_len**, which is *keeping turbulence alive* parameter (of the thermal circulation term fc in the equation for TKE), which takes into account the effects of turbulence forcing due to subgrid coherent circulations (like large eddies/convection), has the same effect as tkhmin: increase pat_len is equivalent to increase of tkhmin. pat_len parameter is highly uncertain, because of the lack of knowledge of this effect. For more information regarding turbulence closure models for SBL see Zilitinkevich S. et al. (2012).

2.3 rlam_heat

Meaning: rlam_heat [no units] is the parameter which linearly determines **the heat resistance length of laminar layer**; so that the higher is rlam_heat the higher is the resistance of laminar layer for heat transfer, and consequently, the lower is the heat transfer between the surface and the lower atmosphere. The vertical description of the transfer layer is illustrated in the following Fig. 2 (Buzzi, 2008):

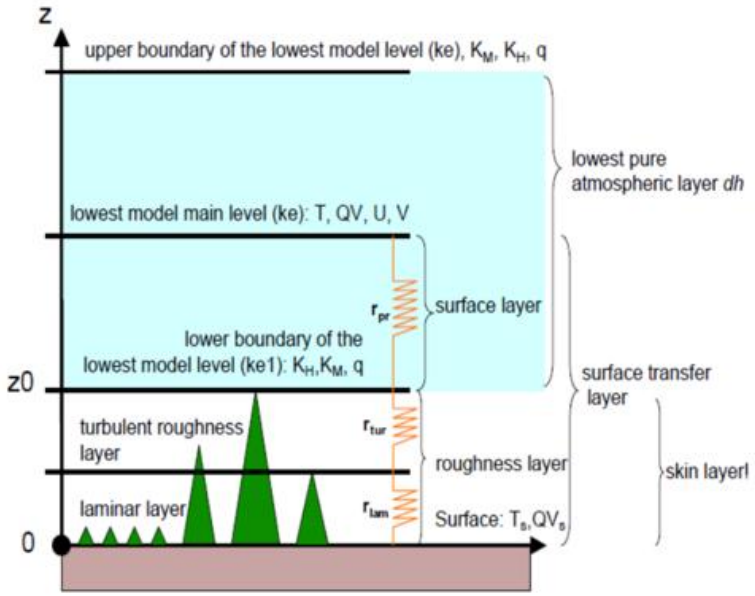

Figure 2: The surface transfer layer and its sub-layers: the surface layer (or Prandtl layer), the turbulent roughness layer and the laminar layer. For each sub-layer transport resistances for vector and scalar quantities are computed. The surface layer extends from the height corresponding to the roughness length Z_0 (level with the index ke1) to the lowest atmospheric main level (level with index ke), where the turbulent diffusion coefficients and all the model variables are known. At the bottom of the surface layer only the turbulence related variables as the diffusion coefficients are known. The roughness layer is placed below the height equal to the roughness length and is treated as a skin layer.

The formula for the heat resistance length of the laminar layer is below (Cerenzia, 2013):

"...momentum and heat resistance lengths for laminar layer are calculated according to:

$$dz_{sg,m} = r_{lam,m}\frac{z_0}{SAI} \tag{9}$$

$$dz_{sg,h} = r_{lam,h}\frac{z_0}{SAI} fakt \frac{K_h con_m}{K_m con_h} \tag{10}$$

where:

- $r_{lam,m}$ *and* $r_{lam,h}$ *are scaling factors set by default respectively to 0 and 1 and modifiable in the namelist,*
- z_0 *is the roughness length,*
- SAI *is the Surface Area Index that includes both the transpirant and the non-transpirant surfaces,*

- *fakt is a factor that increases the laminar resistance length in case the gridbox is over water:*

$$fakt = 1 + (1 - NINT(fr_{land}))(rat_sea - 1) \tag{11}$$

with fr_{land} the ratio between land and water surfaces in the gridbox and rat_sea a parameter sets to 20 and modifiable by namelist,

- *con_m and con_h are respectively the kinematic viscosity and conductivity.*

..."

Expected effect: During days with **unstable** conditions and warm surface, typical to summertime days in Switzerland (but also to warm unstable wintertime days, for example in Italy), we expect that increasing rlam_heat will decrease the heat fluxes upward from the warm surface, leading to less effective heating of the lower atmospheric layers, i.e. lower 2m-temperature and **lower Tmax (in summertime)**. In addition, that should cause to slight decrease of instability, which may lead to **decrease in convective precipitation (in summertime)**. During **stable** conditions, with cold surface, typical to wintertime nights, but also to wintertime cold days near the surface, and sometimes to summertime nights, we expect that increasing rlam_heat will decrease the heat runoff from the warm atmosphere to the surface, leading to heating of the lower atmospheric layers, i.e. higher 2m-temperature. That will **increase Tmin at wintertime nights, increase Tmax at wintertime cold-surface days, and sometimes increase Tmin at stable summertime nights.**

2.4 rat_sea

Meaning: rat_sea [no units], has the same effect as rlam_heat, but over sea. In equation 10 (Cerenzia, 2013) for the **heat resistance length of laminar layer**, *fakt* parameter is rat_sea in case of pure sea grid point (according equation 11).

We expect that the effect of rat_sea will be pronounced only over the sea or near sea regions, like Italy, but not over Switzerland. Generally, **the effect of rat_sea over Switzerland should be noisy**. In near coast areas (like in Italy), at wintertime, when the sea is relatively warm, the increase of rat_sea should decrease the temperature and humidity fluxes from the sea, leading to **decrease of precipitation**. In cyclonic situations, these fluxes decrease, may significantly flatten the cyclones. In near coast areas (like in Italy), at summertime, the precipitation is more often developed over the land, so the effect of rat_sea should be less pronounced. **Note**: in near coast areas (like in Italy), the effect of changes in rlam_heat and rat_sea is the same! For example, increasing rlam_heat from 1 to 5 will have the same effect as increasing rat_sea from 20 to 100.

Example for rat_sea effect over the sea (Eastern Mediterranean): In order to check, whether rat_sea parameter is important in regions which are affected by the Mediterranean Sea, a simple experiment was performed for the heavy rain event over the Eastern Mediterranean during 10-14.12.2013.

Fig. 3 shows the 24h accumulated precipitation over Israel for rat_sea=100 and Fig. 4 for rat_sea=1.

Fig. 5 presents the mean-sea-level pressure (for 11.12.2013 12UTC) over the Eastern Mediterranean for rat_sea=100 and Fig. 6 for rat_sea=1.

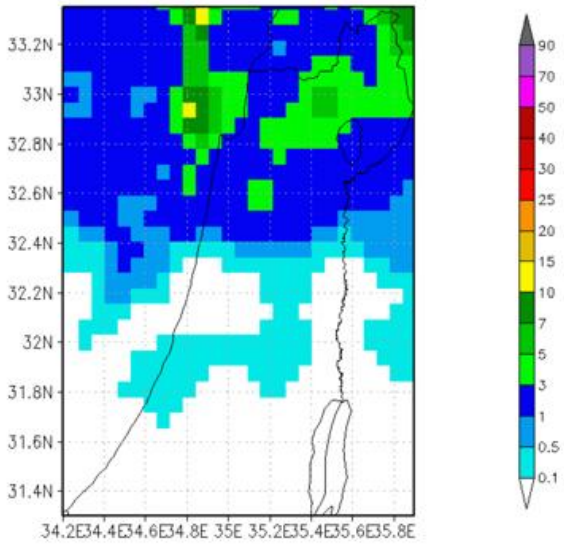

Figure 3: 24h accumulated precipitation over Israel 10.12.2013 for rat_sea=100.

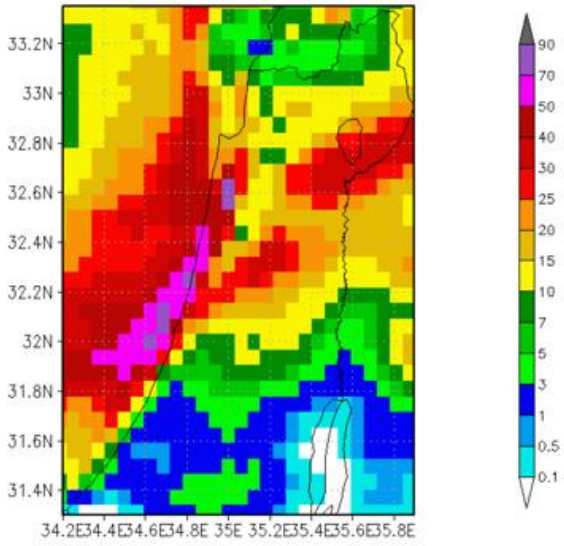

Figure 4: 24h accumulated precipitation over Israel 10.12.2013 for rat_sea=1.

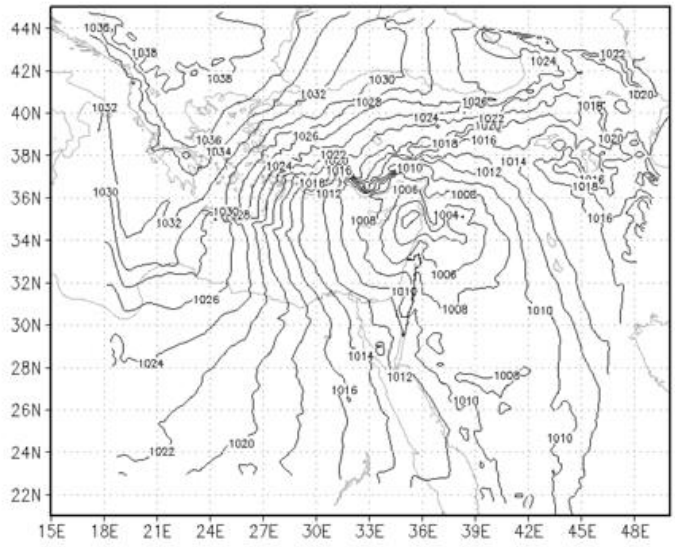

Figure 5: Mean sea level pressure (for 11.12.2013 12UTC) over the Eastern Mediterranean for rat_sea=100.

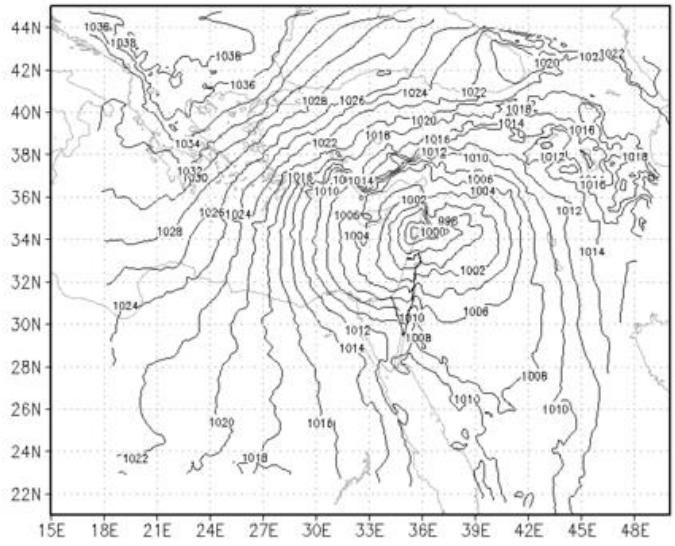

Figure 6: Mean sea level pressure (for 11.12.2013 12UTC) over the Eastern Mediterranean for rat_sea=1.

One can see that in case of rat_sea=1 the cyclone is much deeper and the accumulated precipitation is 10-20 times (!) larger than for rat_sea=100. **Conclusion: in coastal areas the rat_sea parameter might be highly important.**

3 The actual sensitivity to the tested parameters

3.1 Division of Switzerland into three climatically unique areas

In order to identify the general sensitivity of the COSMO forecasts to the parameters variations, there was a need to divide Switzerland area into a small number of climatically unique areas. Previously, Switzerland area was divided into 152 regions, yielding noisy effect of the parameters variations on the COSMO forecast, especially on the precipitation field. Therefore, we have divided Switzerland area into three climatically unique areas, according to Frei (2013), as presented in Fig. 7. The areas were defined as following:

- North - the area to the north of the Alpine crest, mostly coincides with the Swiss Plateau.
- Alps - the area of Alpine crest.
- South - the area to the south of the Alpine crest, mostly coincides with Ticino region.

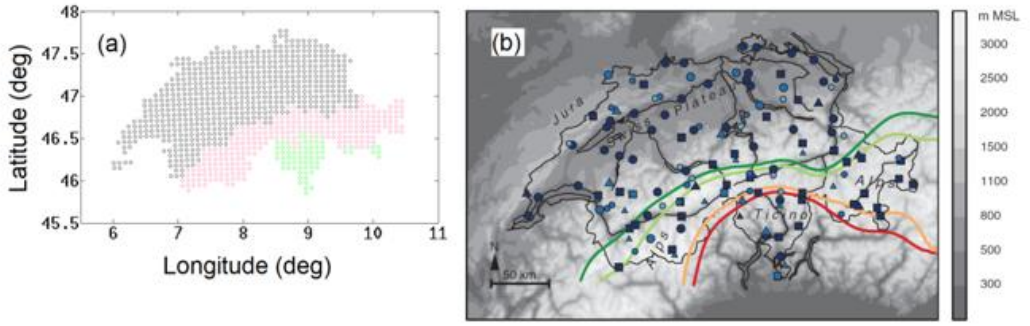

Figure 7: Division of Switzerland into three climatically unique areas, according to Frei (2013). (a) The three areas mapped to the COSMO 7km grid. (b) The original Frei (2013) topographical map. The green and the red lines were used for the areas definition.

3.2 Maximum 2m-temperature (Tmax) sensitivity

For identifying the general sensitivity of Tmax to the parameters variations, for each of the 4 parameters, we present 2 time series: for its minimum and maximum allowed values, respectively, while keeping the other parameters at their default values:

- rlam_heat: COSMO simulations LRLAM and HRLAM
- tkhmin: COSMO simulations LTKH and HTKH
- rat_sea: COSMO simulations LRATS and HRATS
- tur_len: COSMO simulations LTURL and HTURL

In addition, we present the time series of REF COSMO simulation (red), where all the 4 parameters keep their default values, and the observations time series OBS (black). As described in the Introduction, we have performed separate analysis for January and June 2008. Figs 8 and 9 present the 10 Tmax time series (described above) for January and June 2008, respectively.

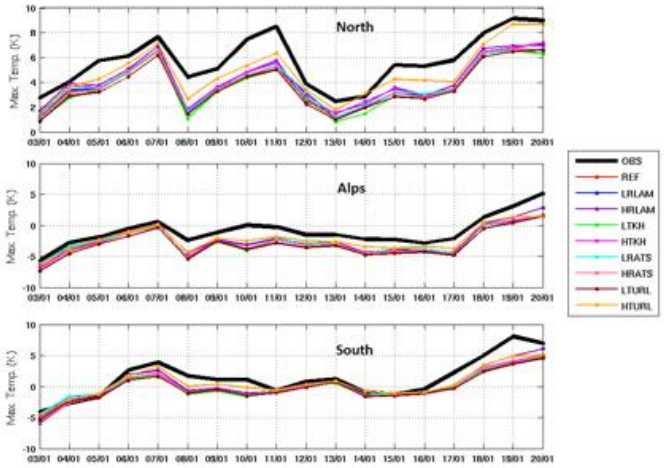

Figure 8: Tmax time series for January 2008, for the observations (black) and nine selected COSMO-7km simulations (colored).

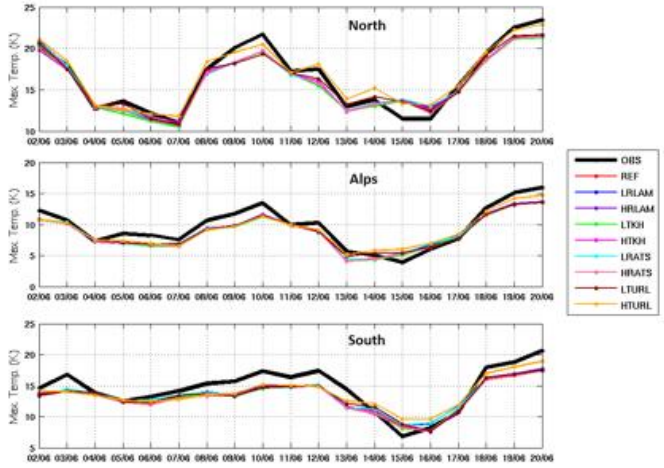

Figure 9: Tmax time series for June 2008, for the observations (black) and nine selected COSMO-7km simulations (colored).

Subtracting the observed Tmax from the simulated, we have constructed Tmax error distributions. Fig. 10 presents the Tmax error distributions for January (a) and June (b) 2008, respectively, for the nine selected COSMO-7km simulations.

In the following, we present typical examples for Tmax sensitivity for the North region

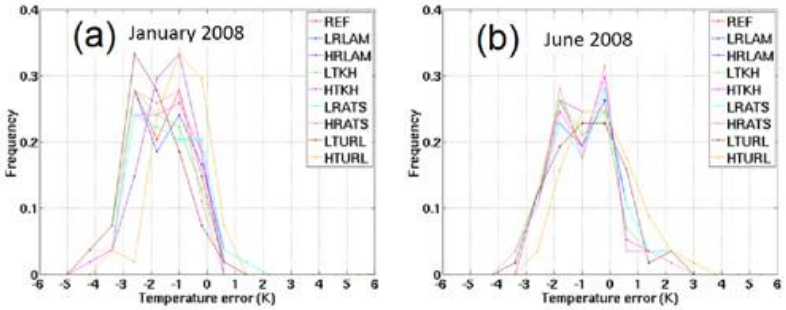

Figure 10: Tmax error distributions for January (a) and June (b) 2008, for the nine selected COSMO-7km simulations.

during different days for the 3 parameters separately (tur_len, rlam_heat and tkhmin; no tests for rat_sea due to technical problems). Several additional simulations for intermediate values of each of the parameters were performed. Fig. 11 presents Tmax sensitivity on tur_len parameter for 12.01.2008, typical for wintertime (a), and for 10.06.2008, typical for summertime (b), respectively. Fig. 12 presents Tmax sensitivity on rlam_heat parameter for 11.01.2008, typical for wintertime (a), and for 03.06.2008, typical for summertime (b), respectively. Fig. 13 presents Tmax sensitivity on tkhmin parameter for 11.01.2008, typical for wintertime (a), and for 03.06.2008, typical for summertime (b), respectively.

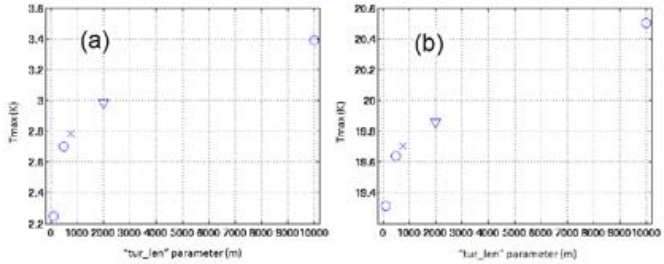

Figure 11: Tmax sensitivity on tur_len parameter for region North on 12.01.2008, typical for wintertime (a), and for 10.06.2008, typical for summertime (b), respectively.

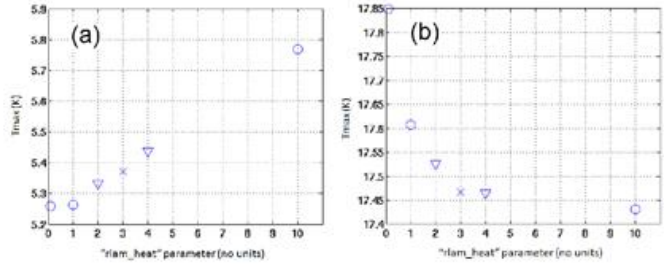

Figure 12: Tmax sensitivity on rlam_heat parameter for region North on 11.01.2008, typical for wintertime (a), and for 03.06.2008, typical for summertime (b), respectively.

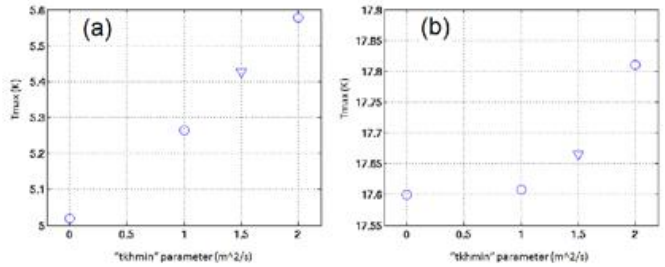

Figure 13: Tmax sensitivity on tkhmin parameter for region North on 11.01.2008, typical for wintertime (a), and for 03.06.2008, typical for summertime (b), respectively.

Conclusions regarding Tmax sensitivity to the 4 parameters variations

- The COSMO simulations of Tmax are generally colder than the observed values (as will be seen from analyzing Tmin in the next Section, the COSMO 2m-temperature day-night amplitude is too low). On January the COSMO underestimation is around 2K and on June around 1K (Figs. 8, 9, 10)
- **Generally, none of the COSMO simulations is warm enough (Figs. 8, 9). Therefore, the CALMO method will not solve the problem of Tmax underestimation using the 4 tested parameters, but only slightly improve the Tmax forecast. In order to solve the Tmax underestimation problem, one should calibrate different COSMO parameters (like soil scheme parameters, radiation scheme parameters, etc.)**
- As expected from the physical meaning of tur_len (see Section 2.1), the higher is tur_len the higher is the 2m-temperature (Figs. 10, 11). The sensitivity is very clear (about 1K) and the noise is low.
- As expected from the physical meaning of rlam_heat (see Section 2.3), the sensitivity of Tmax on rlam_heat depends on the stability conditions at specific day. On cold winter days, the stratification is often stable, so the increase of rlam_heat prevents the heat run-off from the lower atmosphere to the soil, leading to increase of Tmax. That is exactly the case on Fig. 12a. The stable stratification on that day is presented in Fig. 39 in Section 10. On summer days, the profile is often unstable, so the increase of rlam_heat prevents the warm soil to heat the lower atmosphere, leading to decrease of Tmax. That is exactly the case on Fig. 12b. The unstable stratification on that day is presented in Fig. 40 in Section 10.
- As expected from the physical meaning of tkhmin (see Section 2.2), the sensitivity of Tmax on tkhmin depends on the stability conditions at specific day. On cold winter days, the stratification is often stable, then the increase of tkhmin keeps the turbulence alive, leading to increase of Tmax. That is exactly the case on Fig. 13a. The stable stratification on that day is presented in Fig. 39 in Section 10. On summer days, the profile is often unstable, then tkhmin does not play any role, and its effect on Tmax is noisy. That is exactly the case in Fig. 13b. The unstable stratification on that day is presented in Fig. 40 in Section 10.
- It is expected that the effect of rat_sea over Switzerland is noisy. However, for technical reasons the sensitivity checks were not yet performed.

3.3 Minimum 2m-temperature (Tmin) sensitivity

For identifying the general sensitivity of Tmin to the parameters variations, for each of the 4 parameters, we present the same 10 time series, as in Section 3.2 above, both for January and June 2008. Figs. 14 and 15 present the 10 Tmin time series for January and June 2008, respectively.

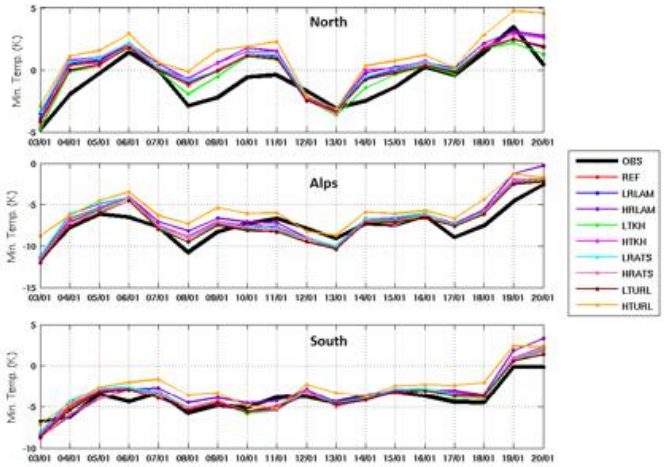

Figure 14: Tmin time series for January 2008, for the observations (black) and nine selected COSMO-7km simulations (colored).

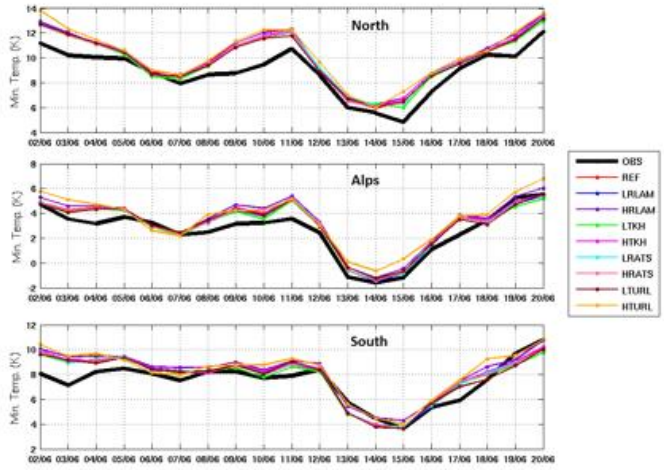

Figure 15: Tmin time series for June 2008, for the observations (black) and nine selected COSMO-7km simulations (colored).

Subtracting the observed Tmin from the simulated, we have constructed Tmin error distributions. Fig. 16 presents the Tmin error distributions for January (a) and June (b) 2008, respectively, for the nine selected COSMO-7km simulations.

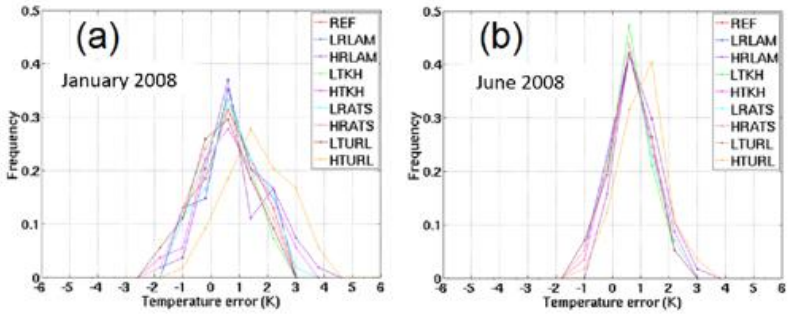

Figure 16: Tmin error distributions for January (a) and June (b) 2008, for the nine selected COSMO-7km simulations.

In the following, we present typical examples for Tmin sensitivity for the North region during different days for the 3 parameters separately (tur_len, rlam_heat and tkhmin; no tests for rat_sea due to technical problems). Fig. 17 presents Tmin sensitivity on tur_len parameter for 11.01.2008, typical for wintertime (a), and for 10.06.2008, typical for summertime (b), respectively. Fig. 18 presents Tmin sensitivity on rlam_heat parameter for 11.01.2008, typical for wintertime (a), and for 10.06.2008, typical for summertime (b), respectively. Fig. 19 presents Tmin sensitivity on tkhmin parameter for 11.01.2008, typical for wintertime (a), and for 10.06.2008, typical for summertime (b), respectively.

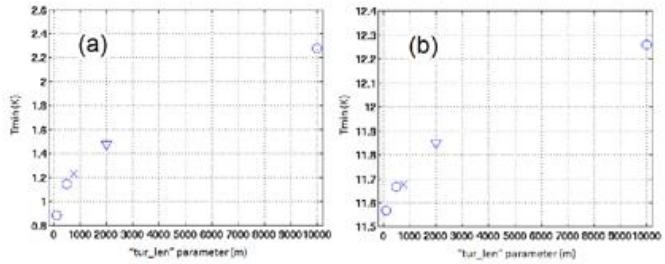

Figure 17: Tmin sensitivity on tur_len parameter for region North on 11.01.2008, typical for wintertime (a), and for 10.06.2008, typical for summertime (b), respectively.

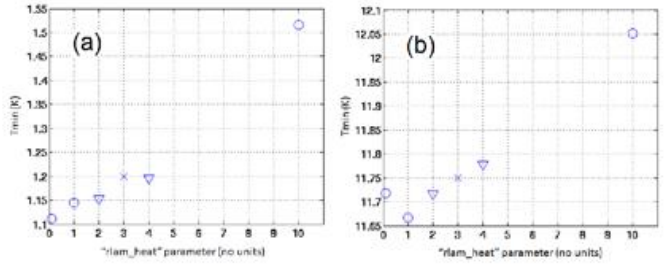

Figure 18: Tmin sensitivity on rlam_heat parameter for region North on 11.01.2008, typical for wintertime (a), and for 10.06.2008, typical for summertime (b), respectively.

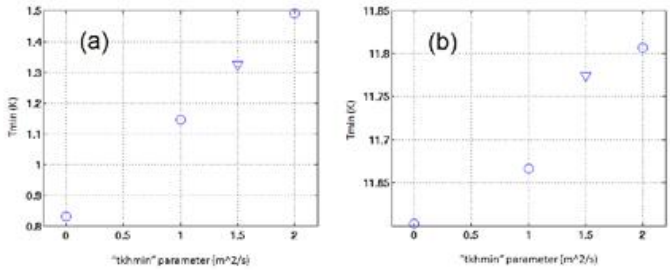

Figure 19: Tmin sensitivity on tkhmin parameter for region North on 11.01.2008, typical for wintertime (a), and for 10.06.2008, typical for summertime (b), respectively.

Conclusions regarding Tmin sensitivity to the 4 parameters variations

- The COSMO simulations of Tmin are generally warmer than the observed values (the COSMO 2m-temperature diurnal amplitude is too low). The COSMO overestimation is around 0.5-1K (Figs. 14, 15, 16).
- **Generally, none of the COSMO simulations is cold enough (Figs. 14, 15). Therefore, the CALMO method will not solve the problem of Tmin overestimation using the 4 tested parameters, but only slightly improve the Tmin forecast. In order to solve the Tmin overestimation problem, one should calibrate different COSMO parameters (like soil scheme parameters, etc.).**
- As expected from the physical meaning of tur_len (see Section 2.1), the higher is tur_len the higher is the 2m-temperature (Figs. 16, 17). The sensitivity is very clear (about 1K) and the noise is low.
- As expected from the physical meaning of rlam_heat (see Section 2.3), the sensitivity of Tmin on rlam_heat depends on the stability conditions at specific night. Generally, on nights the stratification is often stable, so the increase of rlam_heat prevents the heat run-off from the lower atmosphere to the soil, leading to increase of Tmin. That is exactly the case on Figs. 18a, 18b. The stable stratification on these nights is presented in Figs. 39 and 41 in 10, respectively.
- As expected from the physical meaning of tkhmin (see Section 2.2), the sensitivity of Tmin on tkhmin depends on the stability conditions at specific night. Generally, on nights the stratification is often stable, then the increase of tkhmin keeps the turbulence alive, leading to increase of Tmin. That is exactly the case on Figs. 19a, 19b. The stratification on winter night is generally much more stable than on summer night, leading to much larger effect of Tmin on tkhmin (Fig. 19a). The stable stratification on these nights is presented in Figs. 39 and 41 in 10, respectively.
- It is expected that the effect of rat_sea over Switzerland is noisy. However, for technical reasons the sensitivity checks were not yet performed.

3.4 24h accumulated precipitation (Pr) sensitivity

For identifying the general sensitivity of Pr to the parameters variations, for each of the 4 parameters, we present the same 10 time series, as in sections 3.2 and 3.3 above, both for January and June 2008. Figs. 20, 21 present the 10 Pr time series for January and June 2008, respectively.

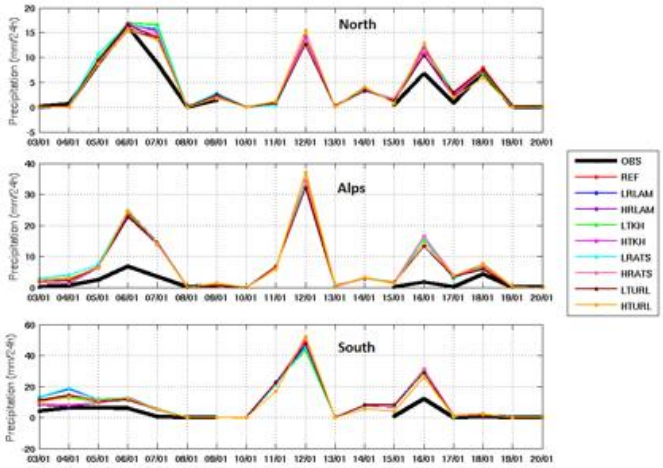

Figure 20: Pr time series for January 2008, for the radar measurements (black) and nine selected COSMO-7km simulations (colored). The period 10.01-14.01 is missing from the radar data.

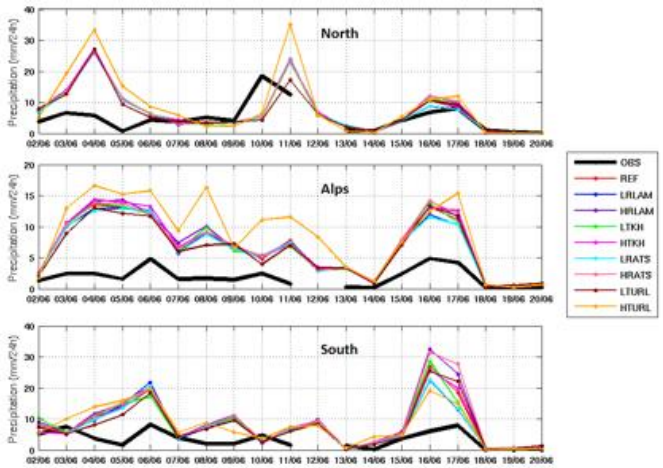

Figure 21: Pr time series for June 2008, for the radar measurements (black) and nine selected COSMO-7km simulations (colored). The day 12.06 is missing from the radar data.

Subtracting the measured Pr from the simulated, we have constructed Pr error distributions. Fig. 22 presents the Pr error distributions for January (a) and June (b) 2008, respectively, for the nine selected COSMO-7km simulations.

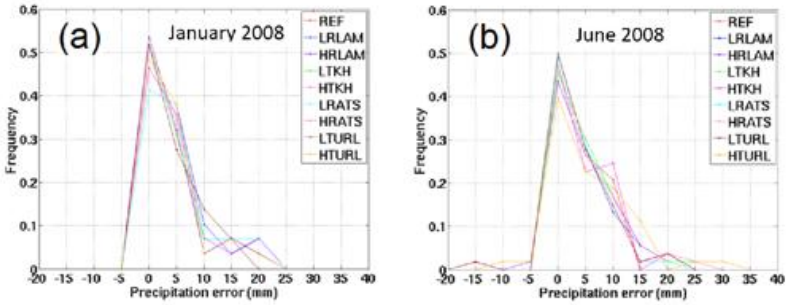

Figure 22: Pr error distributions for January (a) and June (b) 2008, for the nine selected COSMO-7km simulations.

In the following, we present typical examples for Pr sensitivity for the North region during different days for the 3 parameters separately (tur_len, rlam_heat and tkhmin; no tests for rat_sea due to technical problems).

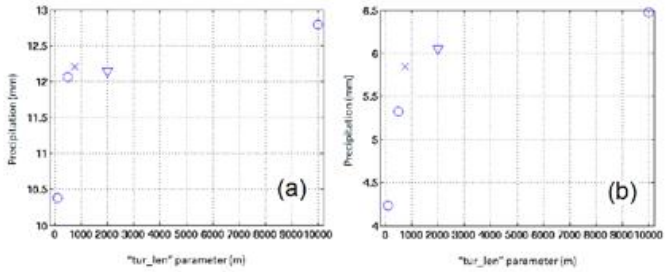

Figure 23: Pr sensitivity on tur_len parameter for region North on 16.01.2008, typical for wintertime (a), and for 10.06.2008, typical for summertime (b), respectively.

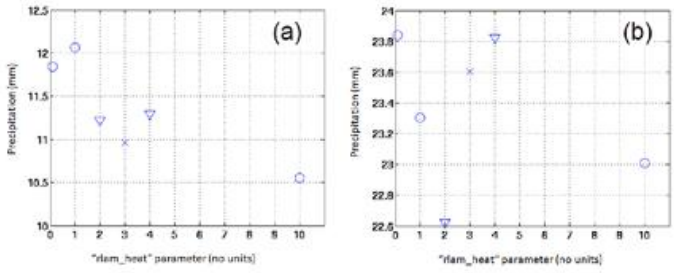

Figure 24: Pr sensitivity on rlam_heat parameter for region North on 16.01.2008, typical for wintertime (a), and for 11.06.2008, typical for summertime (b), respectively.

Fig. 23 presents Pr sensitivity on tur_len parameter for 16.01.2008, typical for wintertime (a), and for 10.06.2008, typical for summertime (b), respectively. Fig. 24 presents Pr sensitivity on rlam_heat parameter for 16.01.2008, typical for wintertime (a), and for 11.06.2008, typical for summertime (b), respectively. Fig. 25 presents Pr sensitivity on tkhmin parameter for 16.01.2008, typical for wintertime (a), and for 11.06.2008, typical for summertime (b), respectively.

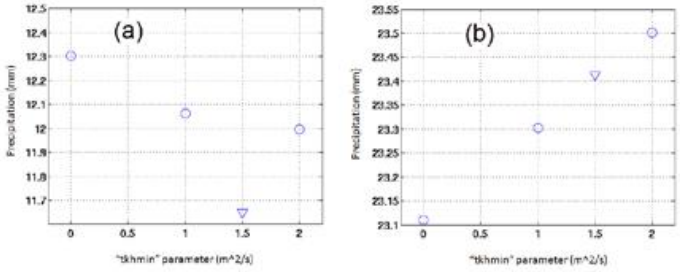

Figure 25: Pr sensitivity on tkhmin parameter for region North on 16.01.2008, typical for wintertime (a), and for 11.06.2008, typical for summertime (b), respectively.

Conclusions about 24h accumulated precipitation sensitivity to the 4 parameters variation

- The COSMO simulations generally overestimate the observed precipitation, especially on summertime (Figs. 20, 21, 22).
- **Generally, none of the COSMO simulations is dry enough (Figs. 20, 21). Therefore, the CALMO method will not solve the problem of precipitation overestimation using the 4 tested parameters, but only slightly improve the precipitation forecast. In order to solve the precipitation overestimation problem, one should calibrate different COSMO parameters (like microphysics scheme parameters, etc.).**
- As expected from the physical meaning of tur_len (see Section 2.1), the higher is tur_len the higher is the convective precipitation (Figs. 21, 22b, 23b). This sensitivity is very clear (up to 30%). However, the stratiform precipitation, more typical to wintertime (over Switzerland) generally exhibits little and noisy effect as function of tur_len (Figs. 20, 22a, 23a).
- As expected from the physical meaning of rlam_heat (see Section 2.3), the sensitivity of precipitation on rlam_heat is generally noisy (Fig. 24). On warm days with convective precipitation, we would expect that increase of rlam_heat will slightly decrease precipitation, but this effect is not presented at the examples above.
- As expected from the physical meaning of tkhmin (see Section 2.2), the sensitivity of precipitation on tkhmin (which is important in very stable conditions) is noisy.
- It is expected that the effect of rat_sea over Switzerland is noisy (in coastal areas like Italy, the effect should be very significant). However, for technical reasons the sensitivity checks were not yet performed.

4 The Meta-Model

In the following, we will focus on the 3 parameters rlam_heat, tkhmin and tur_len (rat_sea will not be used in the Meta-Model due to technical problems). Following the theory of Meta-Model construction (Neelin et al., 2010 and Bellprat et al., 2012), for any parameters combination [rlam_heat, tkhmin, tur_len], for a given day i and a region r, the COSMO field F (in our case Tmax, Tmin or Pr) may be approximated by 3-dimensional polynomial of order 2:

$$F_{i,r} \cong F_{i,r}^{d} + c_{i,r} + a_{i,r}^{(1)} x_1 + B_{i,r}^{(1,1)} x_1^2 + a_{i,r}^{(2)} x_2 + B_{i,r}^{(2,2)} x_2^2 + a_{i,r}^{(3)} x_3 + B_{i,r}^{(3,3)} x_3^2 + \\ + B_{i,r}^{(1,2)} x_1 x_2 + B_{i,r}^{(1,3)} x_1 x_3 + B_{i,r}^{(2,3)} x_2 x_3 \quad (12)$$

Where:

$$x_1 = \frac{rlam_heat - rlam_heat_d}{rlam_heat_{max} - rlam_heat_{min}}; x_2 = \frac{tkhmin - tkhmin_d}{tkhmin_{max} - tkhmin_{min}}; \quad (13)$$

$$x_3 = \frac{tur_len - tur_len_d}{tur_len_{max} - tur_len_{min}}$$

The index d stands for default. For default values of the 3 parameters, i.e. $[x_1 = 0, x_2 = 0, x_3 = 0]$, the approximated field should be close to $F_{i,r}^{d}$. The constants $c_{i,r}, a_{i,r}^{(1,2,3)}, B_{i,r}^{(1,2,3\times 1,2,3)}$ are obtained using several COSMO simulations, as described in the following. Each simulation (for given parameters values) yields $F_{i,r}$. When sufficient number of simulations is performed, one can interpolate the different known values of $F_{i,r}$ as function of $[x_1, x_2, x_3]$ using the 3D polynomial in eq. (12) above. The sufficient number is $2N + 0.5N(N-1) + 1$, so that for N=3 the sufficient number of simulations to be performed is 10.

Now the question arises: what is the quality of such interpolation? The following factors are important for the interpolation to be realistic (to be able to replace the COSMO simulations):

- The choice of parameters values (combinations) for COSMO simulations should be specific. In this work the **design** is chosen according to Bellprat (2012).
- The default values of the parameters should be located close to the **center of their allowed ranges**. Otherwise, in the empty parameter regions, the parabolic fit will reach very high (or very low) unrealistic peaks. The problem is, that the default values of rlam_heat and tur_len are significantly shifted from the centers of their allowed ranges: for rlam_heat: [0.1 1 10], and for tur_len: [100 500 10000]. That problem will be discussed and solved in section 4.1 below.
- The simulated COSMO field $F_{i,r}$ should **not be noisy** as function of the parameters $[x_1, x_2, x_3]$. In other words, the sensitivity of $F_{i,r}$ on $[x_1, x_2, x_3]$ should be higher than the noise level. However, various COSMO fields are noisy for various parameters. That issue will be discussed and solved in section 4.2 below.
- Use as many as possible additional constrain simulations (for additional parameters combinations). The added value of these simulations is discussed in section 4.3 below.

4.1 The Meta-Model: solution to the parabola problem

As mentioned, the default values of the parameters should be located close to the **center of their allowed ranges**. Otherwise, in the empty parameter regions, the parabolic fit will reach very high (or very low) unrealistic peaks. For example, we focus on the Tmax dependence on tur_len parameter for the North region on 12.01.2008. Fig. 26 presents the parabolic fit (blue dashed line) for 3 tur_len values (a) and 4 tur_len values (b). One can see that in the empty tur_len regions, the parabolic fit reaches very high unrealistic peaks. When adding one more tur_len value (b), the fit improves, but still exhibits unrealistically high peak. Our solution to that problem is **fitting the parabola to logarithm of the**

parameter, or more precisely: parabolic fit to $log(tur_len/100)$ (instead of to tur_len), and parabolic fit to $log(rlam_heat+1)$ (instead of to rlam_heat). In simple words, logarithm of a parameter brings the far away parameter values closer to the others, eliminating the empty parameter regions, and causing the parabolic fit to be more monotonic. Fig. 26 presents these fits by red solid lines. One can see that these fits are much more reasonable.

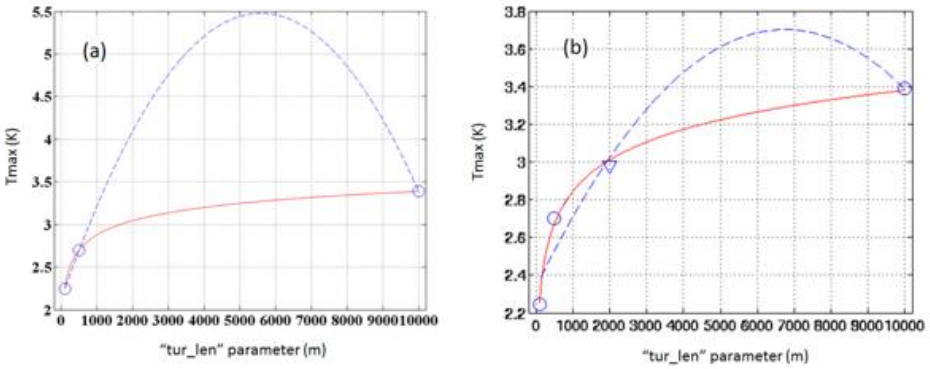

Figure 26: Tmax dependence on tur_len parameter for the North region on 12.01.2008. The parabolic fit (blue dashed line) and the parabola of logarithm fit (red solid line) are shown, for 3 tur_len values (a) and 4 tur_len values (b).

Important to mention:

- The exact dependence of the COSMO forecasts on its parameters is generally very complicated and not parabolic. Therefore, the parameter original definition, its logarithm or any other function of the parameter, all have the same "right to exist". So, generally, one may choose any function of the parameter which makes the parabolic fit more reasonable.
- For all the examples presented in Section 3, the parabolic fit to logarithm of the parameter yields much better results (not shown here).
- We do not use logarithm of tkhmin because its default value is located at the center of its allowed range [0 1 2].

4.2 The Meta-Model: solution to the noise problem

The simulated COSMO field $F_{i,r}$ should not be noisy as function of the parameters $[x_1, x_2, x_3]$. In other words, the sensitivity of $F_{i,r}$ on $[x_1, x_2, x_3]$ should be higher than the noise level. However, various COSMO fields are noisy for various parameters as was presented in Sections 2 and 3 above. As mentioned, for a given COSMO field $F_{i,r}$ one has to construct the 3D polynomial interpolation (12) as function of the parameters $[x_1, x_2, x_3]$. However, in case when one (or some) of the parameters yields noisy effect on $F_{i,r}$, for example x_1, the fit (12) will be problematic for 2 reasons:

- The fit (12) will not represent the true COSMO behavior in x_1 direction.
- The fit is performed using least mean squares method. The attempt to get the best fit in x_1 direction (which is noisy), may spoil the fit quality in the other directions (x_2, x_3), which are not noisy.

Therefore, we have implemented a new approach, which automatically detects the noisy parameter(s) for a given field/day/region, and neglects it (them) in the fitting formula (12).

The following steps are performed automatically:

- For a given field/day/region, a simple parabolic fit is performed (and the correlation R^2 is calculated) to each of the parameters separately.
- In case that R^2 is too low (we chose the threshold of 0.7), the noisy parameter is neglected in the fitting formula (12). For example, if for a given field/day/region, the parabolic fit for x_1 yields $R^2 = 0.4$, the fitting polynomial (12) will be reduced to:

$$F_{i,r} \cong F^d_{i,r} + c_{i,r} + a^{(2)}_{i,r} x_2 + B^{(2,2)}_{i,r} x_2^2 + a^{(3)}_{i,r} x_3 + B^{(3,3)}_{i,r} x_3^2 + B^{(2,3)}_{i,r} x_2 x_3 \qquad (14)$$

Consequently, the best possible fit will be constructed for each field/day/region. However, it is important to mention, that the effect of neglecting the noisy parameter plays an important role only in case when the response to the parameter variation is high (but noisy). However, usually when the response is high it is not noisy, and vice versa when the response is noisy, it is usually low. Therefore the procedure presented above, will usually play not significant role, but in some rare cases be, in contrast, very important.

4.3 The Meta-Model: additional constrain simulations

As was mentioned previously, the sufficient number of simulations for constructing the Meta-Model using formula (12) is $2N + 0.5N(N-1) + 1$, so that for N=3 the sufficient number of simulations to be performed is 10. However, it is obvious that adding more simulations, i.e. more parameter combinations, will better define the Meta-Model fit (12). According the theory for the parameters combinations design (Neelin et al., 2010 and Bellprat et al., 2012), it is important to perform **more than one interaction simulation** (simulation when 2 parameters are shifted to their minimum or maximum allowed values). For the 3 parameters *rlam_heat* $\in$ [0.1 1 10] , *tkhmin* $\in$ [0 1 2] , *tur_len* $\in$ [100 500 10000] the sufficient simulations are: [1 1 500], [0.1 1 500], [10 1 500], [1 0 500], [1 2 500], [1 1 100], [1 1 10000]; and 3 interaction simulations: [0.1 0 500], [0.1 1 100], [1 0 100].

In order to demonstrate the importance of additional simulations for the Meta-Model fit quality, Antigoni Voudouri (HNMS) performed also the following simulations:

- 7 additional interaction simulations: [10 2 500], [10 1 10000], [1 2 10000], [0.1 2 500], [10 0 500], [0.1 1 10000], [10 1 100]
- and 4 constrain simulations (changing the value of 1 parameter each time): [2 1 500], [4 1 500], [1 1.5 500], [1 1 2000].

From the simulations above, 2 Meta-Models were constructed. In order to verify their quality, additional test simulation was performed [3 0.5 750], which was not used for the Meta-Model fits. Fig. 27 shows a scatter plot for simulated precipitation (as an example), where each point represents one region at one day for the period 3-20.1.2008. The y-axis shows the Meta-Model estimation minus the reference (simulation with default parameters values), and the x-axis shows the COSMO simulation results minus the reference. In Fig. 27a the Meta-Model was constructed using the minimum number of simulations, while in Fig. 27b, the

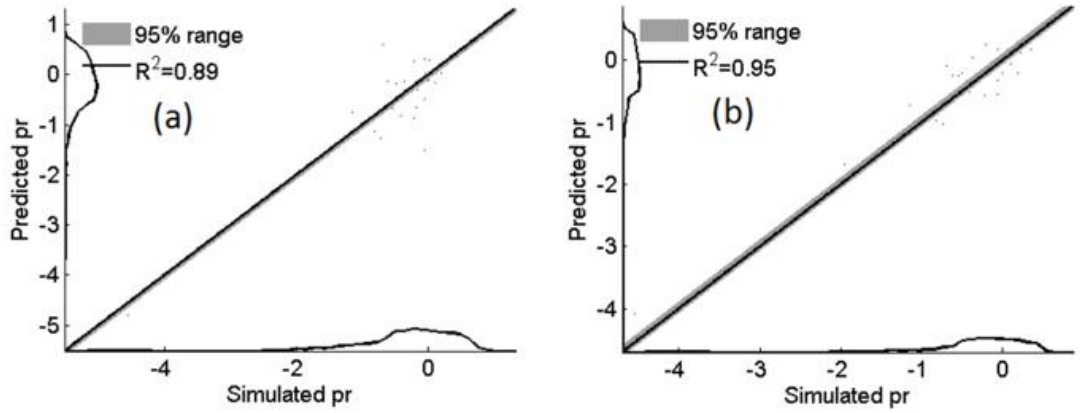

Figure 27: Estimating the Meta-Model quality for reproducing the precipitation field by comparing it with a test COSMO simulation for the period 3-20.1.2008. (a) The Meta-Model was constructed using the minimum number of simulations; (b) the Meta-Model was constructed using additional interaction and constrain simulations. In both axes, the REF simulation values were subtracted.

Meta-Model was constructed using additional simulations, as described above. Comparing the correlations ($R^2 = 0.89$ for case (a) and $R^2 = 0.95$ for case (b)), one can see a clear benefit for the Meta-Model quality when using additional simulations.

5 Performance score

After the Meta-Model is constructed, one has an estimation for the COSMO field $F_{i,r}$ for any day i and region r for any combination of the parameters [rlam_heat, tkhmin, tur_len]. The next step is to find the best parameters combination, i.e. the combination which yields $F_{i,r}$ forecasts which are the closest to the observations. In case only one field is verified, for example Tmax only, the general method is the following:

- Chose one combination of the parameters (here we define the combination index as p).
- Using the Meta-Model, calculate the forecast $F_{i,r}$ for every day and every region.
- Collect the observations $O_{i,r}$ for every day and every region.
- Calculate the RMSE for the given parameters combination:

$$(RMSE)_p = \sqrt{\frac{1}{N_{regs} N_{days}} \sum_{regions} \sum_{days} (F_{p,i,r} - O_{i,r})^2} \tag{15}$$

  Where: N_{regs} is the number of regions and N_{days} is the number of days.

- Calculate $(RMSE)_p$ for large number of parameters combinations (10000 in this report).
- Among all $(RMSE)_p$, find the parameters [rlam_heat, tkhmin, tur_len] combination which yields the minimal $(RMSE)_p$.

5.1 Normalization

The calculation presented above is not normalized, and therefore does not tell the whole story. The quality of COSMO forecast strongly depends on the region and the season. For example, the forecast with Tmax error of 5K in the Alps at winter may be actually better than with error of 3K in the Swiss Plateau at summer. Therefore one needs to normalize the forecast errors by a value which reflects the forecast complexity for a given day and region. However this value should not be dependent on any parameters combination, so normalization by typical forecast error is not appropriate. Therefore, we propose to normalize the forecast errors by the observations standard deviation σ_r at a given region r over a period of about a month (the period should not be too short in order to contain large enough sample, but not too long in order to represent the variability of a specific season):

$$\sigma_r = \sqrt{\frac{1}{N_{days}} \sum_{days} (O_{i,r} - \overline{O}_{i,r})^2} \tag{16}$$

Internal COSMO variability

There is an option to normalize also by internal COSMO variability adding it to σ_r (eq. 16 above). The COSMO forecast depends on the initial conditions, so that in principle, slightly different initial conditions may slightly change the forecast. Since the initial conditions are not perfectly defined, there is a hidden internal variability in the COSMO forecasts. This internal variability could be revealed by disturbing the initial conditions and calculating the forecasts standard deviation. However, currently this option is not available and is not used in this report.

5.2 Combined score for Tmax, Tmin and Precipitation

The final purpose of the CALMO project is to be able to find the parameters combination which improves the overall COSMO forecast. Therefore, the performance score should combine as many atmospheric fields as possible. Otherwise, there is a danger of choosing parameters combination which improves, for example, Tmax forecasts but spoil other important forecast fields. The first option is to use the following combination:

$$(RMSE)_{p,tot} = \sqrt{\frac{1}{N_{regs} N_{days}} \sum_{regions} \sum_{days} \left[\frac{(F_{Tmax,p,i,r} - O_{Tmax,i,r})^2}{\sigma^2_{Tmax,r}} + \frac{(F_{Tmin,p,i,r} - O_{Tmin,i,r})^2}{\sigma^2_{Tmin,r}} + \frac{(F_{Pr,p,i,r} - O_{Pr,i,r})^2}{\sigma^2_{Pr,r}} \right]} \tag{17}$$

The normalization by σ_r as presented above will cause the Tmax, Tmin and Pr terms to be dimensionless. However, these terms generally will have different weights. Here, there is a possibility for the user, to define these weights, i.e. to define which fields are more important to him to predict correctly. In this report we define the same weights for the 3 fields Tmax, Tmin and Pr. To do so, we normalize each term by its value averaged over all the parameters combinations, i.e.

$$W_F = \frac{1}{N_{comb}} \sum_{p} \left[\frac{1}{N_{regs} N_{days}} \sum_{regions} \sum_{days} \frac{(F_{p,i,r} - O_{i,r})^2}{\sigma^2_r} \right] \tag{18}$$

where: N_{comb} is the number of parameter combinations (10000 in this report).

Consequently, the final score used in this report is:

$$S_p = \sqrt{\frac{1}{N_{regs}N_{days}} \sum_{regions} \sum_{days} \left[\frac{(F_{Tmax,p,i,r} - O_{Tmax,i,r})^2}{W_{Tmax}\sigma^2_{Tmax,r}} + \frac{(F_{Tmin,p,i,r} - O_{Tmin,i,r})^2}{W_{Tmin}\sigma^2_{Tmin,r}} + \frac{(F_{Pr,p,i,r} - O_{Pr,i,r})^2}{W_{Tmin}\sigma^2_{Pr,r}} \right]} \tag{19}$$

which yields the same weights for the 3 fields Tmax, Tmin and Pr. For convenience, we define additional scores for each of the 3 fields separately:

$$S_{Tmax,p} = \sqrt{\frac{1}{N_{regs}N_{days}} \sum_{regions} \sum_{days} \frac{(F_{Tmax,p,i,r} - O_{Tmax,i,r})^2}{W_{Tmax}\sigma^2_{Tmax,r}}} \tag{20}$$

$$S_{Tmin,p} = \sqrt{\frac{1}{N_{regs}N_{days}} \sum_{regions} \sum_{days} \frac{(F_{Tmin,p,i,r} - O_{Tmin,i,r})^2}{W_{Tmin}\sigma^2_{Tmin,r}}} \tag{21}$$

$$S_{Pr,p} = \sqrt{\frac{1}{N_{regs}N_{days}} \sum_{regions} \sum_{days} \frac{(F_{Pr,p,i,r} - O_{Pr,i,r})^2}{W_{Pr}\sigma^2_{Pr,r}}} \tag{22}$$

The scores 20, 21, 22 will be used in Figs. 33 and 34 in Section 6 below.

At the next stage of the CALMO project we have to reconsider the score for precipitation, since RMSE type score is not optimal for that field. The general direction should be introducing a precipitation scores based of precipitation thresholds, like Fractions Brier Score. In addition, when the additional verified fields will be defined, such as sounding temperature and humidity profiles, we will have to formulate appropriate scores for these fields.

6 Results of parameters calibration

Following the discussion in Section 4, the Meta-Model was constructed for 3 COSMO fields Tmax, Tmin and Pr as function of the parameters [rlam_heat, tkhmin, tur_len], for the periods of 3-20.01.2008 and 2-20.06.2008, separately. In order to verify their quality, additional test simulation was performed [3 0.5 750], which was not used for the Meta-Model fits. Figs. 28 and 29 show scatter plots for simulated Tmax (left panels), Tmin (centered panels) and Pr (right panels), where each point represents one region at one day, for the periods of 3-20.01.2008 and 2-20.06.2008, respectively. The y-axes show the Meta-Model estimation minus the reference (simulation with default parameters values), and the x-axes show the COSMO simulation results minus the reference. For the tested parameter combination, the correlations R^2 between the COSMO forecasts and the Meta-Model estimations are generally high. Consequently, the overall method seems to prove itself: one can use the Meta-Model to reproduce COSMO forecasts for various parameters combinations.

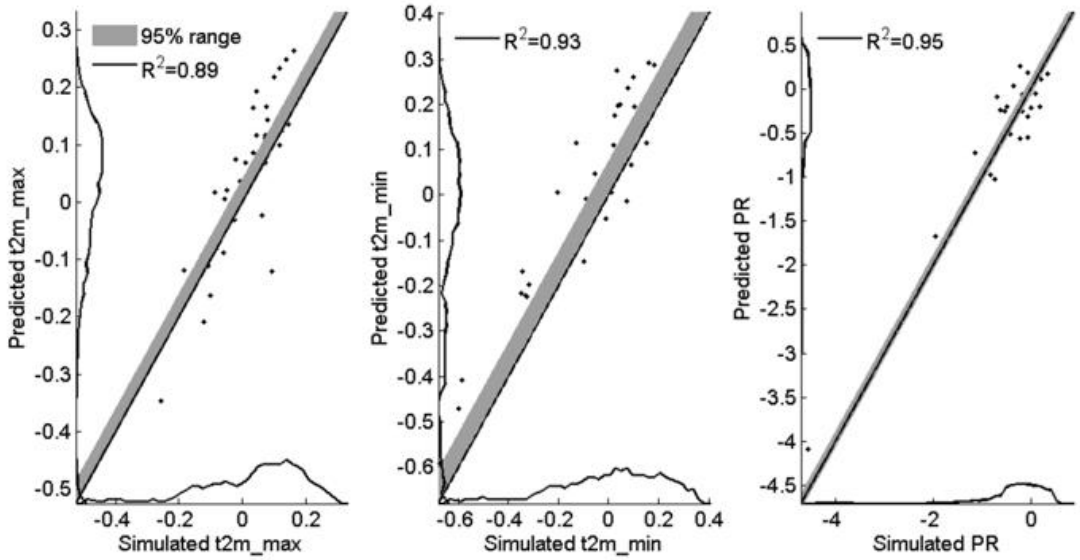

Figure 28: Estimating the Meta-Model quality for reproducing Tmax (left panel), Tmin (centered panel) and Precipitation (right panel) fields, by comparing them with a test COSMO simulation for the period 3-20.1.2008. In both axes, the REF simulation values were subtracted.

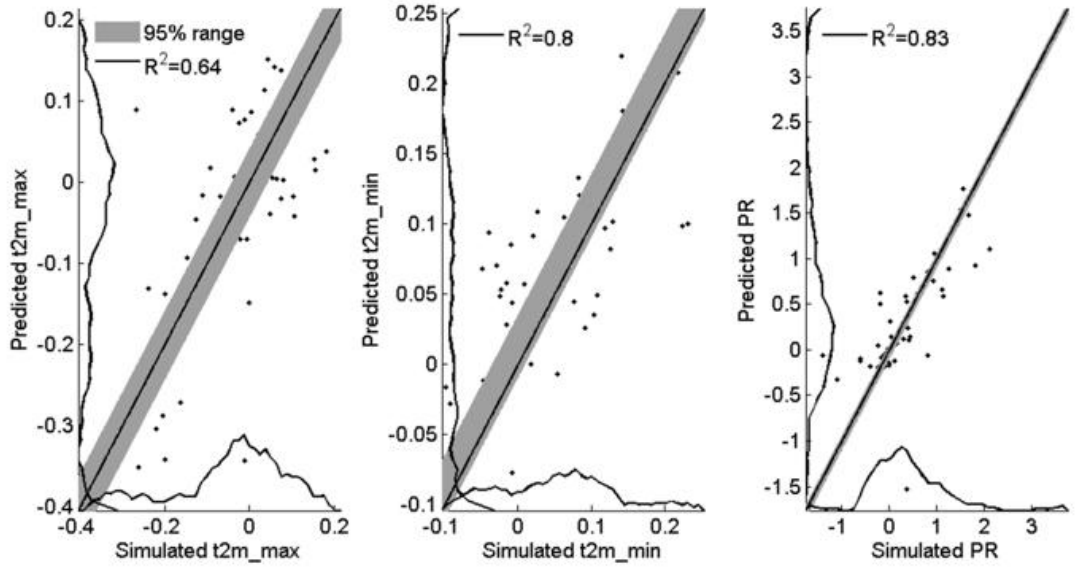

Figure 29: Estimating the Meta-Model quality for reproducing Tmax (left panel), Tmin (centered panel) and Precipitation (right panel) fields, by comparing them with a test COSMO simulation for the period 2-20.6.2008. In both axes, the REF simulation values were subtracted.

In order to analyze the general contributions of the various parameters to the constructed Meta-Model, we have calculated the normalized (by their standard deviation) and averaged (over fields, days and regions) linear, quadratic and interaction coefficients in the formula 12. These contributions are presented in Fig. 30 for the periods 3-20.01.2008 (left panel) and 2-20.06.2008 (right panel), respectively. One can see that generally tur_len and rlam_heat are more dominant in the Meta-Model than tkhmin. This result is physically expected, since in contrast to the other parameters, tkhmin plays a significant role only in highly stable atmospheric conditions, and therefore is important mainly for Tmin but not Tmax and precipitation.

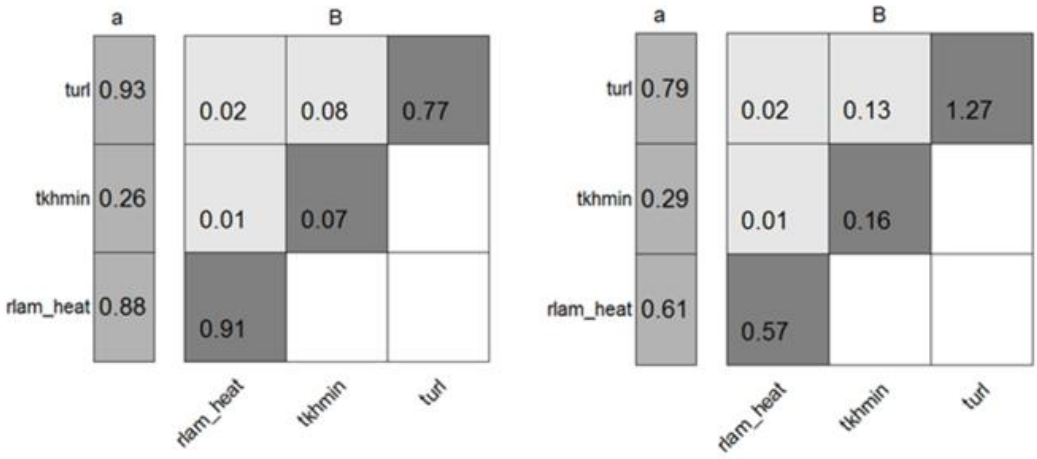

Figure 30: Contributions of the various parameters to the constructed Meta-Model. The presented linear, quadratic and interaction coefficients in the formula 12 were normalized (by their standard deviation) and averaged (over fields, days and regions). These contributions are presented for the periods 3-20.01.2008 (left panel) and 2-20.06.2008 (right panel), respectively.

Following the discussion in Section 5, we have used the Meta-Model to calculate the overall score S_p (see eq. 5.2) for any given parameters combination. Figs. 31 and 32 present the contours of S_p deviation, i.e. $S_p - \overline{S}_p$, for pairwise parameters combinations only, for the periods of 3-20.01.2008 and 2-20.06.2008, respectively. The upper panels represent rlam_heat and tkhmin combinations (while keeping tur_len default); the centered panels represent rlam_heat and tur_len combinations (while keeping tkhmin default); the lower panels represent tur_len and tkhmin combinations (while keeping rlam_heat default). The lower is the S_p deviation value, the better is the score, and the better is the specific parameters combination for the forecast quality. One can see, that for improving the forecast during January 2008 (Fig. 31), the tur_len has to be relatively high, rlam_heat as high as possible, and tkhmin as low as possible. On June 2008 (Fig. 32), all the 3 parameters should be as low as possible.

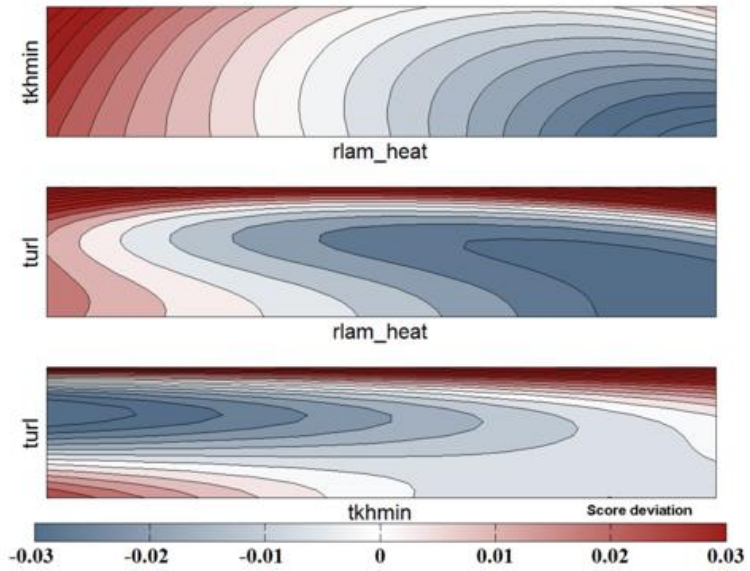

Figure 31: Contours of S_p (see eq. 5.2) deviation, i.e. $S_p - \overline{S}_p$, for pairwise parameters combinations only, for the period of 3-20.01.2008. The upper panel represents rlam_heat and tkhmin combinations (while keeping tur_len default); the centered panel represents rlam_heat and tur_len combinations (while keeping tkhmin default); the lower panel represents tur_len and tkhmin combinations (while keeping rlam_heat default). The lower is the S_p deviation value, the better is the score, and the better is the specific parameters combination.

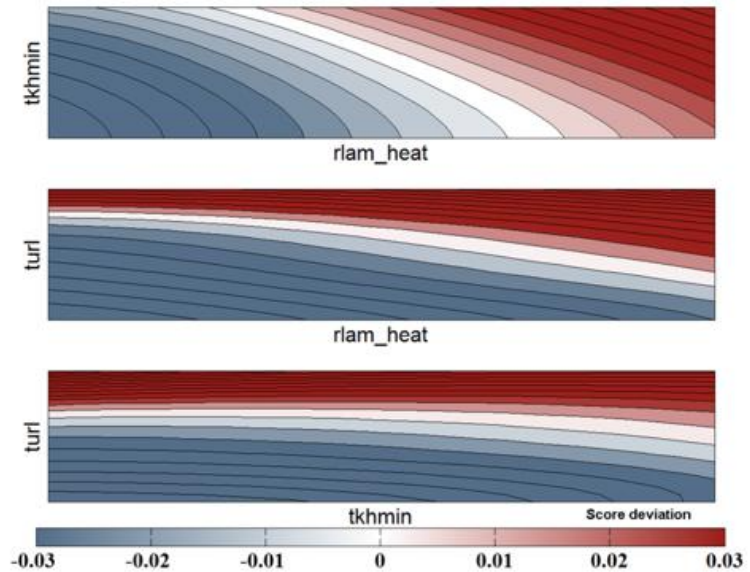

Figure 32: Same as Fig. 31 but for the period of 2-20.06.2008.

In order to analyze the origin of these results, we present similar plots for the 3 fields Tmax, Tmin and Pr, separately, using the scores 20, 21, 22 on Fig. 33 for 3-20.01.2008 and on Fig. 34 for 2-20.06.2008. Starting with the wintertime (3-20.01.2008) presented in Fig. 33, one can see the expected parameters dependencies:

a As discussed in Section 3.2, COSMO forecasts generally underestimate Tmax, so we expect the scores to be better for higher Tmax forecasts. As discussed in Section 2, higher tur_len, higher tkhmin and higher rlam_heat (on wintertime stable conditions), all lead to higher Tmax forecasts. That explains the results of the left panels on Fig. 33.

b As discussed in Section 3.3, COSMO forecasts generally overestimate Tmin, so we expect the scores to be better for lower Tmin forecasts, i.e. exactly the opposite of Tmax case. Consequently, lower tur_len, lower tkhmin and lower rlam_heat should lead to better Tmin forecasts. That explains the results of the centered panels on Fig. 33.

c As discussed in Section 3.4, COSMO forecasts generally overestimate precipitation, so we expect the scores to be better for lower precipitation forecasts. As discussed in Section 2, lower tur_len should decrease precipitation, tkhmin should be not significant, and higher rlam_heat may decrease precipitation (spoiling wintertime stable conditions). That explains the results of the right panels on Fig. 33, where we clearly see the advantage of low tur_len and high rlam_heat.

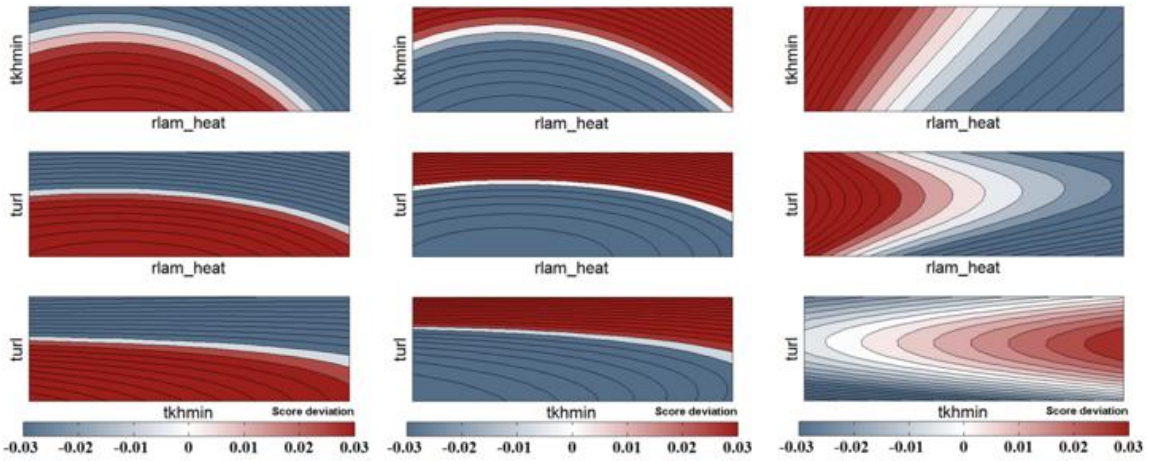

Figure 33: Contours of $S_{Tmax,p}$ (see eq. 20) deviation (left panels), $S_{Tmin,p}$ (see eq. 21) deviation (centered panels), and $S_{Pr,p}$ (see eq. 22) deviation (right panels), for pairwise parameters combinations, for the period of 3-20.01.2008. The upper panels represent rlam_heat and tkhmin combinations (while keeping tur_len default); the centered panels represent rlam_heat and tur_len combinations (while keeping tkhmin default); the lower panels represent tur_len and tkhmin combinations (while keeping rlam_heat default). The lower are the scores deviation values, the better is the specific parameters combination for the forecast quality.

For the summertime (2-20.06.2008) presented in Fig. 34, one can again see the expected parameters dependencies:

d Regarding Tmax and Tmin, the results are generally similar to the wintertime. However, the increase of rlam_heat at summer day, may reduce the low levels heating (by

the warm soil), leading to unwanted decrease in Tmax. That explains the slight difference of the Tmax dependence on rlam_heat between the wintertime (Fig. 33 left panels) and the summertime (Fig. 34 left panels).

e As discussed in Section 3.4, COSMO summertime forecasts highly overestimate precipitation, so we expect the scores to be better for lower precipitation forecasts. As discussed in Section 2, lower tur_len should highly decrease convective precipitation (typical to summertime), and tkhmin should be not significant. That exactly explains the results of the right panels on Fig. 34, where we clearly see the advantage of low tur_len. However, the low rlam_heat preference, as can be seen on Fig. 34 right panels, is not understood at this stage.

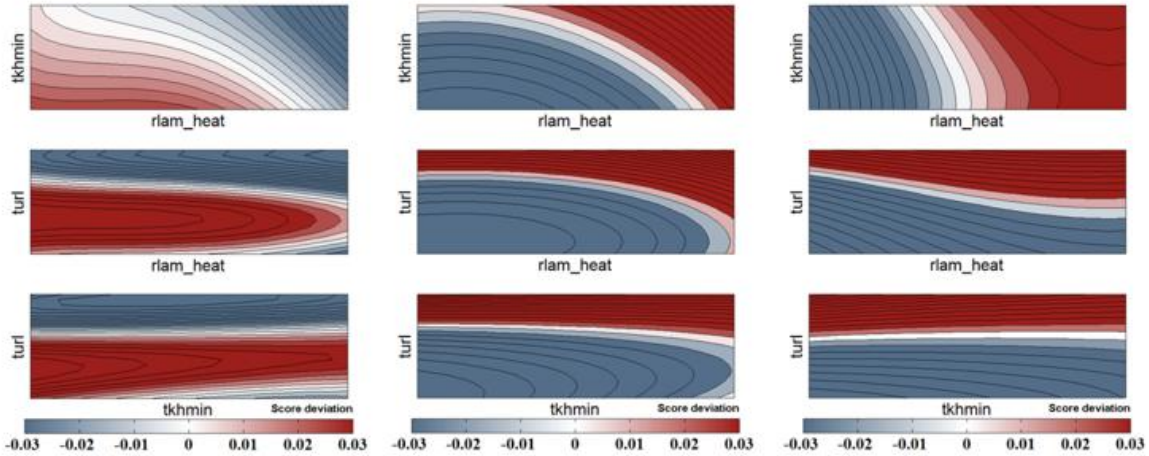

Figure 34: Same as Fig. 33 but for the period of 2-20.06.2008.

At the next stage of the calibration procedure, the S_p scores were calculated for 10000 parameters combinations, filling the parameters space in a Latin Hypercube design (Bellprat et al., 2012). Figs. 35a (for 3-20.01.2008) and 35b (for 2-20.06.2008) present S_p scores distributions, together with the score of the reference (REF) simulation (obtained using default values for all the parameters). For convenience, the distributions are presented as function of $\widetilde{S_p} = 1 - (S_p/S_{p,ref})$, so that:

- $\widetilde{S_p} < 0$ means that the score is worse than of the REF simulation;
- $\widetilde{S_p} = 0$ means that the score is equal to the REF simulation;
- $0 < \widetilde{S_p} < 1$ means that the score is better than of the REF simulation (1 is the best possible score).

One can see that definitely there are parameters combinations which should yield better forecasts than the current default parameter values (REF simulation). On summertime (Fig. 35b), the default parameters combination seems to be already well chosen (on the tail of the scores distribution), so by choosing different parameters combination, we can improve the forecast only slightly. However, on wintertime (Fig. 35a), there is a big range of parameter combinations which would significantly improve the forecast.

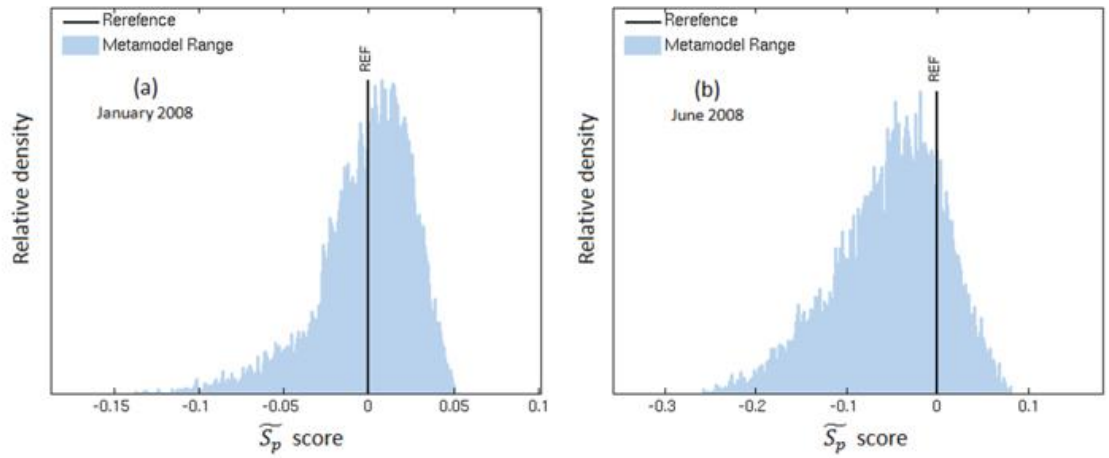

Figure 35: S_p scores distributions (for 10000 parameter combinations), together with the score of the reference (REF) simulation, for the period 3-20.01.2008 (a) and 2-20.06.2008 (b). For convenience, the distributions are presented as function of $\widetilde{S_p} = 1 - (S_p/S_{p,ref})$, so that the higher is $\widetilde{S_p} > 0$ means that the score is better than of the REF simulation.

7 Conclusions and considerations towards the next stage of CALMO project

Finally, the optimal parameters combinations for January and June 2008 were defined, and are presented in Table 1:

	rlam_heat [0.1 **1** 10]	tkhmin [0 **1** 2]	tur_len [100 **500** 10000]
January 2008	8.22	0.02	1037
June 2008	0.17	0.02	102

Table 1: Optimal parameters combinations for January and June 2008.

Antigoni Voudouri performed COSMO simulations with the optimal parameters combinations for January and June 2008. Figs. 36a (for 3-20.01.2008) and 36b (for 2-20.06.2008) present S_p scores distributions, together with the scores of the reference (REF) simulation and of the optimal parameters (Best) simulation.

From Fig. 36, one can see that the Best simulation indeed improved the forecasts comparing to the REF simulation! **This result is very encouraging, showing that the Meta-Model is able to reproduce the COSMO simulations in parameters space, and therefore can be used to calibrate the COSMO model.** It is also interesting, that the COSMO simulation score for the Best simulation is indeed very close to the Best possible score estimated by the Meta-Model. Pirmin Kaufmann (MeteoSwiss) performed the verifications of the optimal parameters simulation in comparison with the REF simulation, using the official MCH procedure. Generally, these verifications also show the advantage of the Best COSMO simulation over the REF simulation. Highlights of these verifications are presented in Section 11.

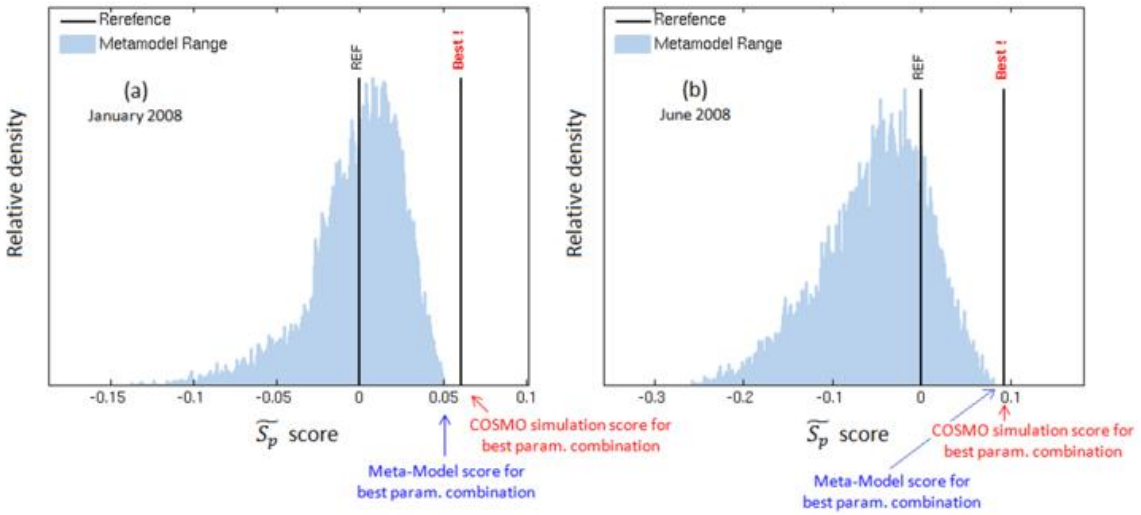

Figure 36: S_p scores distributions (for 10000 parameter combinations), together with the score of the reference (REF) simulation, and the optimal parameters (Best) simulation, for the period 3-20.01.2008 (a) and 2-20.06.2008 (b). For convenience, the distributions are presented as function of $\widetilde{S_p} = 1 - (S_p/S_{p,ref})$, so that the higher is $\widetilde{S_p} > 0$ means that the score is better than of the REF simulation. Best simulation indeed improved the forecasts comparing to the REF simulation!

Considerations towards the next stage of CALMO project

The optimal parameters combinations are very different between January and June 2008, which is generally unwanted. The following actions may improve the results and make them more reliable:

- For each of the verified fields, we have to choose (to calibrate) the **specific parameters which are the most significant for these fields**. For Tmax we may need to focus on soil and radiation schemes parameters, while for precipitation, we may need to consider also microphysical parameters, etc.
- It is important to **extend the set of verified fields** to include sounding profiles of temperature and humidity, integrated water vapor, etc. Otherwise, there is a danger of choosing parameters combination which improves, for example, Tmax forecasts but spoil other important forecast fields.
- It is important to **extend the tested periods** for at least several months. Currently the periods were definitely too short, which makes the results less reliable.
- Presumably, different parameters combinations should improve the COSMO forecast at different seasons (as shown above). Therefore, one could think of possibility to automatically modify the operational COSMO parameters on different seasons (and even for different parts of the domain), however these ideas stand beyond the scope of the CALMO project.

It is however important to mention, that even without performing the steps above, **we showed that the calibration method works and the Meta-Model is generally able to reproduce the COSMO forecasts**. In principle, it is reasonable to perform the COSMO simulation with the selected parameters combination for different periods

(which were not used to construct the Meta-Model), for example January and June but at a different year. That would be a final approval whether the forecasts are indeed better (than with default parameters combination).

8 The Terra standalone (TSA) soil scheme for the CALMO project

As part of the next stage of the CALMO project, it is planned to calibrate parameters from the COSMO soil scheme Terra, for example the hydraulic soil conductivity. In contrast to the regular COSMO parameters, the change in Terra parameters affects the COSMO forecasts with a significant delay (up to several years) via slow adaptation of the soil temperature and moisture profiles. Therefore, in order to calibrate the Terra parameters for specific year (2013 for example), one has to make the parameter changes several years earlier, and run the COSMO model in a cycle, slowly adapting the soil profiles to the parameter change. Moreover, errors in soil profiles caused by interpolation of soil fields from a coarse model disappear slowly, also on the scale of several years. Therefore, in order to obtain appropriate initial conditions in the soil (without interpolation errors), one again has to make the interpolation of soil fields several years earlier, and run the COSMO model in a cycle, slowly "forgetting" the interpolation errors. However, performing several years pre-run of the COSMO model (in a cycle mode) is computationally expensive. Instead, it is decided to use the Terra "standalone" (TSA) program driven by COSMO atmospheric analyses (from MeteoSwiss archive). The method is to initialize soil profiles from a coarse model interpolation, change the parameters of TSA (if needed), and run it for several years (prior to the tested year). Then, the obtained soil profiles will be installed as initial soil conditions for the COSMO model runs (for the tested year). With the great support from Jean-Marie Bettems (MeteoSwiss), Guy de Morsier (MeteoSwiss) and Julian Todter (Frankfurt University), we have run TSA for 3 years (2010-2012) with resolutions of 2.2 and 1.1 km (currently for the default soil parameters configuration), and prepared the soil initial conditions for the COSMO runs at the next stage of the CALMO project.

9 Appendix A: Transform of the 2m-temperature observations to the model grid

The 2m-temperature daily-mean, maximum and minimum observations data over Switzerland was originally transformed to a 2km-grid by C. Frei (MeteoSwiss), following the method described in Frei (2012). This 2km-grid (original grid) has a real (not smoothed) topography. In order to compare the 7km COSMO model results with the observations, one had first to transform the 2m-temperature observations data to the 7km **smoothed** topography grid of the COSMO model (target grid). Following the recommendation of C. Frei, the chosen method was the following:

a For every grid point in the target grid (red dot on Fig. 37) find the nearest 9 neighbors on the original grid (blue dots on Fig. 37).

b Plot the 2m-temperature values of these neighbors vs. their altitude (blue and red X on Fig. 38).

c Perform a linear fit of the data, which will be the local 2m-temperature profile.

d Having the altitude of the target grid point use the obtained linear regression to calculate its 2m-temperature.

e Perform this operation (a-d) for every target grid point, for every day.

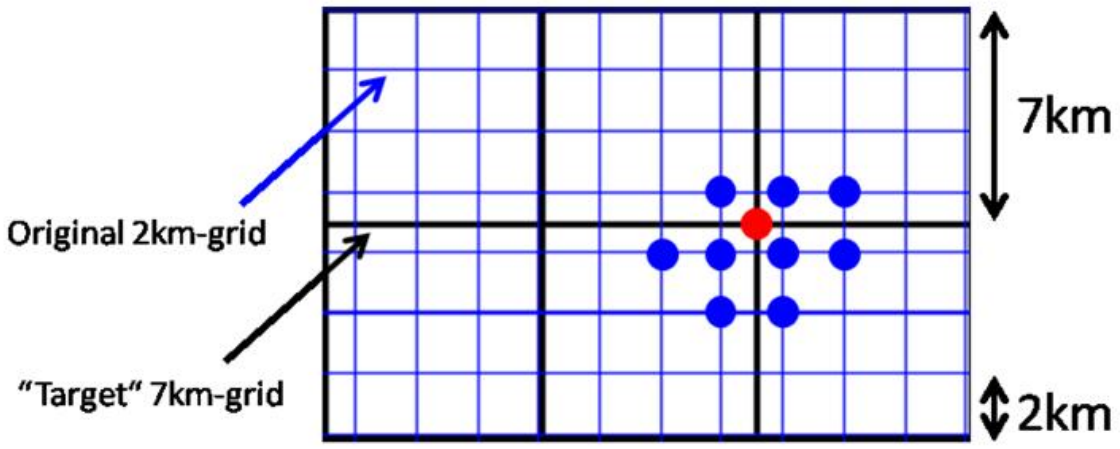

Figure 37: Transform of 2m-temperature observations from the original 2km-grid with the real topography to a target 7km-grid with a smoothed topography.

An example for the calculation of the measured 2m-temperature at a target grid point (Lat=46.07°/Lon=7.49°) on 10.01.2008 is presented on Fig. 38.

This example shows the following:

- The correction to the measured temperature (from the old method of interpolation used before to the new one) is important, of the order of several degrees Kelvin (-2K in this example).
- The local 2m-temperature profile is indeed linear (the results are similar for other regions and other days).

- The local 2m-temperature vertical gradient is unique (-5.8K/km in this example) for a given grid point area for a given day.

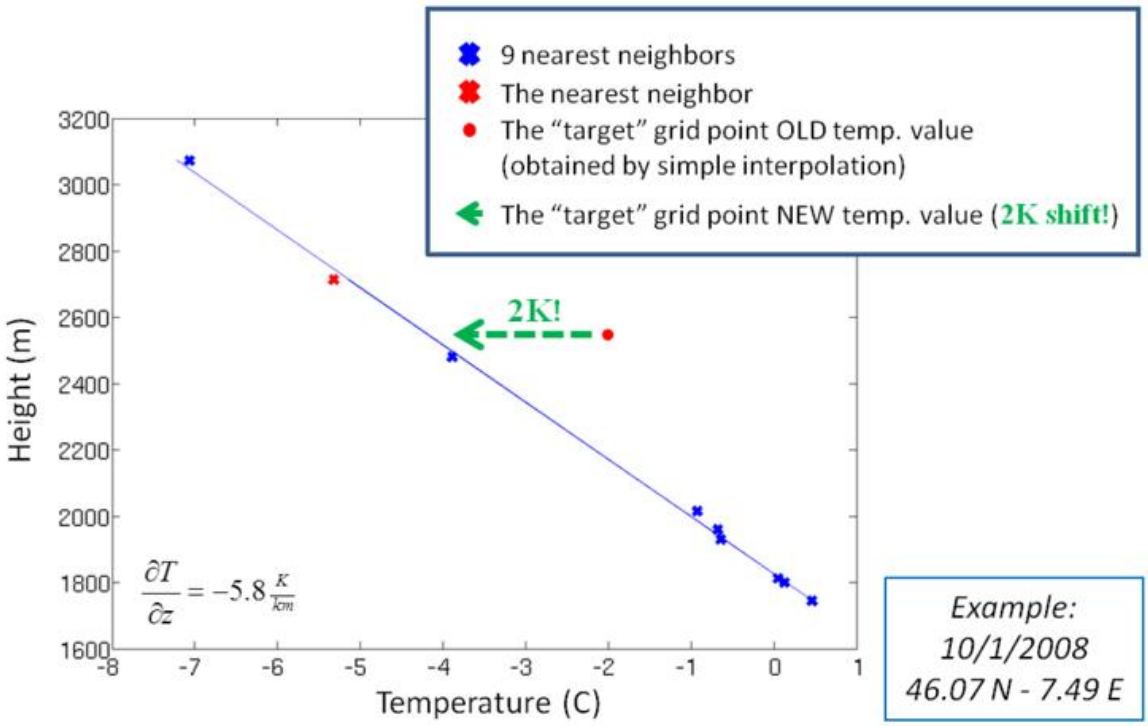

Figure 38: An example for the calculation of the measured 2m-temperature at a target grid point (Lat=46.07°/Lon=7.49°) on 10.01.2008.

10 Appendix B: Examples of stable and unstable conditions over Switzerland

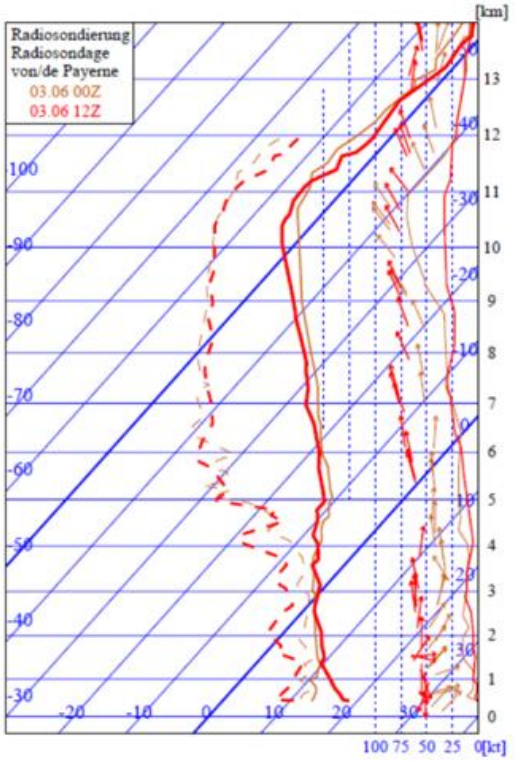

Figure 40: The unstable low level stratification on 03.06.2008 (reference from Section 3). MeteoSwiss radiosounding site at Payerne, Switzerland.

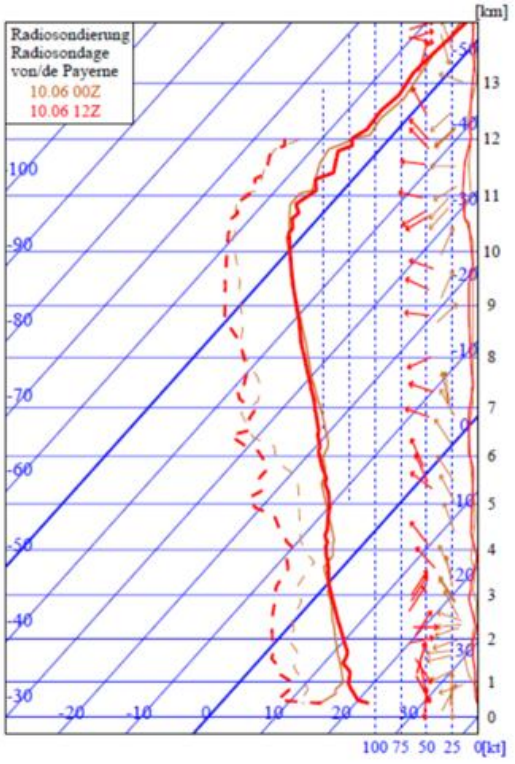

Figure 41: The stable low level stratification during night of 10.06.2008 (reference from Section 3). MeteoSwiss radiosounding site at Payerne, Switzerland.

11 Appendix C: MCH verification results for the optimal parameters simulation

Pirmin Kaufmann (MeteoSwiss) performed the verifications of the optimal parameters Best simulation in comparison with the REF simulation, using the official MCH procedure, for the periods of 2-20/1/2008 and 2-20/6/2008. Generally, these verifications show the advantage of the Best COSMO simulation over the REF simulation. Several highlights of these verifications are presented below, for the following verification domain (Fig. 42):

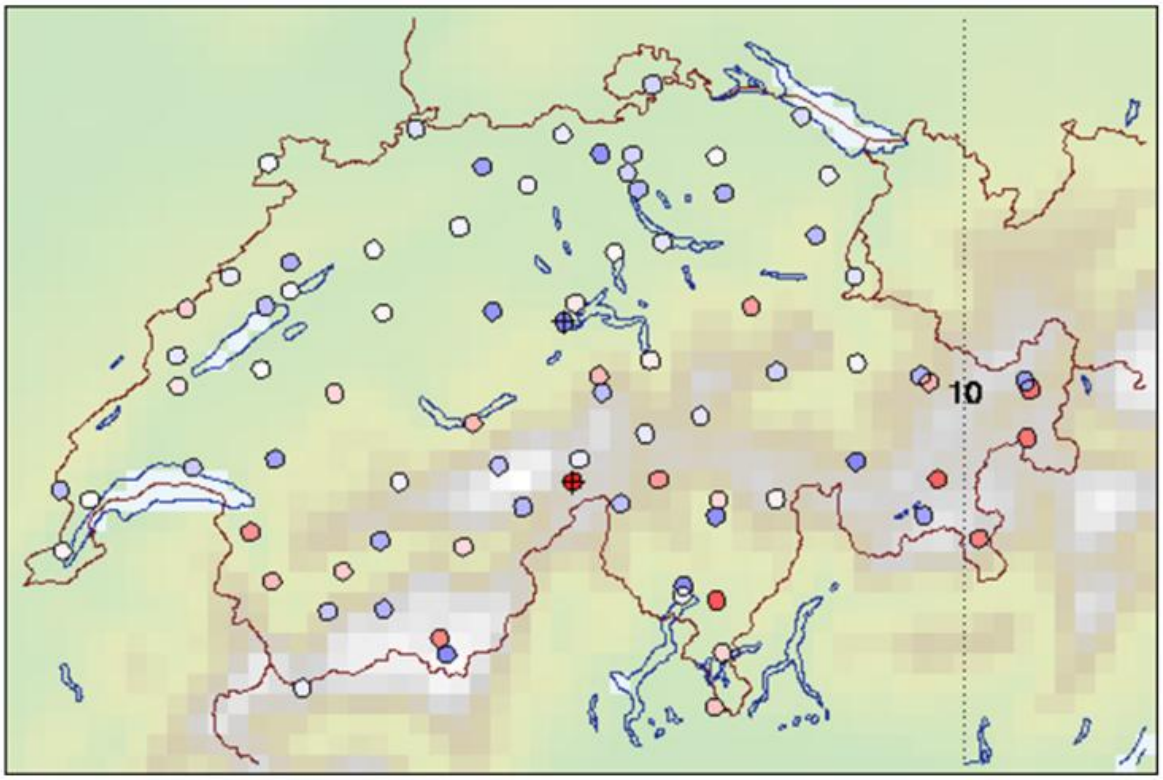

Figure 42: Verification domain.

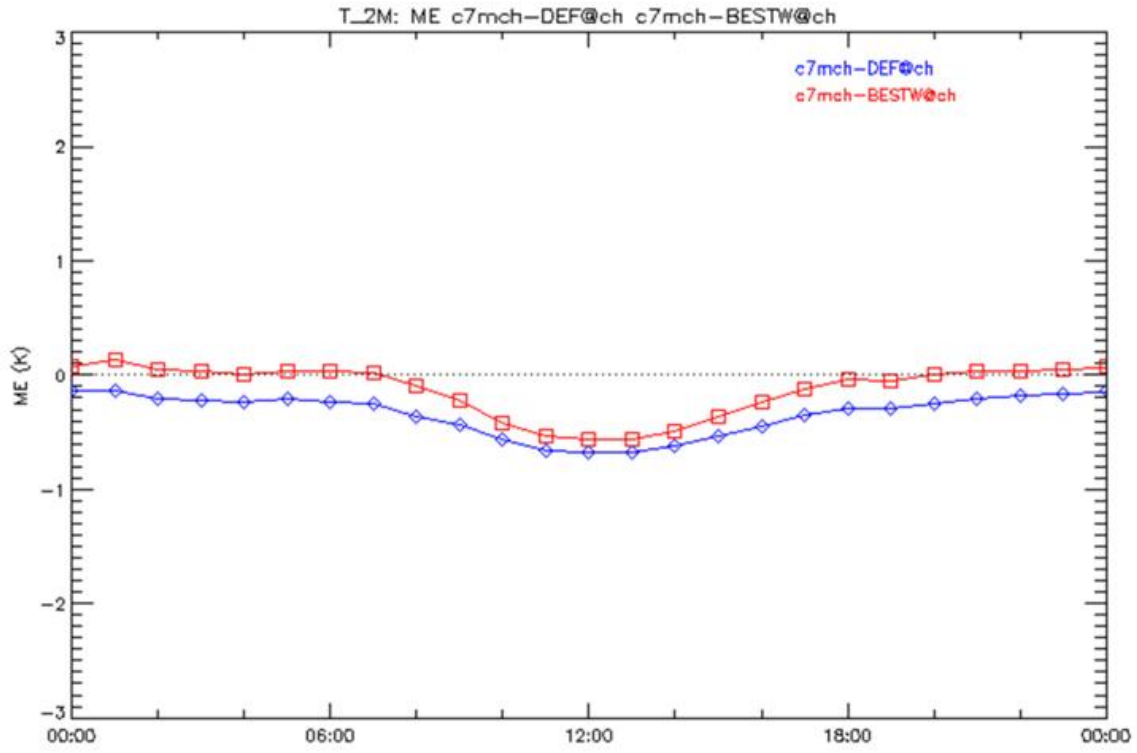

Figure 43: 2m-temperature diurnal cycle mean error for the REF (blue) and the Best (red) simulations, for the period 2-20/1/2008. The Best simulation is clearly better than REF simulation.

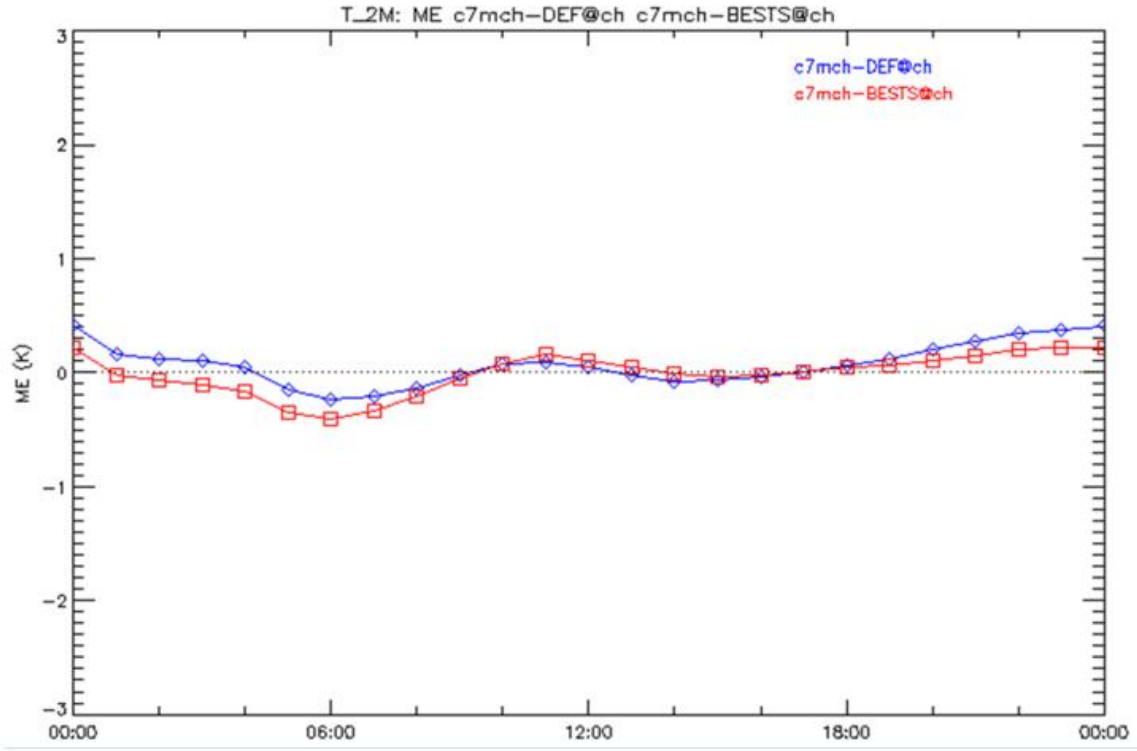

Figure 44: 2m-temperature diurnal cycle mean error for the REF (blue) and the Best (red) simulations, for the period 2-20/6/2008. The Best and REF simulations are of similar quality.

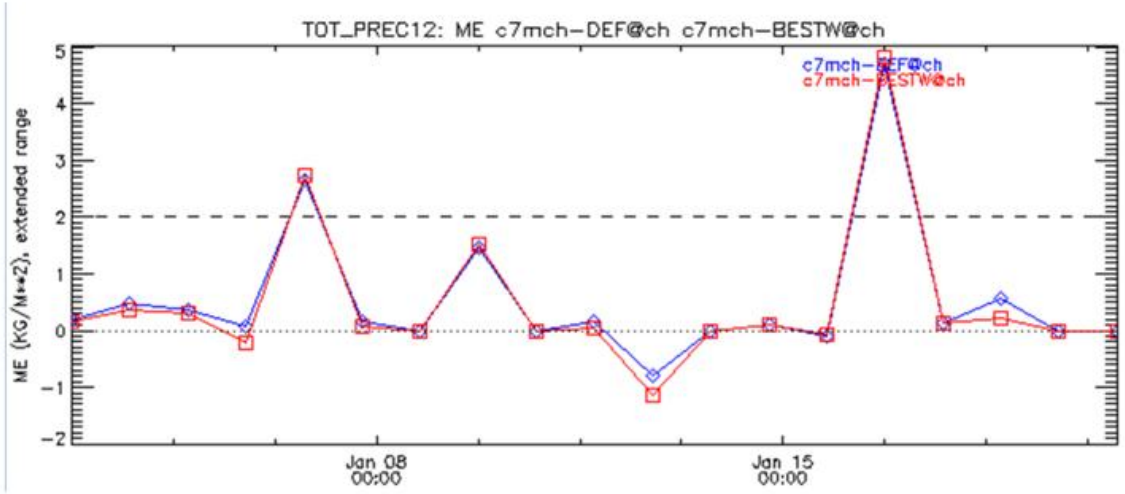

Figure 45: Mean error time series of the 12h accumulated precipitation for the REF (blue) and the Best (red) simulations, for the period 2-20/1/2008. The Best and REF simulations are of similar quality.

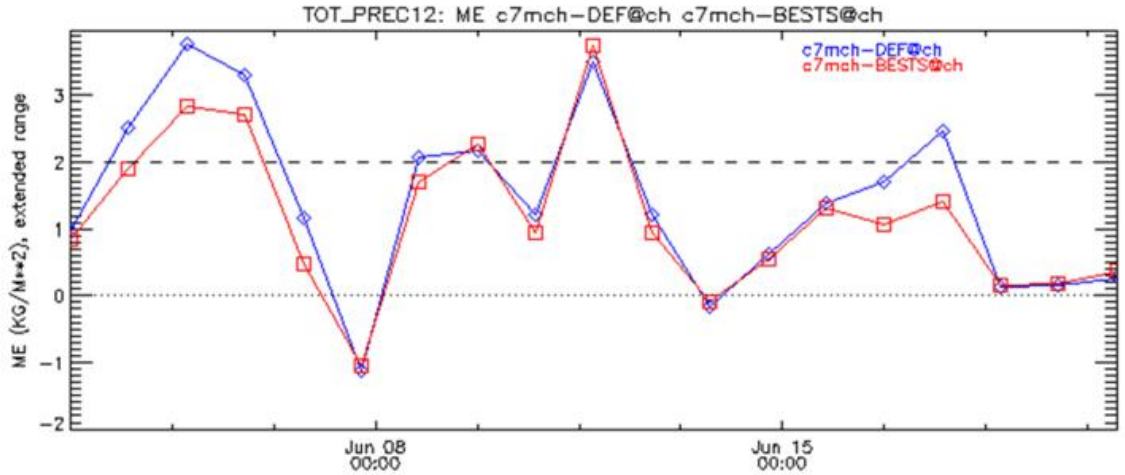

Figure 46: Mean error time series of the 12h accumulated precipitation for the REF (blue) and the Best (red) simulations, for the period 2-20/6/2008. The Best simulation is clearly better than REF simulation.

Acknowledgments

The CALMO project is based on the objective calibration method which was developed and implemented in regional climate model by Omar Bellprat and Christoph Schär (ETH). Special thanks to Omar Bellprat for providing the calibration code framework. The figures in Section 6 are based on the plots of Bellprat (2012). We are grateful for the support from and valuable discussions with Yoav Levi (head of R&D at IMS), Alon Shtivelman (IMS), Yitzhak Yosef (IMS), Simon Krichak (TAU), Guy de Morsier (MeteoSwiss), Oliver Fuhrer (MeteoSwiss), Marco Arpagaus (MeteoSwiss), Julian Tödter (GUF), and Ines Cerenzia (ARPA-EMR). We are thankful to Pirmin Kaufmann (MeteoSwiss) for performing the verifications of the optimal parameters simulation using the official MCH procedure and to Massimo Milelli (ARPA Piemonte) for the work he performed editing this report.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW) and Romania (NMA). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

Abstract

A tracer module is implemented in the COSMO model in version 5.0 and higher. This model component offers a set of functionalities commonly required for the treatment of new prognostic variables (tracers) like memory management, input and output support or the computation of advective transport. It allows for a simplified introduction of tracers into the COSMO code, for a coherent treatment of tracers and for a well-structured code without redundancies. Application of this module may range from the tracing of air masses to the handling of microphysics species or aerosols.

1 Introduction

Water in all phases and various isotopic forms, volatile chemical compounds, radionuclides or aerosols are all important components of our atmosphere. The adequate representation of these tracers is thus a crucial theme for atmospheric modeling.
We use the term *tracer* to designate any substance present in the atmosphere as a trace constituent and which can be transported passively, i.e. without influencing the flow (except if the user chooses to implement a coupling term).

A consistent and flexible treatment of tracers in atmospheric models becomes increasingly important as the complexity of these models augments by the introduction of new submodules describing additional processes and implying the consideration of additional species and even including other environmental compartments. A clear trend in the extension of atmospheric models towards Earth's system models has been observed in the past decades. All atmospheric models which have made important steps into this direction handle tracers in general modules providing basic functionalities like memory management or advective transport to the submodules (hereafter called tracer clients) (e.g. Rast, 2009). Example of tracer clients are the microphysics, atmospheric chemistry modules, etc.

Traditionally, adding a new tracer variable into COSMO required extensive and tedious code modifications, since all tracers were treated as individual variables. The result was abundant code redundancy, bugs and inconsistencies in the treatment of the individual tracers. The general tracer module described here should facilitate extensions of the COSMO model by providing a comprehensive API (Application Programming Interface) to the tracer client. Consistency in the tracer treatment is promoted through the unity of the code describing a given process (e.g. advection). This also simplifies code maintenance and introduction of new features.

In this technical report a general description of the new tracer module can be found in section 2. A short user's guide explains how to use the tracer module by showing concrete examples (section 3) whereas section 4 provides some technical details on the implementation for model developers. Section 5 presents the results obtained with the tracer enabled version. Issues that might arise with this version are discussed in section 6 and conclusions are drawn in section 7.

2 Description of the tracer module

The tracer module consists in four new source code files, `src_tracer.f90`, `data_tracer.f90`, `src_tracer_metadata.f90`, `data_tracer_metadata.f90`. Extensive modifications to the existing COSMO source code files had to be performed as well, changing the programming paradigm based on individual variables for an automated treatment of the species (by looping over all tracers). in order to bring the required functionalities (see section 2.2) in an automated form for the tracers.

The tracer API is a collection of few subroutines and functions that can be called by the tracer client from any part of the COSMO code. They serve to define and retrieve tracers as well as their corresponding metadata (attributes storing information about the tracers). All subroutines and functions which can be called by the tracer client are located in the source file `src_tracer.f90` and are described in detail in section 2.3. Useful named constants are made available in the `data_tracer.f90` module. The source code files `src_tracer_metadata.f90` and `data_tracer_metadata.f90` contain low-level functions for handling metadata and are not called directly by the tracer client.

Basic information about the tracer (metadata) such as its name or the operations it has to undergo (e.g. advection, turbulent mixing, etc.) has to be passed to the tracer module upon definition of a new tracer. This is the so-called set of standard metadata. A short description of the mandatory standard metadata and of the optional standard metadata is provided in table 1 and table 2 respectively. No default value is provided for the mandatory metadata whereas the default value is used for the optional standard metadata if the user provides no specification of these items.

Table 1: Basic set of standard metadata: mandatory items

Identifier	**Type**	**Definition**	**Default value**
T_NAME_ID	CHAR	Tracer name	-
T_GRBPARAM_ID	INT	GRIB parameter number	-
T_GRBTABLE_ID	INT	GRIB table number	-
T_PARENT_ID	CHAR	Parent subroutine name (subroutine which defines the tracer)	-
T_UNITS_ID	CHAR	Units	-

Table 2: Basic set of standard metadata: optional items

Identifier	Type	Definition	Default value
T_NCSTDNAME_ID	CHAR	Standard name	"undefined"
T_NCLONGNAME_ID	CHAR	Long name	"undefined"
T_ADV_ID	INT	Do advection? Options: - T_ADV_OFF: no advection - T_ADV_ON: advection	T_ADV_OFF
T_DIFF_ID	INT	Do horizontal hyperdiffusion? Options: - T_DIFF_OFF: no horiz. hyperdiffusion - T_DIFF_ON: horiz. hyperdiffusion	T_DIFF_OFF
T_TURB_ID	INT	Do turbulent mixing? Options: - T_TURB_OFF: no turbulent mixing - T_TURB_1D: vertical turb. mixing - T_TURB_3D: 3-dimensional turb. mixing	T_TURB_OFF
T_CONV_ID	INT	Do passive convective transport? Options: - T_CONV_OFF: no passive convective transp. - T_CONV_ON: passive convective transp.	T_CONV_OFF
T_INI_ID	INT	Type of initial condition Options: - T_INI_ZERO: initialize to zero - T_INI_FILE: initialize using data from file	T_INI_ZERO
T_LBC_ID	INT	Type of lateral boundary condition Options: - T_LBC_ZERO: zero value - T_LBC_FILE: values read from file - T_LBC_CST: constant value - T_LBC_ZEROGRAD: zero-gradient condition	T_LBC_ZERO
T_BBC_ID	INT	Type of bottom boundary condition Options: - T_BBC_ZEROFLUX: zero flux condition - T_BBC_ZEROVAL: zero value condition - T_BBC_SURF_VAL: values provided in a surface field	T_BBC_ZEROFLUX
T_RELAX_ID	INT	Do boundary relaxation? Options: - T_RELAX_OFF: no relaxation - T_RELAX_FULL: relaxation at all boundaries - T_RELAX_INFLOW: relaxation at inflow boundary only	T_RELAX_FULL
T_DAMP_ID	INT	Do Rayleigh damping? Options: - T_DAMP_OFF: no damping - T_DAMP_ON: damping	T_DAMP_ON
T_CLP_ID	INT	Do clipping? Options: - T_CLP_OFF: no clipping - T_CLP_POSDEF: clipping	T_CLP_OFF

2.1 Assumptions

Some basic assumptions have been made about the tracers in order to keep a concise tracer API and ensure a uniform tracer treatment.

The tracers are scalar, 3-dimensional prognostic (i.e. time dependent) variables defined on the full model grid. They are defined along the three main spatial dimensions (rotated longitude `rlon`, rotated latitude `rlat`, model level `level`) of the COSMO grid. The tracers live at the mass-point (center of the grid box) collocated with temperature and pressure (`rlon, rlat, level`). It is not possible to have tracers on the staggered positions of the Arakawa-C/Lorenz COSMO grid (Schättler et al. 2011 or Doms 2011).

2.2 Functionalities of the tracer module

All basic functionalities which are common to all tracers as for example the allocation of the memory and transport by advection are provided. In a broad sense, the tracer module handles the infrastructure operations (related to the definition, the storage and the input/output of a variable) and the operations related to what is referred in COSMO as the "dynamics" (Schättler et al., 2011). It does not handle processes which are specific to a tracer or to a tracer class (basically the operations belonging to the "physics" according to the COSMO vocabulary or to additional submodules).

The prognostic equation for a tracer can be derived from the prognostic equation for water vapor (equation 3.148 in Doms, 2011):

$$\frac{\partial q^v}{\partial t} = \underbrace{-\left\{\frac{1}{a\cos\varphi}\left(u\frac{\partial q^v}{\partial \lambda} + v\cos\varphi\frac{\partial q^v}{\partial \varphi}\right)\right\} - \dot{\zeta}\frac{\partial q^v}{\partial \zeta}}_{ADV} \underbrace{- (S^l + S^f)}_{SRC/SINKS} \underbrace{+ M_{q^v}}_{MIX} \tag{1}$$

Expanding the third term (MIX) of equation (1) using its definition (equation 3.153 in Doms, 2011) and reordering the terms, we get:

$$\frac{\partial q^v}{\partial t} = \underbrace{ADV}_{A} + \underbrace{DIFF}_{B} + \underbrace{TURB}_{C} + \underbrace{CONV}_{D} + \underbrace{RELAX}_{E} + \underbrace{DAMP}_{F} + \underbrace{SRC/SINKS}_{G} \tag{2}$$

The terms in equation (2) are:

- A: horizontal and vertical advection (as described in chapters 4.4.2 and 4.4.3 of Doms, 2011)
- B: horizontal hyperdiffusion (or computational mixing) (as described in chapter 6.2 of Doms, 2011)
- C: turbulent mixing (as described in chapter 4.3.3 of Doms, 2011 and in chapter 3 of Doms et al., 2011)
- D: moist convection (as described in chapter 6 of Doms et al., 2011)
- E: boundary relaxation (as described in chapter 5.2 of Doms, 2011)
- F: Rayleigh damping (as described in chapter 6.4 of Doms, 2011)

- G: sources and sinks (in the case of qv, microphysical sources and sinks from/to the liquid and solid phases)

Written for an arbitrary tracer, equation (2) becomes:

$$\frac{\partial \psi}{\partial t} = \underbrace{ADV}_{A} + \underbrace{DIFF}_{B} + \underbrace{TURB}_{C} + \underbrace{CONV}_{D} + \underbrace{RELAX}_{E} + \underbrace{DAMP}_{F} + \underbrace{SRC/SINKS}_{G} \qquad (3)$$

Equation (3) is a general equation valid for any tracer ψ. The tracer module takes care of the 6 first terms (A to F). It means that these terms can be computed in an automated way by the tracer module. The tracer client simply has to set correctly the corresponding metadata (table 2). The 7th term, the sources and the sinks, is not computed by the tracer module, since this term is specific for each tracer. The tracer module simply makes available a tendency field that can be used to store the sources and the sinks. It is the responsibility of the tracer client to fill this term with the sources and the sinks appropriated for its tracer. Sources and sinks might be emissions, chemical transformations, phase changes or fluxes from/to the soil for instance.

We describe the functionalities of the tracer module in more details in the following subsections. If a standard metadata controls a functionality, it is added in brackets after the subsection title. The possible values for the standard metadata are listed in table 2.

2.2.1 Tracer definition and memory management

The definition of a new tracer is done by a call to the tracer API (described in section 2.3). Memory required by the tracer, its boundary values and its tendency field is handled internally by the tracer module. Pointers to these data fields can be retrieved by the tracer client by calling the tracer API.

2.2.2 I/O methods

In order to Input/Output (I/O) a field in COSMO, the variable has to have a corresponding entry in the `var` structure in the subroutine `setup_vartab`. The tracer module now automatically does this operation. An entry in the `var` structure is performed for the tracer and this tracer no longer appears explicitly in the code of the subroutine `setup_vartab`.

Any tracer can thus be read from and/or written out to file. However, associated fields like the tendency or a possible surface field cannot be read or written out in an automated way for the moment. This is further discussed in section 6.

The tracers can either be read/written in GRIB format or in NetCDF format like any other field in COSMO. Output is possible on model levels (`ml`), levels of constant pressure (`pl`) or levels of constant height (`zl`).

The relevant configuration switches are the following ones (namelist `INPUT_IO`):

- `yform_read`: determines the input format (GRIB or NetCDF)
- `yform_write`: determines the output format (GRIB or NetCDF)

- `yvarml`, `yvarpl`, `yvarzl`: determines the list of variables to output on the model levels, pressure levels and height levels, respectively

In order to write a tracer out, it must simply be added to the corresponding output list (`yvarml`, `yvarpl`, `yvarzl`). In order to read a tracer from file (as initial or/and as boundary condition), the metadata `T_INI_ID` and `T_LBC_ID` have to be set to `T_INI_FILE` and `T_LBC_FILE`, respectively. The model then automatically searches for the corresponding fields in the initial and boundary condition files and stops execution should they be missing.

2.2.3 Advection (`T_ADV_ID`)

The type of advection used for scalar quantities depends on the dynamical core selected by the user and on namelist switches that further refine the choice of a specific algorithm used for advection. The tracer module currently implements all major existing options and additionally offers the possibility to turn off advective transport for each tracer separately (e.g. for idealized cases or sensitivity studies).

For the Leapfrog core, the standard advection scheme for tracers is a second-order centered difference scheme in the horizontal and an implicit scheme in the vertical. Although certain species are transported using alternative advection schemes (e.g. semi-Lagrangian advection for precipitating microphysics species), the tracer module only implements the standard advection scheme (second order centered difference) for the tracers.
In the Runge-Kutta dynamical core a namelist switch allows a global selection (valid for all tracers) of the advection scheme. A complete list of the schemes is given below and a description of these schemes is provided in Doms (2011).

The relevant configuration switches are the following ones (namelist `INPUT_DYN`):

- `l2tls`: determines if the Leapfrog dynamical core or the Runge-Kutta one should be used
- `y_scalar_advect`: determines which scheme should be used in case of the Runge-Kutta core (van Leer, PPM, Bott2, Bott4, Van Leer Strang, PPM Strang, Bott2 Strang, Bott 4 Strang, Semi-Lagrange 3 MF, Semi-Lagrange 3 SFD)

The tracer module reproduces the advection as it is coded in the original code. Bottom and lateral boundary conditions used in this code part may not be consistent with the choices made by the tracer client (`T_LBC_ID` and `T_BBC_ID`).

2.2.4 Horizontal hyperdiffusion (`T_DIFF_ID`)

Horizontal hyperdiffusion is an artificial diffusion (computational mixing) performed to smooth the solution of the thermodynamical equations obtained by numerical integration. Two different schemes are available in the COSMO model (Doms, 2011) and both have been implemented for the tracers. Horizontal diffusion can also be switched off globally or for each tracer separately (see table 2).

The tracer module reproduces the horizontal diffusion as it is coded in the original code. Lateral boundary conditions used in this code part may not be consistent with the choice

made by the tracer client (T_LBC_ID).

The relevant configuration switches are the following ones (namelist INPUT_DYN):

- lhordiff: determines globally if horizontal diffusion should be activated
- itype_hdiff: determines which scheme should be used (4th order linear or 4th order linear monotonic with orographic limiter)
- hd_corr_trcr_in: determines the correction factor for scalar (tracers) used for the diffusion in the domain
- hd_corr_trcr_bd: determines the correction factor for scalar (tracers) used for the diffusion at the boundaries

2.2.5 Turbulent mixing (T_TURB_ID)

Different options are available for the turbulent mixing of tracers. Most of them compute the diffusion only in the vertical direction while an option enables to compute additionally the horizontal diffusion. The tracer module only implements the widely used options (i.e. prognostic TKE-based scheme with an implicit treatment using either a Dirichlet or a Neumann boundary condition at the Earths surface) and also the new option to have a 3-dimensional turbulent mixing. The option to switch off turbulent mixing for each tracer individually is made available.

The relevant configuration switches are the following ones (namelist INPUT_PHY):

- ltur: determines globally if turbulent mixing should be activated
- itype_turb: determines the parameterization used for turbulent diffusion (only value 3 is accepted for the tracers)
- imode_turb: determines the mode (implicit vs. explicit) of turbulent diffusion (only value 0 or 1 are accepted for the tracers)
- l3dturb: determines if horizontal diffusion should be computed in addition

The type of lower boundary condition is relevant for the turbulent mixing. This condition can be set using the metadata T_BBC_ID (see table 2).

More information about the turbulent mixing in the COSMO model can be found in Doms et al. (2011) and Buzzi (2008).

2.2.6 Passive convective transport (T_CONV_ID)

Passive transport of scalar quantities by convection was previously not available in the COSMO model. For the tracers, passive transport by convection using the Tiedtke scheme is implemented. It is done in an analogous way as for the momentum components in COSMO and follows ECMWF (2011). Other convection schemes available in COSMO (Kain-Fritsch, Bechtold, shallow-convection based on Tiedtke) are not implemented for the tracers and thus

cannot be selected for the tracers. It is possible to activate passive transport by convection for each tracer individually.

The relevant configuration switches are the following ones (namelist `INPUT_PHY`):

- `lconv`: determines globally if subgrid-scale convection should be activated
- `itype_conv`: determines the parameterization used for subgrid-scale convection (only value 0 is accepted for the tracers)

2.2.7 Lateral boundary conditions (`T_LBC_ID`)

Different types of lateral boundary condition (BC) can be applied to the tracers (see table 2). If boundary data coming from a coarser model are available in an input file, these data can be used as boundary condition. If such data are lacking for a tracer, other values can be used at the boundaries. One can choose between a value of zero at all boundaries, a constant value (which has to be defined in the code by the user) or a zero-gradient method, in which the values of the first line of the computing domain are chosen as boundaries.

There is no relevant configuration switch (except for the microphysics species).

2.2.8 Initial condition (`T_INI_ID`)

Different types of initialization can be applied for the tracers (see table 2). If initialization data coming from a coarser model or from an analysis are available in an input file, these data can be used as initial condition (IC). If such data are lacking for a tracer, an initialization using a value of zero can be chosen.

There is no relevant configuration switch (except for the microphysics species).

2.2.9 Boundary relaxation (`T_RELAX_ID`)

Boundary relaxation is performed in the COSMO model to gradually blend the solution of the model with the boundary values and thus avoid abrupt transitions in the fields and possible contamination of the solution due to numerical noise created by reflection at the boundaries. The scheme used is described in Doms (2011).
Boundary relaxation for each tracer can either be switched off (e.g. in case of idealized studies), can be performed at all boundaries or only at the inflow boundaries (like it is often done for precipitation quantities in COSMO.

The relevant configuration switches are the following ones (namelist `INPUT_DYN`):

- `rlwidth`: specifies the width of the relaxation zone (must be greater than 0 to perform relaxation)

2.2.10 Rayleigh damping (T_DAMP_ID)

Rayleigh damping may be applied in the COSMO model to avoid the reflection of gravity waves, which might occur at the top of the model due to its formulation as a rigid lid. Two types of damping are available in COSMO and for the tracers: damping by relaxing against the boundary fields or by relaxing against the filtered forecast fields (Doms, 2011). Additionally damping can be activated/deactivated on an individual basis for each.

The relevant configuration switches are the following ones (namelist `INPUT_DYN`):

- `lspubc`: determines globally if Rayleigh damping should be performed in the upper layers
- `itype_spubc`: specifies the type of Rayleigh damping
- `rdheight`: specifies the height of the damping layer bottom in meters (must be smaller than the top of the model domain to perform damping)

2.2.11 Clipping (T_CLP_ID)

Several clippings are performed throughout the COSMO code to ensure positive values for positive definite variables. Clipping removes thus negative values in order to ensure positive definiteness. We also offer this functionality for the tracers. It is possible to switch on or off the clipping for each tracer independently.

There is no relevant configuration switch.

Remark: For some species, different types of clipping are used at different locations in the COSMO code. The tracer module does not use different clipping types but consistently use the same method across the whole code.

2.2.12 COSMO options not implemented

Some existing schemes/configurations available in the COSMO model are not implemented for the tracers. These schemes/configurations have been considered as not relevant, outdated or as a major violation of a coherent tracer treatment. It is the case of:

- Semi-Lagrange advection in the Leapfrog dynamical core
- Positive definite advection scheme using Euler time stepping in the Leapfrog dynamical core
- Turbulent mixing in case $itype_turb \neq 3$ and $imode_turb \leq 2$
- Convective tracer transport for schemes other than the Tiedtke scheme (Kain-Fritsch, shallow convection, Bechtold)
- Special clipping types (e.g. massflux correction scheme)

2.3 The tracer module API

The tracer module API consists of the subroutines and functions stored in the source file `src_tracer.f90` as well as some predefined constants in the source file `data_tracer.f90`.All tracer module subroutine names start with `trcr_`. They provide methods to the tracer client for handling a specific tracer and its associated metadata or for handling a metadata for all tracers, and also some facilities (e.g. memory management), which are not specific to one tracer client.

A general feature of the tracer module is the ability to access any tracer or metadata by either its name or its index. The second option is much faster since it does not imply string comparison and is also the method to use in loops over all tracers (or over a subset of them).

All tracer module subroutines return an error status code (`ierr`) as the first argument. Any non-zero value indicates an error. A function which translates this error code into a human readable string is provided (see `trcr_errorstr` below). It is the tracer clients responsibility to check the status code returned and handle the error gracefully.

2.3.1 Methods for tracer handling

The methods described in this section are the ones the tracer client will use in order to define, access, modify tracers from the client code.

trcr_new This subroutine serves to define a new tracer. It must be called by the tracer client each time a new tracer has to be added to the COSMO model. It should be called from a meaningful location in the code (generally from an `organize_xxx` subroutine). Once the memory has been allocated by the tracer module (see `trcr_alloc` below) no more tracers can be defined.

The subroutine arguments are summarized in table 3 (in the correct order). Mandatory arguments have to be specified in each call of `trcr_new`. The other arguments can be passed or not. If they are not passed, the default value of the corresponding metadata is used (see table 2). Many arguments directly correspond to a metadata of the new tracer. Where this is the case, the corresponding metadata identifier is given in parenthesis after the definition of the argument.

A unique short name for the tracer has to be provided. It serves to identify the tracer and, at the same time, is the variable name for the NetCDF format (Unidata, 2011). The units have to be specified and should follow the SI system (International System of Units) if possible. These are the units used for reading and writing out the tracer. A GRIB parameter number as well as a GRIB table number has to be given as well. For standard meteorological variables, a specific GRIB number is dedicated to a specific variable. For some tracers, it might be more complicated since the WMO (World Meteorological Organization) has not attributed a fixed number to them. In that case, a GRIB parameter number and GRIB table number which are not yet occupied has to be chosen. The owner (or parent) name, i.e. the name of module which is in charge of the tracer, has to be passed as well.

Table 3: Aguments for `trcr_new`

Argument	Definition	Type	Intent	Mandatory?
`ierr`	Error status	`INT`	`OUT`	Yes
`yshort_name`	Tracer short name (`T_NAME_ID`)	`CHAR`	`IN`	Yes
`iGRIBparam`	Tracer GRIB parameter number (`T_GRBPARAM_ID`)	`INT`	`IN`	Yes
`iGRIBtable`	Tracer GRIB table number (`T_GRBTABLE_ID`)	`INT`	`IN`	Yes
`yparent`	Name of tracer owner (`T_PARENT_ID`)	`CHAR`	`IN`	Yes
`yunits`	Tracer units (`T_UNITS_ID`)	`CHAR`	`IN`	Yes
`ystandard_name`	Tracer standard name (`T_NCSTDNAME_ID`)	`CHAR`	`IN`	No
`ylong_name`	Tracer long name (`T_NCLONGNAME_ID`)	`CHAR`	`IN`	No
`itype_adv`	Advection specification (`T_ADV_ID`)	`INT`	`IN`	No
`itype_diff`	Horizontal hyperdiffusion specification (`T_DIFF_ID`)	`INT`	`IN`	No
`itype_turbmix`	Turbulent mixing specification (`T_TURB_ID`)	`INT`	`IN`	No
`itype_passconv`	Passive transport by convection specification (`T_CONV_ID`)	`INT`	`IN`	No
`itype_ini`	IC specification (`T_INI_ID`)	`INT`	`IN`	No
`itype_lbc`	Lateral BC specification (`T_LBC_ID`)	`INT`	`IN`	No
`itype_bbc`	Bottom BC specification (`T_BBC_ID`)	`INT`	`IN`	No
`itype_relax`	Relaxation specification (`T_RELAX_ID`)	`INT`	`IN`	No
`itype_damp`	Rayleigh damping specification (`T_DAMP_ID`)	`INT`	`IN`	No
`itype_clip`	Clipping specification (`T_CLP_ID`)	`INT`	`IN`	No
`idx_trcr`	Tracer index	`INT`	`OUT`	No

It is also strongly recommended to specify a standard name and a long name for the tracer. This should be done with respect to the CF conventions (Eaton et al., 2011) and a table of possible standard names is available on the Lawrence Livermore National Laboratory web-page[1].

Optionally, it is also possible to get back a unique index which can be used to identify the tracer (as a replacement for the tracer name in the `trcr_get` subroutine).

We also encourage to specify all other optional arguments of `trcr_new` which determine the behavior of the tracer. The possible values for the arguments are summarized in table 2.

trcr_get This subroutine enables the tracer client to retrieve a pointer to the tracer in order to perform specific operations (e.g. microphysics, atmospheric chemistry, etc.). The subroutine has to be called in each module or each subroutine (usually once per module should be enough) for each tracer and each time level required.

The subroutine arguments are summarized in table 4 (in the correct order).

Table 4: Aguments for `trcr_get`

Argument	Definition	Type	Intent	Mandatory?
`ierr`	Error status	`INT`	`OUT`	Yes
`idx_trcr`	Tracer index	`INT`	`IN`	Yes
or				
`yname`	Tracer name	`CHAR`	`IN`	Yes
`ptr`	Pointer to the tracer data	`REAL, POINTER`	`OUT`	No
`ptr_bd`	Pointer to the tracer boundary data	`REAL, POINTER`	`OUT`	No
`ptr_tens`	Pointer to the tracer tendency data	`REAL, POINTER`	`OUT`	No
`ptr_surf`	Pointer to the tracer surface field	`REAL, POINTER`	`OUT`	No
`ptr_tlev`	Time level for the pointers	`INT`	`IN`	No

Either the name or the index of the tracer (which can be retrieved using the subroutine `trcr_get_index` or directly during the tracer definition with `trcr_new`) has to be passed as input argument.

Pointers to the following data can be retrieved:

- a 3-dimensional pointer `ptr(:,:,:)` to the tracer data for the time level `nnow` or for the time level specified by the optional argument `ptr_tlev`. The pointer is dimensioned with `(ie, je, ke)`.

[1] http://cf-pcmdi.llnl.gov/documents/cf-conventions/1.6/cf-conventions.pdf

- a 4-dimensional pointer `ptr_bd(:,:,:,:)` to the tracer boundary data. The pointer is dimensioned with `(ie, je, ke, 2)`.
- a 3-dimensional pointer `ptr_tens(:,:,:)` to the tracer tendency data. The pointer is dimensioned with `(ie, je, ke)`.
- a 2-dimensional pointer `ptr_surf(:,:)` to the tracer surface data for the time level `nnow` or for the time level specified by the argument `ptr_tlev`. The pointer is dimensioned with `(ie, je)`.

Care should be taken not to call this subroutine excessively (e.g. in loops over all gridpoints) due to performance reasons (especially if the tracer name is used to retrieve the data instead of the tracer index).

trcr_get_ntrcr This function returns the total number of tracers currently handled by the tracer module (table 5). It has no argument. This function is used to create the upper bound of the loops over all tracers for instance (e.g. `DO iztrcr= 1, trcr_get_ntrcr()`).

Table 5: Aguments for `trcr_get_ntrcr`

Argument	Definition	Type	Intent	Mandatory?
result	Number of tracers	INT	-	-

trcr_get_index This subroutine returns the unique index identifying the tracer given its name.
The subroutine arguments are summarized in table 6 (in the correct order).

Table 6: Aguments for `trcr_get_index`

Argument	Definition	Type	Intent	Mandatory?
ierr	Error status	INT	OUT	Yes
yname	Tracer name	CHAR	IN	Yes
idx	Tracer index	INT	OUT	Yes

trcr_errorstr This function returns a meaningful error message for any error code issued by the tracer module. The input argument is the error code (see table 7). This error number can come from any subroutine of the tracer API listed in this section.

Table 7: Aguments for `trcr_errorstr`

Argument	Definition	Type	Intent	Mandatory?
ierr	Error status	INT	IN	Yes
result	Error message	CHAR	-	-

2.3.2 Methods for metadata handling

A tracer metadata describes a property or determines a specific behavior of a tracer substance. Apart from the standard set of metadata every tracer has (see tables 1 and 2), the tracer module allows the tracer client to define, set and retrieve arbitrary metadata for each tracer substance. This section describes the API methods available to the tracer client for handling the metadata associated with its own tracers. A metadata can be a single `integer`, `real`, `double`, `character`, `logical` as well as a one-dimensional array of any of these types. The methods for handling metadata are overloaded and the tracer client has a single interface for all of the above types. The interfaces are described in more details below. For simplicity reasons, we do not mention `real` and `double` for each interface but only `real` in this documentation.

trcr_meta_define Define a new metadata and provide its default value. The subroutine arguments are summarized in table 8 (in the correct order).

Table 8: Aguments for `trcr_meta_def`

Argument	Definition	Type	Intent	Mandatory?
`ierr`	Error status	`INT`	`OUT`	Yes
`yname`	Metadata name	`CHAR`	`IN`	Yes
`ydefault`	Default metadata value	`INT`	`IN`	Yes
or				
"	"	`REAL`	"	"
or				
"	"	`DOUBLE`	"	"
or				
"	"	`CHAR`	"	"
or				
"	"	`LOGICAL`	"	"
`iidx`	Metadata index	`INT`	`OUT`	No
`protect`	Flag to protect the metadata from possible deletion	`LOGICAL`	`IN`	No

The name of the metadata has to be provided as well as a default value. The default value will be applied to the metadata for all tracers, except if another value is specified for a given tracer (using `trcr_meta_set`, see below). The type of the default value determines the type of the metadata.

Optionally, the index of the metadata in the metadata structure can be obtained for more efficient access and it is also possible to protect the metadata from deletion by another tracer client.

trcr_meta_set Store values for a given metadata (identified by its name or index) for a specific tracer or for all tracers at once. The subroutine arguments are summarized in table 9 (in the correct order).

Table 9: Aguments for `trcr_meta_set`

Argument	**Definition**	**Type**	**Intent**	**Mandatory?**
`ierr`	Error status	`INT`	`OUT`	Yes
`itrcr`	Tracer index	`INT`	`IN`	Yes
or				
`ytrcr`	Tracer name	`CHAR`	`IN`	Yes
or				
nothing				
`imeta`	Metadata index	`INT`	`IN`	Yes
or				
`ymeta`	Metadata name	`CHAR`	`IN`	Yes
`ydata`	Specified value	`INT`	`IN`	Yes
or				
"	"	`REAL`	"	"
or				
"	"	`CHAR`	"	"
or				
"	"	`LOGICAL`	"	"

The name or the index of the metadata to set has to be provided as well as the value to store. If a tracer name or a tracer index is specified, then the value given will be used only for this tracer. If the tracer name or index is omitted, it is assumed that the tracer client wants to store metadata for all tracers and the last dimension of the value array needs to correspond to the number of tracers. The type of the values has to be of the same type (`INT`, `REAL`, `CHAR`, `LOGICAL`) than the default value provided to `trcr_meta_define`.

trcr_meta_get Retrieve a given metadata for a specific tracer or for all tracers at once. The subroutine arguments are summarized in table 10 (in the correct order).

Table 10: Aguments for `trcr_meta_get`

Argument	Definition	Type	Intent	Mandatory?
`ierr`	Error status	`INT`	`OUT`	Yes
`itrcr`	Tracer index	`INT`	`IN`	Yes
or				
`ytrcr`	Tracer name	`CHAR`	`IN`	Yes
or				
nothing				
`imeta`	Metadata index	`INT`	`IN`	Yes
or				
`ymeta`	Metadata name	`CHAR`	`IN`	Yes
`ydata`	Specified value	`INT`	`OUT`	Yes
or				
"	"	`REAL`	"	"
or				
"	"	`CHAR`	"	"
or				
"	"	`LOGICAL`	"	"

The name or the index of the metadata has to be provided and its value will be returned. If a tracer name or a tracer index is specified, then the value is returned only for this tracer. But if the tracer name or index is omitted, the value of the specified metadata will be returned for all tracers. The value array needs to be dimensioned accordingly.

2.3.3 Infrastructure methods

These methods are low-level methods used to manipulate the data structures and the information related to the tracers and the metadata. These methods are called only once in the code and should not be called by the tracer client, as they are already implemented in the model code.

trcr_init This subroutine is called at the beginning of the initialization phase and defines and initializes the mandatory metadata with default values, initializes some indices and nullifies some pointers used in the tracer module.

trcr_alloc This subroutine allocates the memory for the data structures used to save the tracers, their tendency and boundary fields and initializes these structures. It is called only once during the allocation phase of the COSMO model. After a call to this routine, no more tracers can be defined and a call to `trcr_new` will result in an error.

trcr_setup_vartab This subroutine is called from `organize_data.f90` and mimics the COSMO subroutine `setup_vartab`. This is a necessary operation in order to do I/O with the tracers. Additionally, we also associate a pointer to the corresponding surface field if this is required.

trcr_print This subroutine is called only once from `lmorg.f90` after the allocation phase. This routine produces a summary of all tracers and the associated metadata in the standard output of the COSMO model. The standard output should be checked by all tracer clients to make sure that their tracers are correctly handled (i.e. that the values of the metadata have been set accordingly to their needs).

trcr_cleanup This subroutine deallocates the memory allocated in `trcr_alloc`. It is called only once at the end of the COSMO program. After a call to this routine, any tracer data is lost an all calls to `trcr_get` or `trcr_meta_get` will result in an error.

3 A short user's guide

In this section, we first show briefly how we replaced the existing microphysics variables by the tracer module. This example should help users who already have their tracers coupled to the COSMO model (e.g. COSMO-ART) in making use of the tracer module. In a second example, we outline the main steps to introduce a new tracer into the model.

3.1 The microphysics example

We have replaced the current treatment of all microphysics species (water vapor: `qv`, cloud water: `qc`, cloud ice: `qi`, rain: `qr`, snow: `qs`, graupel: `qg`) by the tracer module. The microphysics species are no longer handled as individual global variables but are now packed in the data structures related to the tracers and can only be defined, accessed and modified using the tracer methods.

3.1.1 The generic code parts

In all code parts where actions that can now be performed by the tracer module were executed, we could simply remove the code lines related to the microphysics species. This is for instance the case of the allocation (`src_allocation.f90`), the filling of the `var` structure (`src_setup_vartab.f90`) or the handling of the I/O for initial and boundary conditions (`organize_data.f90`). These actions are common to all tracers.
An example of a code section which is generic for all tracers can be found in Fig. 1. In this code section, the list of the variables that need initial conditions to be read from file is generated. On the left panel, the original code is shown. The generation of the variable list implied to add each variable explicitly (i.e. using its name). In the new version, shown on the right panel, the metadata `T_INI_ID` is tested for each tracer and if this metadata indicates that IC have to be read from file (`T_INI_FILE`) then the tracer name is added to the list.

3.1.2 The specific code parts

In code parts that are specific to the microphysics, the original code could be kept almost unchanged. The main change is the access to the data. In the original code, a `USE` statement of the module `data_fields.f90` is performed in order to get access to the microphysics variables (`qv`, `qc`, etc.) and these variables can then be used directly. In the new version, some `trcr_get` have to be performed instead to retrieve the microphysics variables. An

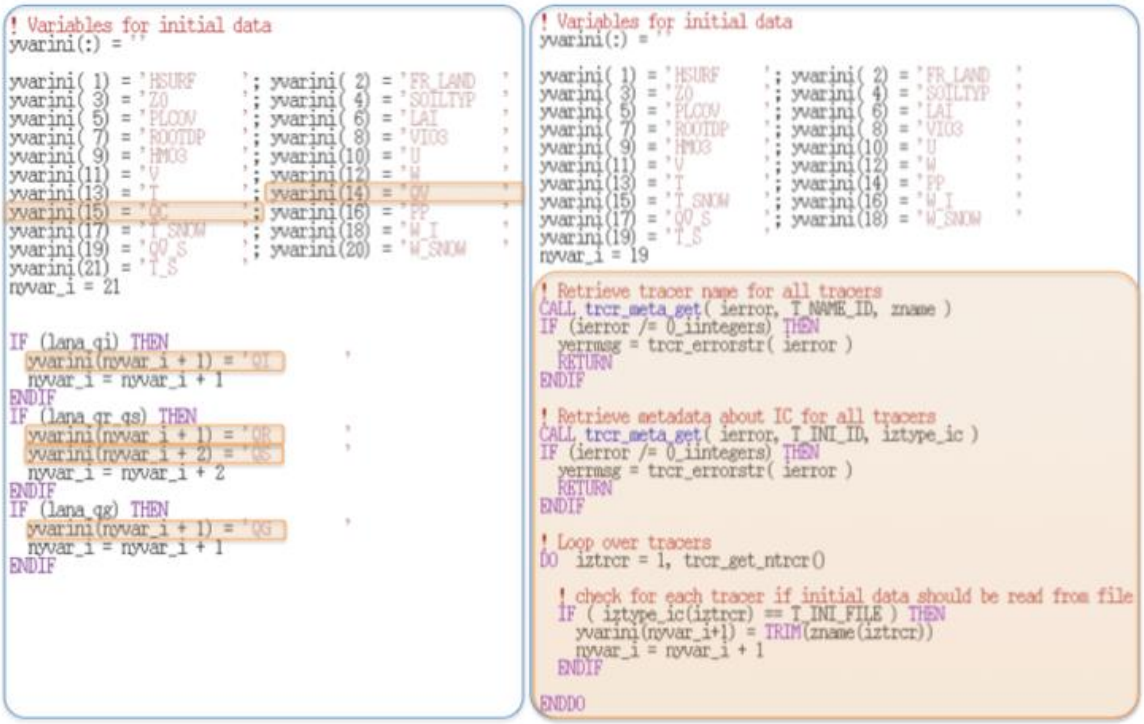

Figure 1: Replacement of the microphysics species in a generic code section
left panel: original code (without tracer); right panel: new code (with tracer)

example can be seen in Fig. 2. This code section is extracted from the subroutine `hydci_pp`, which computes the rate of change of temperature, cloud water, cloud ice, vapor, rain and snow due to microphysical processes related to the formation of grid scale precipitation. On the left panel (original code version), it becomes clear that each microphysics specie is accessed using the corresponding global variable defined in the source file `data_fields.f90` (`USE data_fields` statement). It is then used in the code at the time level `nx`. In the tracer version (shown on the right panel), local pointers are defined for each microphysical species for each required time level. Then the data are accessed using the statements `CALL trcr_get` for each variable at the required time level. These pointers are 3-dimensional pointers. The local pointers can then be used instead of the global variables in the parameterization.

It is crucial to notice that the tracer client now has to work with pointers instead of allocated fields. This implies for instance that all instances of `IF(ALLOCATED(my_var))` have to be replaced by `IF(ASSOCIATED(my_var))`. The validity of a pointer (which points on a given variable for a given time step) is not longer than one time step, whereas an allocated variable is valid throughout the whole simulation (thanks to the swapping of the time steps).

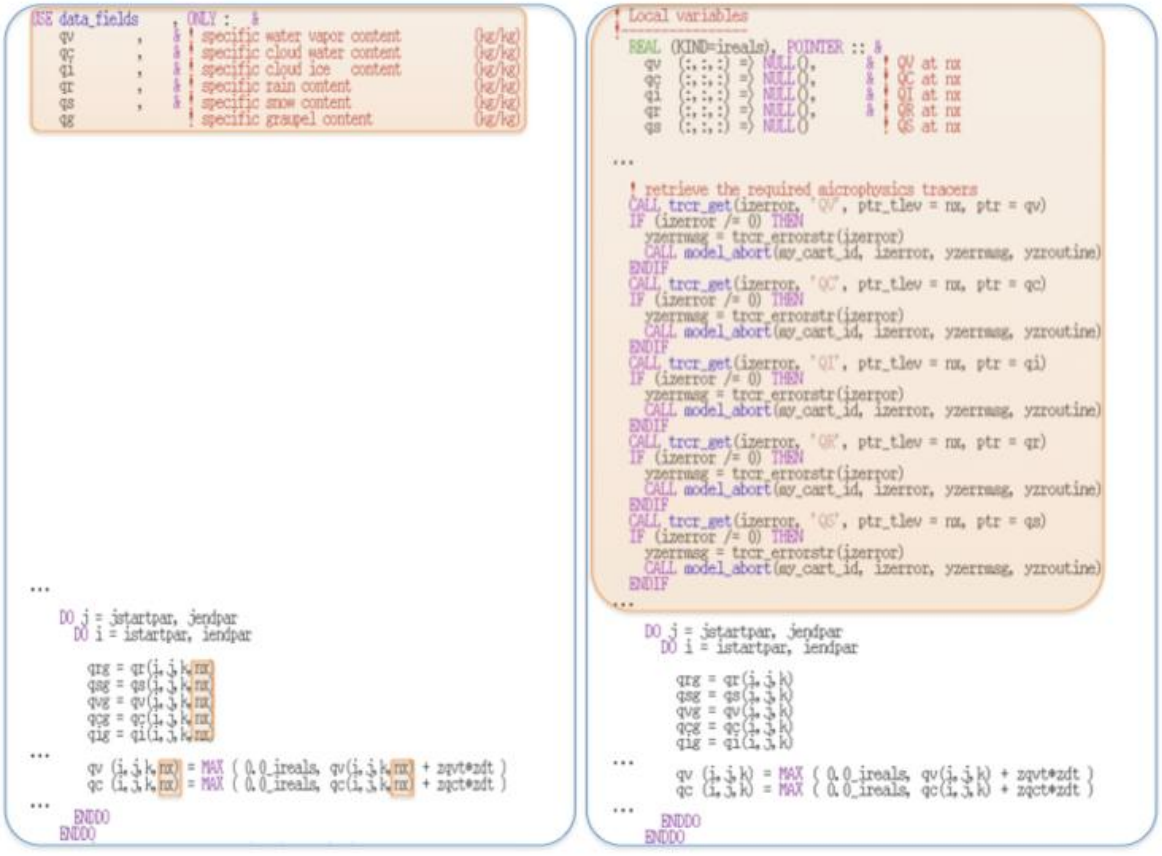

Figure 2: Replacement of the microphysics species in a specific code section
left panel: original code (without tracer); right panel: new code (with tracer)

3.1.3 The microphysics specificities in generic code parts

Major difficulties when replacing the existing treatment of the microphysics species by the tracer module methods arose in the code sections generic to all tracers. Indeed, numerous inconsistencies are present in the advection, in the turbulent mixing, in the treatment of the

lateral boundary conditions and in the time stepping for the microphysics species. Although these operations should usually be handled in a consistent way for all tracers, we could not harmonize the treatment of the microphysics species for backwards compatibility reasons. We had to find a solution to handle these specificities without altering the integrity of the tracer module. We made use of the metadata to distinguish these special cases. **The use of these special metadata is not recommended to other tracer clients and they will be removed from the code over time.**

We list below the metadata that we have defined to reproduce the original treatment of the microphysics species, the possible values and the default (i.e. the standard treatment for other tracers). We do not recommend using these metadata for other tracers without intensive testing. Indeed, it is not clear at all for most of them why the behavior they are activating is required for some microphysical species and if it would be meaningful for other species. Caution is thus required when manipulating these metadata.

CLP_10E-12 At the end of the turbulent mixing for the Leapfrog dynamical core, a clipping is performed to ensure that the positive definite quantities are not exhibiting negative values. In case of cloud ice (`qi`), another clipping method than the usual one is performed. Any value smaller than `10E-12` is set to zero instead of clipping only the negative values (i.e. smaller than `0`). The metadata `CLP_10E-12` is set to `FALSE` for all tracers except for `qi`. It means that we perform the usual clipping (clipping of the negative values only) for all tracers except for `qi` (for which we clip any value smaller than `10E-12`).

Remark: this metadata is only active for `qi` if the standard metadata `T_CLP_POSDEF` has been set to `TRUE`.

MASSFLX_CLP At the end of the turbulent mixing for the Leapfrog dynamical core and the Runge Kutta core, a clipping is performed to ensure that the positive definite quantities are not exhibiting negative values. In case of water vapor (`qv`) and cloud water (`qc`), a mass-flux correction scheme can be used instead of the usual clipping method. This is activated by a hard-coded internal switch (`lmassf_diffusion`) in the original code. The metadata `MASSFLX_CLP` is set to `FALSE` for all tracers except for `qv` and `qc`. It means that we perform the usual clipping for all tracers except for `qv` and `qc` (for which we redistribute the clipped mass).

Remark: this metadata is only active for `qv` and `qc` if the standard metadata `T_CLP_POSDEF` has been set to `TRUE`.

ADD_CLP_ADV When using the advection in the Runge-Kutta core not written in conservation form (`ltrcr_conserv_form=.FALSE.`), a clipping is performed at the end of the advection routine (`advection_pd`) but only for the precipitating species (`qr`, `qs`, `qg`). The metadata `ADD_CLP_ADV` is set to `TRUE` for these species whereas it is set to `FALSE` for any other tracer, thus activating this additional clipping only for the three species mentioned above. This metadata is of course only active if advection is performed (i.e. if the metadata `T_ADV_ID` has been set to `T_ADV_ON`).

BD_0GRAD_FORCED Several types of lateral boundary condition can be chosen using the metadata T_LBD_ID. This type is then used at several locations in the code, among others in the advection. A routine (lateral_boundaries_zerograd in the new code, western_boundary, eastern_boundary, southern_boundary and northern_boundary in the original code) in the advection part of the Runge Kutta core (subroutine advection_pd) sets the lateral boundaries in case of a zero-gradient boundary condition type. This routine should thus only be called if T_LBC_ID is set to T_LBC_ZEROGRAD. However this is done in any case for qi, qr, qs and qg in case the boundaries are not read from a file in the original code. We thus have to define a metadata which overwrites the boundary settings in the advection (for Runge Kutta) for these species except if the boundaries are read from file (T_LBC_FILE). BD_0GRAD_FORCED is thus set to FALSE for all tracers except for the above mentioned species. This metadata is of course only active if advection is performed (T_ADV_ON).

BD_SET_FORCED The type of lateral boundary condition is also used at the end of the dynamics computation (section 6.3.1 of lmorg.f90). At this location, the boundaries are set in case a zero-value (T_LBC_ZERO) or zero-gradient (T_LBC_ZEROGRAD) boundary condition has been chosen. For the precipitating species however, this boundary settings is done also if the boundaries have been read from file and the type (zero-value or zero-gradient) is defined according to the namelist switch itype_lbc_qrsg in the original code. In order to reproduce this behavior, the switch BD_SET_FORCED is introduced. It is set to zero for all species except for the precipitating species. For them, it is set to 1 or 2 according to the value of the namelist switch itype_lbc_qrsg. A value of 1 means a zero-gradient boundary condition whereas a value of 2 means a zero-value boundary condition.

SP_ADV_LF Advection in Leapfrog is normally done using centered differences and a Leapfrog time stepping scheme. The vertical advection is done implicitly. This default is applied to all tracers and to qv and qc. In the original code however, qi, qr, qs and qg are advected using others schemes. qi is advected using a positive definite scheme based on an Euler forward time stepping scheme. The vertical advection is also positive definite and is solved explicitly. For the precipitating species, a semi-Lagrange scheme with a Leapfrog time stepping is used. We use the metadata SP_ADV_LF to reproduce these various schemes. The default, SP_ADV_LF=1, is applied to all tracers except the species mentioned above; the normal Leapfrog scheme is used. For qi, the metadata SP_ADV_LF is set to 2, in order to make use of the Euler forward time stepping scheme. For the precipitating species, SP_ADV_LF is set to 3, inducing the use of the semi-Lagrange scheme.

Remark: A correct treatment of T_ADV_OFF is guaranteed only for the default Leapfrog scheme.

3.1.4 Treating the surface field

For any prognostic variable, there are possibly associated fields: the tendency fields, the boundary field, a surface field or an emission field for instance. In the current COSMO code, the only field that can be associated directly to a variable is the boundary field. This is dictated by the way COSMO defines a variable (i.e. by the composition of the var structure). It means that only the boundary field can be handled properly in an automated way.

However, in order to treat correctly the bottom boundary condition in case a surface field

should be used (`T_BBC_ID` set to `T_BBC_SURF_VAL`), we need an automated method to relate a surface field to the tracer. The method currently used is constrained by the variable handling in COSMO and is not very satisfying. The tracer client has to define the surface field (in `data_fields.f90`), to allocated it (in `src_allocation.f90`), to fill the `var` structure for it (in `src_setup_vartab`), to update it (in `lmorg.f90`) and to deallocate it (in `src_allocation.f90`) himself or herself. In the tracer routine `trcr_setup_vartab`, we search in the `var` structure for a field named like the tracer field but with an extension `_S` (`QV_S` for `QV` for instance). If such a field is found, the pointer `ptr_surf` in the tracer structure is associated to this field. We check that this pointer is associated in case `T_BBC_SURF_VAL` has been chosen for the tracer.

This method is inflexible; the name of the surface field must be constructed using the name of the tracer and the `_S` extension. And it is laborious, the tracer client having to perform lots of operations to handle this field. Care is required when a surface field should be used as bottom boundary condition.

3.2 How to introduce a new tracer?

The introduction of a new tracer is relatively straightforward using the tracer module.

The general workflow to introduce a new tracer can be summarized in:

- Defining the tracer: name, GRIB information, set of dynamics operation to undergo, type of initial and boundary conditions
- Defining associated metadata: determine if some information has to be attached to the tracer and if yes, define and set these metadata
- Defining initial and boundary conditions if needed (in case they are not read from file and should not have a zero value or a zero-gradient)
- Retrieving the tracer to perform various actions: computation of the source/sink terms of the tracer and update of the tracer, use of the tracer to compute derived quantities
- Adding the tracer to the output list in the namelist `INPUT_IO`

Each operation listed above has to take place in a meaningful location in the COSMO code. Some basic knowledge of the workflow in COSMO can help to use the tracer module correctly. We describe roughly the COSMO workflow in section 4.2.

3.2.1 Define the tracer and its metadata

The tracer client has to call `trcr_new` from an appropriate location. This appropriate location is usually `organize_physics` for the physical tracers, `src_artifdata` for artificial tracers and the "organizing" routine of associated modules (e.g. the "organizing" routine of the aerosol module in case of aerosols). This has to occur before the allocation phase but after the initialization of the tracer module (i.e. in section 2.1. of `lmorg.f90`). An example of an "organizing" routine can be found in Appendix A.

A crucial task for the tracer client is to choose the type of initial and boundary conditions for the tracer, to define which processes (advective transport, convective transport, etc.) it should undergo. In case of constant boundary conditions, the user has to retrieve the boundary field using the procedure `trcr_get` and assign a value to the corresponding pointer.

In some cases, it might be necessary to define additional metadata. It might be useful for instance to have the molar mass of some chemical tracers. These metadata can be defined at the same place using the procedures `trcr_meta_define` and `trcr_meta_set`.

3.2.2 Retrieve the tracer and its metadata

Wherever the tracer client needs to use its tracer (e.g. in parameterizations of physical or chemical processes), it has to retrieve it using `trcr_get`. The required time step has to be specified. It is also possible to retrieve the tendency, the surface field or the boundary data using the same procedure. An example can be found in Appendix B.

4 Implementation details

This section details some design choices made internally in the tracer module. It is important to note that this information is subject to change at any time and that the tracer client should not write code that assumes any of the information given here.

4.1 Data structures

The main data structures used to manage the tracers at a low level are allocatable arrays of type `REAL`:

- `trcr_data` is a 5-dimensional array dimensioned with `(ie, je, ke, n_trcr, n_tlev)` and contains the tracer fields.
- `trcr_data_bd` is a 5-dimensional array dimensioned with `(ie, je, ke, n_bd, 2)` and contains the boundary field for the tracers.
- `trcr_data_tens` is a 4-dimensional array dimensioned with `(ie, je, ke, n_trcr)` and contains the tendency field for the tracers.

The number of tracers, `n_trcr`, and the number of boundary fields for the tracers, `n_bd`, are updated by each call to `trcr_new`. The method `trcr_get` accesses these data structures and returns 3-dimensional pointers for the tracer data and the tracer tendency and a 4-dimensional pointer for the tracer boundaries.

4.2 Workflow

The COSMO workflow can be roughly described as follows:

1. Initialization phase
   (a) Initialization of the environment and domain decomposition

(b) Read of the namelist variables
(c) Initialization of the tracer module
(d) Definition of the tracers and of their metadata
(e) Allocation
(f) Print of the tracer list and metadata in the standard output
(g) Fill in of the `var` structure (I/O table)
(h) Definition of the variable list to read for IC, BC and for the restart
(i) Read (or computation) of the IC and of the two first BC sets
(j) Initialization of the output variable list
(k) Initialization of the various packages (dynamics, physics, assimilation,)
(l) (Model initialization by digital filtering)

2. Time stepping loop

(a) Time step initialization (read new BC data if needed and interpolate them in time, swap time levels, reset the tendencies to zero)
(b) Computation of the physical parameterizations (first set)
(c) Computation of the dynamics
(d) Setting of special boundaries
(e) Computation of the assimilation
(f) Computation of budgets
(g) Computation of the boundary relaxation
(h) Computation of the physical parameterizations (second set)
(i) Nullification of small values for the tracers
(j) Boundary exchanges
(k) Diagnostics computation
(l) Results output (if needed)

3. Finalization phase

(a) Deallocation of the memory
(b) Collection of the timings
(c) Finalization of the MPI environment

The operations on the tracers cannot be performed in any order but they have to fit into the COSMO workflow.

In order to check that the main tracer operations are done in the right sequence, the tracer module internally uses a status variable which is checked upon every call to the tracer module to ensure a legal calling sequence (state machine). This variable can take the value "start", "define", "alloc" or "finish". At the beginning of the code, the status is "start". `trcr_init` can only be called with this status. At the end of `trcr_init`, the status is changed to "define". `trcr_new` and `trcr_alloc` can only be called for the status "define". At the end of the allocation routine (`trcr_alloc`), the status is changed to "alloc". At this point, it is no longer allowed to define new tracers. The filling of the `var` structure (`trcr_setup_vartab`) and the printing of the tracer list and associated metadata in the standard output have to be

performed for the status "alloc". The subroutines which access the tracer structure, namely `trcr_get_index`, `trcr_check_index` and `trcr_get`, can be called for the status "define" or "alloc", depending on the arguments. `trcr_cleanup` has to be called with the status "alloc" and the status is changed to "finish" at the end of this subroutine.

4.3 Metadata module

The metadata management of the tracer module is handled by a general metadata backend in the source code files `src_tracer_metadata.f90` and `data_tracer_metadata.f90`. The tracer module defines a metadata container (of type `t_metadata`) and pipes all metadata requests from the methods `trcr_meta_define`, `trcr_meta_set` and `trcr_meta_get` to methods of the metadata backend. The metadata backend is not logically linked to the tracer module and can in principle be used for other metadata storage tasks.

Internally, all metadata is stored in a buffer of type `CHARACTER`. The different metadata are typecast using the Fortran `TRANSFER` intrinsic. Depending on the compiler dependent implementation, this allows for efficient access to metadata avoiding data copies.

Access to metadata can potentially be slow when done via name of the tracer and name of the metadata. This is especially the case, when a large number of tracers and metadata have been defined, implying a larger number of string comparisons. Accessing metadata in this way from within loops should be avoided at all costs. Access by tracer index and metadata index will be considerably more efficient. Further efficiency improvements can be achieved with metadata accesses for all tracers at once (omitting the tracer index or name in the metadata access methods, such as `trcr_meta_get`).

There are some internally hardcoded limits of the metadata module, such as the maximum length of the metadata name and the maximum length of strings that can be stored. If these limits are exceeded by any call to the metadata API, an appropriate error is issued. The user can then increase the limits and recompile.

4.4 Performance considerations

The performance has been tested on several platforms (Cray XT systems, Cray XE systems, NEC SX6, Mac OS). The performance of the model code is not changed significantly by our implementation on all tested platforms except for the NEC SX6, where a slowdown of about 10% has been observed. The main reason is vectorization issues. Some optimizations will be done in the future in order to achieve comparable runtime as with the original code. An improvement of the boundary exchange (bulk exchange instead of individual exchange for each tracer) is planned to prevent major performance issues when dealing with numerous tracers.

An experiment has been conducted to analyze the rise of the computing time by adding tracers successively, from zero additional tracers up to 100 additional tracers. For this experiment, COSMO-7 simulations of 24 hours forecast (as run operationally at MeteoSwiss but without any output) have been performed on a Cray XE6 system using 480 processing units. The resulting timings for a various number of tracers are illustrated in Fig. 3.
With zero additional tracers, one hour of simulation takes 21.45 seconds. Fitting a linear regression curve (least squares method) on the data, a slope of 0.7388 is obtained (equation: $time = 20.63 + 0.7388 * num_tracers$). It means that adding one tracer costs about 0.7388 seconds more (out of 21.45 seconds), i.e. an increase of 3.5% of the computing time per

additional tracer is observed. The computing time behaves extremely linearly with respect to the number of tracers.

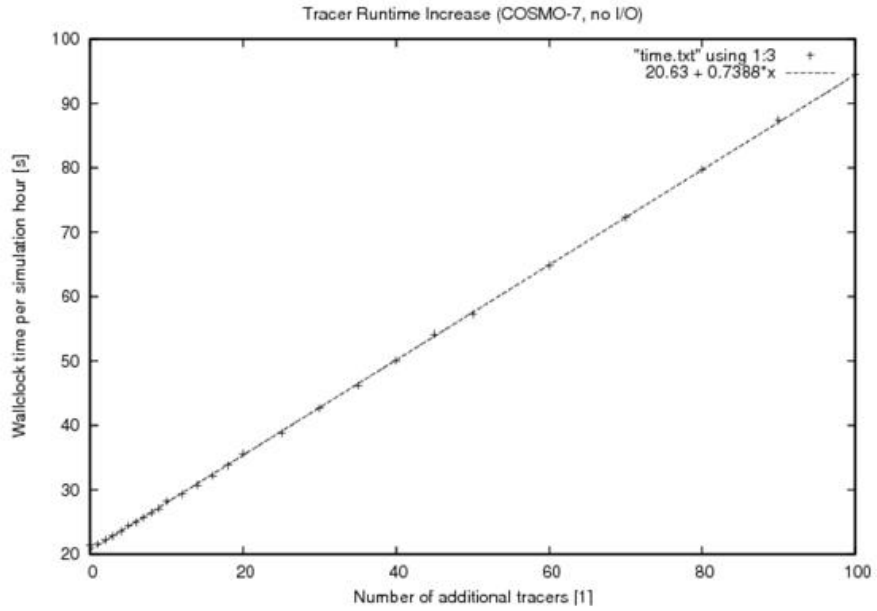

Figure 3: Runtime increase as a function of the tracer number

5 Results

The implementation of the tracer module is a purely technical change made to the code to improve its structure. It does not change the results.

After some code refactoring (mainly operation reordering), we could reproduce most of the results when handling the microphysics species with the tracer module. Some discrepancies have been observed and it turned out that these differences in the results were related to inconsistencies in the treatment of these species in the original code. Making use of the metadata mechanism, it has been possible to reproduce these specificities (inconsistencies) without degrading the integrity of the tracer module itself (see section 3.1.3).

The new code, including the handling of the microphysics species by the tracer module, has been extensively tested for several dozen of configurations. All tests have been successfully passed, i.e. bit-identical results have been obtained for all of them when comparing the original code and the tracer enabled code.

Parallelization has not been altered by our developments and the major configuration options of the original COSMO code are still available in combination with the tracer module.

6 Issues and needs for further refinements

The tracer module offers a facilitated tracer treatment. However it has been implemented in an existing code structure and only parts of this structure have been refactored. A larger effort would be needed to achieve more flexibility in the tracer definition and to reach a solution that could satisfy all tracer clients.

Technical and scientific aspects are still insufficiently well-handled for some tracer clients. From the scientific part, the main issue for a satisfying tracer treatment is related to conservation properties. Mass conservation is not guaranteed with the advection schemes implemented in COSMO. Other properties like the ratio between tracers are not conserved at all. This is not acceptable for several tracer clients.

From the technical side, the tracer module considers all tracers as being equal. We do not have a concept of tracer family for the moment. The possibility for differentiated treatment is left to the user, who can attach a new metadata, which controls a special behavior, to his set of tracers. In some cases, it might nevertheless be advantageous to have at least some "en bloc" methods to retrieve all aerosols in one call for instance. This kind of "en bloc" methods could easily be implemented in a future version.

Another technical limitation of the current COSMO code is related to the inflexible way of defining variables. Each field that has to be read/written has to appear in the `var` structure. This structure contains among others the GRIB number for the element but also some pointers to the variable itself and to the boundary field. This means that a boundary field can be associated to each variable but no other field can be attached to it. A more general way to define a field would help to handle associated fields for the tracers. Usually tracer clients want to have a surface field, an emission, a tendency a flux or other type of fields like a sedimentation velocity attached to their species. For the moment, only the boundary field is completely handled by the tracer module. The tendency field can also be considered as fully covered by the tracer module but cannot be written to output (which was also the case in the original COSMO version). A surface field can be attached to the tracer field if the user has chosen a surface value as bottom boundary condition but the tracer client still has to declare, allocate and define this surface field himself (see section 3.1.4). This solution is not satisfying in a long-term perspective. Emissions or other fields cannot be attached to the tracers in an easy way for the moment. Replacing the `var` structure by a more flexible datatype would alleviate this problem. In a prototype version, pointers can be saved into the metadata as well. This pointer support associated to a better definition of the fields in COSMO would enable to link variables in a convenient way.

Currently, metadata are defined within the code, requiring a new compilation each time a metadata is changed. Handling some of the metadata via namelists would eliminate the need for recompilation.

7 Conclusions

A major code modification has been implemented in the COSMO model for a better treatment of passive, scalar prognostic variables (tracers). The implementation of this tracer mod-

ule is a step towards an efficient, consistent and user-friendly tracer treatment in COSMO. The module has been successfully used for handling the microphysics species (of both the one-moment and the two-moment microphysics schemes) present in the model as well as for tracing air masses (work of Bojan Skerlak, ETH Zürich) and for the forecast of snow water content (Frick, 2012).

The mechanism to attach metadata to a tracer is a powerful functionality, which has been intensively used for the handling of the microphysics species. Indeed, the specificities (inconsistent treatment) present in some code parts for the microphysics species could be reproduced without attempting at the tracer module coherence and operating mode. Replacing the existing treatment of the microphysics species by the tracer module could therefore be done without altering the results.

Although the new module provides rather flexible methods for prognostic variables and convenient extension possibilities, the general definition of a field in COSMO remains inflexible. New methods for variable definition and additional support for pointer saving in the metadata would greatly improve the structure of the COSMO code and open new doors for future developments.

Acknowledgments

We would like to thank Ulrich Schättler, Ulrich Blahak, Michael Baldauf, Jochen Förstner, Matthias Raschendorfer, Axel Seifert, Heini Wernli, Bernhard and Heike Vogel, Daniel Reinert, Christoph Knote, Astrid Kerkweg and Pirmin Kaufmann for useful discussions, suggestions and support. We are grateful to Claudia Frick and Bojan Skerlak who volunteered to serve as guinea pigs!

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.

For any comments and questions, please contact the editor:

1 Introduction

This document explains how to use the VAST software provided by Naima Vela (Arpa Piemonte/University of Turin) developed according to VERSUS2 priority project, task 4: "Introduction of additional statistical techniques in VERSUS".
The software can perform the following tasks:

- Open and read txt files of forecast and observation produced by any external software following an example scheme
- Produce spatial verification of the precipitation field (main goal), wind speed and total cloud cover.
- If the user has the possibility to use the LIBSIM[1] software, VAST can produce its own input files starting from GRIB (observation and forecast) of BUFR (observation)

1.1 Fuzzy verification

Fuzzy verification answers the question:"Which is the link between spatial forecast and a combination of the intensity of the precipitation (or wind speed or total cloud cover) and the scale of the event?"

The scale decomposition methods allow us to diagnose the model errors and performances according to different scales. The scale-intensity approach links the traditional bi-dimensional verification categories: it returns the model skills according to different precipitation intensities (or wind speed or total cloud cover) and spatial scales. It verifies the model over the whole domain. It is useful in the spatial verification of discontinuous fields. It supplies information for both single case studies and forecast systems evaluated over a longer time. Using a neighbourhood verification method an exact correspondence between forecast and observation is not needed.

It is important to understand that this type of verification, for what concerns precipitation, gives better information when performed for case studies on limited areas, so that the patterns can be compared without being overhung by long time or large areas of no rain condition.

2 Software description

The architecture of the VAST software has been produced after a deep study of the IDL code of the Ebert software for fuzzy verification.

2.1 Components

The VAST software is composed by the following files:

- `install.sh`: Shell script that creates the directory tree and places the other scripts in the correct directory

[1]The "`extra software`" for VERSUS users

- `use_libsim.sh`[2]: Shell script that allows LIBSIM users to produce the VAST input files (txt) starting from GRIB and BUFR
- `vast.sh`[3]: Shell script containing all the instructions to execute the different parts of the procedure
- `input_libsim.conf`: Configuration file used by the shell script `use_libsim.sh` to set all the variables that point to directories and name of the files
- `directories.conf`: Configuration file used by the shell script `vast.sh` to set all the variables that point to directories and name of the files
- `input_csv2txt.nml`: Namelist read by `csv2txt.f90` Fortran code containing all the instructions regarding the directories, the name of the files, the internal variables and the parameters
- `input_fuzzy.nml`: namelist read by `read_txt.f90` and `fuzzy_verify.f90` Fortran codes containing all the instructions regarding the directories, the name of the files, the internal variables and the parameters
- `csv2txt.f90`: Fortran code that reads the output files from LIBSIM and transform them into txt files read by VAST
- `read_txt.f90`: Fortran code able to process the input TXT files (observation and forecast) and produce the input for the second and main Fortran code
- `fuzzy_verify.f90`: Fortran code that uses the outputs of the first one to perform the verification.

2.2 Directories' structure

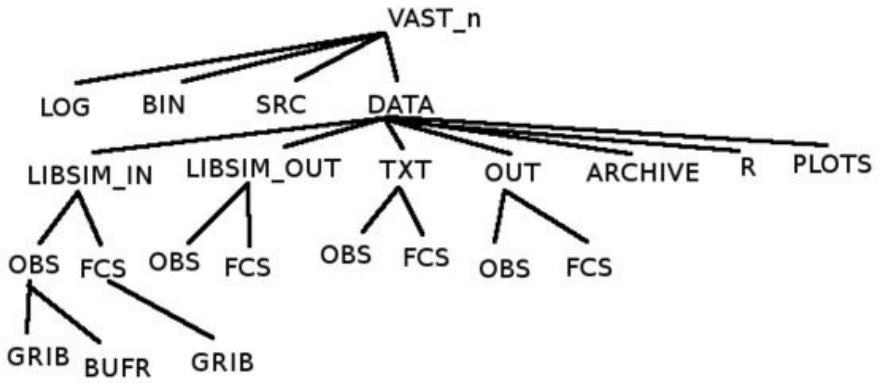

Figure 1: Default structure of the directories of the VAST software

[2]The file will contain numbers to identify the version of VAST to whom it belongs. i.e. `use_libsim_2_0.sh` will be referred to the VAST version 2.0

[3]The file will contain numbers to identify the version of VAST to whom it belongs. i.e. `vast_2_0.sh` will be referred to the VAST version 2.0

In Figure 1 it is possible to see the default structure of the directories in the software. If the presented structure conflicts with the users needs (particular displacement of the storage, or similar problems), it will be necessary to modify the configuration files accordingly.This has been made particularly hard by the requirement of having a common path that leads to the subdirectories (reducing the degrees of freedom of the structure of the software). In particular the user should not modify the relative path that links the `VAST/src` and `VAST/bin` directories.
The shell scripts "`use_libsim.sh`" and "`vast.sh`" will be automatically inserted in the directory "`bin`". The configuration files, the namelists and the Fortran codes will be automatically inserted in the directory "`src`".
If these files need to be displaced differently, the user will have to modify the scripts accordingly.
An archive file containing all the contingency tables calculated by the main Fortran code (`fuzzy_verify.f90`) during the verification will be created every time a verification is performed. It can be found in the directory `VAST/data/ARCHIVE` and it can be recognized by the date and time of the launch of the verification (`vast.sh`).

3 Installation and compilation

The user needs to install the Fortran compiler `gfortran` to use the Fortran codes contained in the package.
The user needs to install `R Project for Statistical Computing` to produce the plots of the needed indexes. In particular, the following libraries (and all their dependencies) need to be installed:

- `fields`
- `gplots`

To install the R packages, the user needs to log in as root, download the packages in the extension `package.tar.gz` and type the following command line:

- `R CMD INSTALL package.tar.gz`

The user needs then to unpack and copy the folder `vast_install` into the desired location by using the command line:

- `tar -xzf vast_install.tar.gz`

The user then needs to move into the `vast_install` directory to change the permissions for the shell script `install.sh` by giving the following command:

- `chmod 777 install.sh`

(The numbers could be different if the user wants to keep a particular category from executing the script)
Then the user needs to run the executable by giving the following command:

- `./install.sh`

The script will create all the directories needed by the software and will copy the scripts in the correct place. If the user needs a different structure for the directories, than it will be necessary to manually modify them and the codes.

Once the directories have been created, the user needs to place the input files in the correct place. If the user is using LIBSIM to pre-process the input files, than they will be put in the `obs` (`GRIB` or `BUFR`) and `fcs/GRIB` folders contained in the directory `VAST/data/LIBSIM_in`. If the user has a different software to produce the input files for VAST, than the preprocessed files must be inserted in the `obs` and `fcs` folders contained in the directory `VAST/data/TXT`.

All the shell scripts (`use_libsim.sh` if needed and `vast.sh`) have to be converted into executable files to be correctly used to produce the verification. To do so the user needs to move to the directory containing the executable files (`bin`) and use the following instruction from command line:

- `chmod 777` *`your_script.sh`*

(The numbers could be different if the user wants to keep a particular category from executing the script)
The compilation of the Fortran codes is automatically performed while launching the executables (`vast.sh` and `use_libsim.sh`).

3.1 NOTE FOR PEOPLE WHO HAVE ALREADY INSTALLED PREVIOUS VERSIONS OF VAST

If the user doesn't want to delete and recreate the directory's structure of VAST, he/she will have to delete all the files contained in the folders `VAST/bin` and `VAST/src` and substitute them with the files contained in the folder `vast_install_2_0` (with the exception of `install.sh`).

3.2 NOTE for users working on a VERSUS machine

If the user is running VAST on a VERSUS machine, it is possible to find all the needed extra packages for R in the directory `vast_install/documentation/R_packages_versus`
It is mandatory to use the given packages to be installed on the VERSUS version of the R software. Nothing changes for the installation instruction.

4 Activities performed by the software

4.1 For LIBSIM users

The LIBSIM users have the possibility to perform their verification starting from standard input files (GRIB or BUFR for the observation, GRIB for the forecast).

4.1.1 The input files

Input observation files: The observation files must be BUFR or GRIB. For a better behaviour of the software (faster and less memory demanding), it would be better to use files (BUFR or GRIB) that only contain the total precipitation variable. The files must be placed in the folder `VAST/data/LIBSIM_in/obs/BUFR` or `GRIB`. Since the files will be collected together by the command "`cat`", it is important that the GRIB files have a `.grb` extension, the BUFR files must have a `.bfr` extension.
Example files can be found in the folder `vast_install/documentation/data/LIBSIM_in/obs`.

Input forecast files: The forecast files must be GRIB. For a better behaviour of the software (faster and less memory demanding), it would be better to use files that only contain the total precipitation variable. The files must be placed in the folder `VAST/data/LIBSIM_in/fcs/GRIB`. Since the files will be collected together by the command "`cat`", it is important that they have a `.grb` extension.
Example files can be found in the folder `vast_install/documentation/data/LIBSIM_in/fcs`.

The characteristics of the input files can be deduced by analysing the example GRIB and BUFR given as examples with the package. Such details can be investigated by using the following commands:

- For GRIB:
  - `wgrib -V filename.grb`
- or
  - `grib_dump filename.grb`
- For BUFR:
  - the user can upload an example file to the url `http://apps.ecmwf.int/codes/bufr/validator/`

In Figure 2 it is possible to read the output of `wgrib -V` *`your_file.grb`* command for an observation GRIB.

```

    transform: south pole lat -32.500000 lon 10.000000  rot angle 0.000000
  min/max data 0 78.7188  num bits 16  BDS_Ref 0  DecScale 0 BinScale -9
```

Figure 3: Output of `wgrib -V filename.grib` for forecast

Regular output files coming from COSMO models fit to this standard.

Thanks to the LIBSIM capabilities, the software works both with GRIB1 and GRIB2 files.

It is important that the **BUFR** files contain **only the hourly cumulate of the precipitation, without any duplicate**.

4.1.2 The configuration files

The elaboration of the input files for LIBSIM is performed thanks to two files: `use_libsim.sh` (the executable) and `input_libsim.conf` (its configuration file).

4.1.3 input_libsim.conf

The first part of the configuration file (Figure 4) contains the list of the directories that must be set for the correct functioning of the software:

```
#DIRECTORIES
#If any change has been made to the structure of VAST, than modify with the actual path
#
#COMMON PATH (up to the directory containing VAST)
common_path='/versus/'
#
#INPUT FILES
#Observation:
#IMPORTANT: comment the path not needed
#If GRIB files (comment if not):
dir_in_obs='VAST/data/LIBSIM_in/obs/GRIB/'
#If BUFR files (comment if not):
#dir_in_obs='VAST/data/LIBSIM_in/obs/BUFR/'
#Forecast
dir_in_fcs='VAST/data/LIBSIM_in/fcs/GRIB/'
#OUTPUT FILES
#Observation
dir_out_obs='VAST/data/LIBSIM_out/obs/'
#Forecast
dir_out_fcs='VAST/data/LIBSIM_out/fcs/'
#Fortran code
dir_src='VAST/src/'
#Executable
dir_bin='VAST/bin/'
#Log
dir_log='VAST/log/'
#
#
#OBSERVATION FORMAT: 'grib' or 'bufr'
#
format='grib'
```

Figure 4: Directories to be set to make the `use_libsim.sh` script work

It is important to notice that the user needs to set the type of input for the observation in two different ways (both need to be done):

- by uncomment the corresponding input path (and commenting the other)
- by setting the variable `format` to grib or bufr

The "`common_path`" variable consists in the absolute path where the `VAST` directory has been located in your machine, and it will be used to complete all the other relative paths (that **should not be modified**).

The second part of the configuration file (Figure 5) is dedicated to the specification of the name of the verification (that will be used to chose the correct output files in the second part of the verification), to specify the run of the model to be verified, to (optionally) select the input files by the leading part of their name (up to 10 carachters) and to select the cumulation period for the verification. The user must be aware of the value of the cumulation time of the input files and set the variable `cum` accordingly (the value must be equal or multiple of the input cumulation time).
Example: If the user have hourly cumulation for the observed precipitation and wants to re-cumulate it on the intervals 0-6, 6-12, 12-18, 18-24 (`cum='00 06'`), the first GRIB must contain the cumulated rain for the hour **one** (which means from 0 to 1).
If the input files are BUFR files, they must contain all the hourly cumulate of the precipitation OR the precipitation already cumulated on the desired period and no other cumulation periods.

```
#NAME OF THE VERIFICATION (string with no gaps)
name='201606_decade1_7km_12h'
#
#RUN (for forecast only, use string like '00', '06', '12', etc)
use_run='00'
#
#
#Identification of the files ('y'/'n')
#If 'y' then add string
add_id='y'
id_file='LAMIN0063'
#
#
#CUMULATION TIME
#The cumulation time must be equal
#or bigger (ONLY for precipitation) than the one
#of the input data
#The cumulation time must be given as follows.
#Ex: '00 03' means three hours cumulation
cum='00 12'
```

Figure 5: Name and cumulate parameters needed by LIBSIM

The third part of the configuration file (Figure 6) is dedicated to the configuration of the grid on which the verification will be performed. It is necessary for the grid to have lower resolution and a smaller area if compared to the forecast input, so that no missing point appear in the final result. The user will be able to check if the forecast grid contains any "holes" by plotting and visualising the CSV (directory `VAST/data/LIBSIM_out`) resulting files (an easy and free way to do that is to use the QGIS software. The user needs to see a perfect LON/LAT regular grid).

```
#GRID PARAMETERS
#The grid borders must be strictly smaller than the original area.
#The grid step must be strictly bigger than the original grid step.
#If the obs and fcs output files don't have the same grid
#it can mean that the selected area is too close to the original one
#(obs or fcs) or that the grid step is too close to the original one
#(obs or fcs) and holes have been left in the new grid.
#If the problem is the area, the user needs to reduce it.
#If the problem is the grid step, the user needs to enlarge it.
#So try with different parameters untill at least the forecast grid
#is regular and contains no holes
#Grid limits
x_min='6.315'
x_max='9.987'
y_min='43.1'
y_max='46.585'
#Number of grid points in each direction (x=lon, y=lat)
nx='39'
ny='40'
```

Figure 6: Grid parameters needed by LIBSIM

The data can include more than one day of precipitation but the grib messages must NOT overlap (i.e. day 01/01/2016 from hour 01 to hour 24 and then day 02/01/2016 from hour 01. **NOT** day 01/01/2016 from hour 01 to hour 72 and then day 02/01/2016 from hour 01.). The author suggests to use the software to verify single case studies (few days) over limited areas (i.e. the Piedmont region), since this kind of verification performs best when precipitation patterns are present and occupy the most part of the verified area. It is important that in the forecast files every date and time appear only once. If more files contain the same date and time (i.e. overlapping forecast runs) the resulting CSV will be overwritten.
The last part of the configuration file (Figure 7) contains the names of the files involved in the preprocessing of the files. The names of the files should be left as default.

```
#
#FORTRAN PROGRAM (should be left as default)
csv2txt_f90='csv2txt.f90'
#EXECUTABLE
csv2txt_exe='csv2txt'
csv2txt_log='csv2txt.log'
csv2txt_stderr='csv2txt_stderr.log'
#
#LISTS (should be left as default)
list_obs='list_obs.dat'
list_fcs='list_fcs.dat'
#
#NAMELIST (should be left as default)
namelist='input_csv2txt.nml'
```

Figure 7: Names of the files used by the preprocessing part of the software with LIBSIM

When all the variables have been set, the script `use_libsim.sh` will perform the following tasks:

- Collect all the input forecast files with the "`.grb`" extention AND the given specifications (run and, if chosen, name of the file) into a single grib called `forecast.grib`
  - it is VERY IMPORTANT that none of the forecast input files are called "`forecast.grib`". If that happens the procedure will cause a conflict and abort the execution
- Use the LIBSIM functionality "`vg6d_transform`" to re-grid the input files
- Count the number of the input messages

- Produce CSV files and place them in the correct directory
- Create a copy of a re-gridded forecast message to use it as a template to re-grid the observation
- Proceed to repeat the same operation for the observation files (with the extention ".grb" or "`.bfr`")
  - in case of grib files, the produced total input file is called "`observation.grib`"
  - in case of bufr files, the produced total input file is called "`observation.bufr`"
  - it is VERY IMPORTANT that none of the observation input files have one of these names. If that happens the procedure will cause a conflict and abort the execution

When all the CSV files are ready and displaced in the correct directory, the script creates lists of these files, and proceeds to compile and run the Fortran code (default is `csv2txt.f90`) that transforms the output of LIBSIM (`.csv`) into the input for VAST (`.txt`). So, to execute this code, the user must **first** complete the namelist file called `input_csv2txt.nml`. The user needs to substitute the example paths with the actual path of the half processed files(this needs to be done before launching the `use_libsim.sh` executable). The patterns to be completed are shown in Figure 8

```
&directories
!Fill in with the actual path (up to the directory containing VAST)
common_path='/versus/'
!Directories of input and output for csv2txt.f90
!(to be modified only if the user made modifications to the structure of VAST)
dirin_obs='VAST/data/LIBSIM_out/obs/'
dirin_fcs='VAST/data/LIBSIM_out/fcs/'
dirout_obs='VAST/data/TXT/obs/'
dirout_fcs='VAST/data/TXT/fcs/'
dir_log='VAST/log/'
&end

&filenames
!Lists of csv files (should be left as default)
filelist_obs='list_obs.dat'
filelist_fcs='list_fcs.dat'
!Name of the verification with no gaps
ver_name='201606_decade1_7km_12h'
&end
```

Figure 8: Configuration file for the Fortran code `csv2txt.f90`

This ends the first part of the procedure, executed through the file `use_libsim.sh`, dedicated to the LIBSIM users only.

4.2 For all users

4.2.1 The input files

The VAST input files must be `txt` files. Their internal structure is very strict but simple to reproduce, as shown in Figure 7

Longitude	Latitude	Value
6.315	43.010	-999.000
6.352	43.010	-999.000
6.389	43.010	-999.000
6.426	43.010	-999.000
6.463	43.010	-999.000
6.500	43.010	-999.000
6.538	43.010	-999.000
6.575	43.010	-999.000
6.612	43.010	0.000
6.649	43.010	0.000
6.686	43.010	0.000
6.723	43.010	0.000
6.760	43.010	0.000
6.797	43.010	0.000
6.834	43.010	0.000
6.871	43.010	0.000
6.908	43.010	0.000
6.946	43.010	0.000
6.983	43.010	0.000
7.020	43.010	0.000
7.057	43.010	0.000
7.094	43.010	0.471
7.131	43.010	1.525
7.168	43.010	1.434
7.205	43.010	0.805

Figure 9: Structure of the `txt` input file (observation or forecast)

The file is composed by:

- One header line containing the **exact** string: " `Longitude Latitude Value`"
- One column containing the longitude values
- One column containing the latitude values
- One column containing the precipitation, wind speed or total cloud cover values (-999 if no data)

The order of the coordinates is important. The first couple of coordinates must be the lower left corner and the longitude is the parameter that increases first. The coordinate values must be the same for the forecast and the observation files. In case of missing data, the "value" column must contain the number -999.
Also the name of the files is important and must follow the scheme:

- `obs_YYYYMMDDHHmm_`*`NameOfTheVerification`*`.txt`
- `fcs_YYYYMMDDHHmm_`*`NameOfTheVerification`*`.txt`

where YYYY is the year, MM is the month, DD is the day, HH is the hour and mm is the minute. The "*NameOfTheVerification*" must be assigned to the variable `ver_name` in the file `input_fuzzy.nml`
From version *2.0* it is possible to verify three different variables with VAST (NOT starting from LIBSIM): precipitation (mm), total cloud cover (%), wind speed (m/s). Once the input files have been loaded the user should modify the "`input_fuzzy.nml`" configuration file.

4.2.2 The configuration files

Once the input files are placed in the correct directory (`VAST/date/TXT/obs` or `fcs`), all the activities will be driven by the executable file `vast.sh`. So, the software needs to read

in the configuration files all the specifications related to this part of the execution. The two configuration files governing this part of the software are `directories.conf` (read by `vast.sh`) and `input_fuzzy.nml` (read by `read_txt` and `fuzzy_verify`). Figure 10 and Figure 11 show the information required by the configuration file `directories.conf`

```
#DIRECTORIES
#
#COMMON PATH (up to the directory containing VAST)
common_path='/versus/'
#
#If any change has been made to the structure of VAST, than modify with the actual path
#
#INPUT TXT files
dirin_obs='VAST/data/TXT/obs/'
dirin_fcs='/VAST/data/TXT/fcs/'
#Files processed by read_txt.f90 and ready to be used by fuzzy_verify.f90
dirout_obs='VAST/data/OUT/obs/'
dirout_fcs='VAST/data/OUT/fcs/'
#Backup of input and output

output_obs_list='list_obs.txt'
output_fcs_list='list_fcs.txt'
r_list='list.r'
#Logs
txt_log='txt.log'
fuzzy_log='fuzzy.log'
txt_stderr='txt_stderr.log'
fuzzy_stderr='fuzzy_stderr.log'
out_txt_log='out_txt.log'
```

Figure 11: File names to be configured for the execution of `vast.sh` (should be left as default with the exception of "`name`")

It is very important for the user to set the variable "`name`" according to the naming of the input files, so that the `vast.sh` executable can chose the correct data to be verified.

Figure 12 and Figure 13 show the information contained in the file `input_fuzzy.nml` and needed by the executable `read_txt`.

```
&common_dir
!Fill in with the actual path (up to the directory containing VAST)
common_path='/versus/'
&end

&directories_txt
!Directories of input and output for txt files
dirin_obs='VAST/data/TXT/obs/'
dirin_fcs='VAST/data/TXT/fcs/'
dirout_obs='VAST/data/OUT/obs/'
dirout_fcs='VAST/data/OUT/fcs/'
dir_log='VAST/log/'
&end
```

Figure 12: Common path and directories to be configured for the execution of `read_txt`. Directories should be left as default.

```

!(should be left as default)
&filenames_txt
filelist_obs='list_obs.dat'
filelist_fcs='list_fcs.dat'
&end
```

Figure 13: File names to be configured for the execution of `read_txt` (should be left as default)

Figure 14 and Figure 15 show the information contained in the file `input_fuzzy.nml` and needed by the executable `fuzzy_verify`. The `filenames` group in the `input_fuzzy.nml` namelist also contains information about the model, the grid and the period of the verification. All these last specifications are read as character strings. Since the period, grid and model variables are used to produce the name of the output files, **they must contain no blanks**.

```
&directories_fuzzy
!Directory observation
dirin_obs='VAST/data/OUT/obs/',
!Directory forecast
dirin_fcs='VAST/data/OUT/fcs/',
!Directory output R )
dir_out='VAST/data/R/',

model='COSMO-I7',
!Grid
grid='COSMO-I7'
!Period
period='201606_1-10'
!File list R (should be left as default)
file_list='list.r'
&end
```

Figure 15: File names to be configured for the execution of `fuzzy_verify` (should be left as default).

In Figure 16 the variables relative to the spatial boxes and the thresholds are shown. The user can choose up to ten different thresholds on which the verification will be performed (the thresholds can be different from those shown in the example). If the user needs less thresholds, the value of the unused thresholds must be -999 (like thresh(10) in Figure 16). All the used thresholds must come before the unused ones (i.e. thresh(1)=0.2, thresh(2)=0.5, thresh(3)=1, thresh(4)=2, thresh(5)=5, thresh(6)=10, thresh(7)=-999, thresh(8)=-999, thresh(9)=-999,thresh(10)=-999. **NOT** thresh(1)=0.2, thresh(2)=-999, thresh(3)=1, thresh(4)=2, thresh(5)=-999, thresh(6)=10, thresh(7)=-999, thresh(8)=20 ,thresh(9)=-999, thresh(10)=-999.)
The user has to indicate the resolution of the grid (in Km) by modifying the variable "grid_step". This will be used to produce the plots (this will be not used if the user choses the "grid points" for the space scale in the plots).
From version *2.0* it is possible to verify 3D boxes of observation and forecast by introducing the **time** dimension. The user should set the variable `n_dimension=1` if a standard 2D verification is required (or whenever there are missing timesteps in observation and/or forecast). The user should use a variable greater than 1 to elaborate 3D boxes.
Example1: n_timesteps=3 $\Longrightarrow$ previous, current, following timestep will be used for the verification
Example2: n_timesteps=5 $\Longrightarrow$ previous two, current, following two timesteps.
Another new feature of version *2.0* is the possibility to verify three differnt variables with VAST (NOT using LIBSIM): the variable is chosen by assigning the value '`pre`' (precipitation, mm), '`tcc` (total cloud cover, %)' or '`win`' (wind speed, m/s) to the `variable` line.

```
&dimensions
!Number of windows (1,3,5,9,17,33,65,...,(2^n)+1)
n_windows=5,
!NEW! Number of different timesteps for 3D box
!Example: n_timesteps=3 => previous one, current, following one
!Example: n_timesteps=5 => previous two, current, following two
!ATTENTION: the higher the number, the slower the process
n_timesteps=3,
!Grid resolution (km) used in plot definition
grid_step=8
!Number of valid thresholds
n_thresh=10,
!Thresholds (array of size 10. Fill with -999 if needed)
thresh(1)=0.2,
thresh(2)=0.5,
thresh(3)=1.0,
thresh(4)=1.5,
thresh(5)=2.5,
thresh(6)=5.0,
thresh(7)=7.5,
thresh(8)=10.0,
thresh(9)=15.0,
thresh(10)=20.0,
!Indicate the variable the user wants to verify:
!'pre' for precipitation (mm)
!'tcc' for total cloud cover (%)
!'win' for wind (m/s)
variable='pre'
&end
```

Figure 16: Spatial box and thresholds to be configured for the execution of `fuzzy_verify`

Figure 17 shows all the details needed by the code regarding the actual verification: methods and scores.
For type one, the methods can be different or the same one repeated (up to six times). A score must be associated to each method (ie: `method1(1)='UP'`, `score1(1)='BIAS'`; `method1(2)='MC'`,`score1(2)='FAR'`. This means that the `BIAS` will be calculated using the `Upscaling` method, while the `FAR` will be calculated using the `Minimum Coverage` method). For type two instead, the score and the method are striclty associated (ie: if `method2(1)='FB'`, then `score2(1)='FSS'`; if `method2(2)='PG'`, then `score2(2)='BSS'`; if `method2(3)='PP'`, then `score2(3)='ETSr'`). Type three only contains one score. The number of the used methods for each type must be indicated through the variables `nm1`, `nm2` and `nm3`. The unused methods and scores must be commented (the indication of the methods and scores must follow the same principle of the threshold indication: unused methods and scores must be placed at the end of the array).

```
&methods_scores
!Number of methods of type 1 (max 6)
nm1=5,
!Methods
!Choose between: UP, MC, YN, FZ, JP, ME
method1(1)='UP',
method1(2)='MC',
method1(3)='YN',
method1(4)='FZ',
method1(5)='ME',
!Scores
!Chose between: BIAS, POD, FAR, ETS (if method=UP),
!               POD, FAR, ETS (if method=MC, YN, FZ, JP)
!               HK (if method=ME)
score1(1)='BIAS',
score1(2)='POD',
score1(3)='FAR',
score1(4)='ETS',
score1(5)='HK ',
!Number of methods of type 2 (max 3)
nm2=3,
!Methods
!These methods are strictly coupled with the scores
!The decision is to calculate them or not
!(comment the line and adjust vector numbers)
method2(1)='FB',
method2(2)='PG',
method2(3)='PP',
!Scores
score2(1)='FSS',
score2(2)='BSS',
score2(3)='ETSr',
!Number of methods of type 3
nm3=1,
!Methods
method3(1)='RM',
!Scores
score3(1)='RMSE'
&end
```

Figure 17: Verification methods to be configured for the execution of `fuzzy_verify`

Examples for method 1:

- The user wants to obtain the following scores: bias, pod, far
- The user wants to use the following method for all the scores: upscaling
- Result:
  - method1(1)='UP'
  - method1(2)='UP'
  - method1(3)='UP'
  - !method1(4)=*whatever, commented*
  - !method1(5)=*whatever, commented*
  - score1(1)='BIAS'
  - score1(2)='POD'
  - score1(3)='FAR'
  - !score1(4)=*whatever, comented*
  - !score1(5)=*whatever, commented*
- The user wants to obtain the following scores: bias, pod, far

- The user wants to use the following methods: upscaling for bias, minimum coverage for pod, yes/no for far
- Result:
  - method1(1)='UP'
  - method1(2)='MC'
  - method1(3)='YN'
  - !method1(4)=*whatever, commented*
  - !method1(5)=*whatever, commented*
  - score1(1)='BIAS'
  - score1(2)='POD'
  - score1(3)='FAR'
  - !score1(4)=*whatever, commented*
  - !score1(5)=*whatever, commented*
- The user wants to obtain the following score: far
- The user wants to calculate FAR with three different methods: upscaling, minimum coverage, yes/no
- Result:
  - method1(1)='UP'
  - method1(2)='MC'
  - method1(3)='YN'
  - !method1(4)=*whatever, commented*
  - !method1(5)=*whatever, commented*
  - score1(1)='FAR'
  - score1(2)='FAR'
  - score1(3)='FAR'
  - !score1(4)=*whatever, commented*
  - !score1(5)=*whatever, commented*

Figure 18 shows the last specifications needed by `fuzzy_verify` to chose the correct data (`ver_name`), set the spatial scale in the plots (`km_points`) and to chose the format of the output (`png_pdf`). The `png_pdf` option must be set to **pdf** if the user is working on a VERSUS machine or with old versions of software R. Version *2.0* asks the user to indicate if their R version is newer ('y') or older ('n') than 3.0.

```
&plot_format
!Is your R version >=3.0? (y/n)
r_version='n'
!'png' or 'pdf'
png_pdf='pdf',
!'km' for kilometers, 'gp' for grid points
km_points='gp',
!NAME OF THE VERIFICATION (string with no gaps)
ver_name='?????'
&end
```

Figure 18: Format information for the making of the plots. Used by `fuzzy_verify`

4.2.3 Performance of the verification

Once that the `vast.sh` executable has been launched, the software performs the verification. These are the main steps of the execution:

- The software uploads the information contained in the configuration file `directories.conf`
- Compiles the Fortran code `read_txt.f90`
- Compiles the Fortran code `fuzzy_verify.f90`
- Creates the list of the input TXT files (forecast and observation)
- Runs the executable `read_txt` using the information stored in the namelist `input_fuzzy.nml`
- Produces the half processed DAT files in the directories `VAST/data/OUT/fcs` and `obs`
- Produces the namelist `VAST/src/output_txt.nml` that contains the information related to the data grid dimensions
- Produces the list of the half processed files used by `fuzzy_verify`
- Runs the executable `fuzzy_verify` using the information stored in the namelists `input_fuzzy.nml` and `output_txt.nml` (that produces the R scripts containing the instructions to create the plots)
- Runs the R command that compiles all the scripts containing the instructions to plot the results
- Moves the half processed data files and the R scripts in the backup directories

At the end of the procedure, the user will find all the desired plots in the folder `VAST/data/PLOTS`. If the user needs to perform small changes in the plots (labels, title, colours, legend displacement, etc.), it will be possible to modify the R scripts (located in the `backup` folder inside the `VAST/data/R` directory) without rerunning the verification.

5 Use, recap for LIBSIM users

Input files: The user needs to place the input files in the correct folders. Observation can be bufr or grib, forecast must be grib.

Configuration file: The user needs to configure the file `input_libsim.conf` by completing all the directories' paths, by commenting the unused path for observation input (BUFR if using GRIB and vice versa), by choosing the type of the input files (BUFR or GRIB), by setting the grid parameters (limits and steps), by choosing the cumulation period (`cum`) and by assigning a name to the verification. The configuration file is contained in the directory `VAST/src/`

Namelist: The user needs to complete the directories' paths.

Executable file: The user can now run the executable file `use_libsim.sh` from the `bin` directory by typing:
`./use_libsim.sh`

The executable will now produce the TXT files needed by VAST and place them in the directories `VAST/data/TXT/obs` and `fcs`.

5.1 Use, recap for non LIBSIM users only

Input observation files: The observation files must be txt files with the same characteristics of the ones contained in the folder `vast_install/documentation/data/TXT/obs` and described before. Their naming must contain the date and the name of the verification, as shown before.
Input forecast files: The forecast files must be txt files with the same characteristics of the ones contained in the folder `vast_install/documentation/data/TXT/fcs` and described before. Their naming must contain the date and the name of the verification, as shown before.

The observation and forecast grid must be exactly the same. The coordinates start from the bottom-left corner of the area and proceed by letting the longitude grow first. It is important that the header corresponds exactly to the one shown in the example files.

5.2 Use, recap for both users

Configuration file `directories.conf`: Before the first use of the software, the user will find question marks in the directories common path to be set. The user should fill in the complete path corresponding to the real position of the directory. The information inside this configuration file need to be inserted in the following way (the part within the quotation marks):

```
Variable='my_variable_name'
Directory='my_directory_path'
```

The comment lines need to be inserted in the following way:

```
# Comment
```

Configuration file `input_fuzzy.nml`:

Before the first use of the software the user will find question marks in the directories common path to be set. The user should fill in the complete path corresponding to the real position of the directory. The information inside this configuration file need to be inserted in the following way (the part within the quotation marks):

```
Variable='my_variable_name'
Directory='my_directory_path'
```

The comment lines need to be inserted in the following way:

```
!  Comment line
```

The user needs then to decide the extension of the larger spatial scale needed for the verification to be performed to set the corresponding parameter. This decision must be related to the total dimension of the grid and the resolution of forecast and observation data. The user also needs to decide which type (types) of verification are the most correct to evaluate the situation to be verified.
The program will perform the verification by increasing the extent of the boxes (if the method requires it) starting from the single grid point up to the desired one following the sequence (1, 3, 5, 7, 9, 17, 33, ..). For each box and for each scale the software will calculate the required indexes.

`Dimensions`:

- `n_windows`: Number of window dimensions (up to 10)
- `n_thresh`: Number of valid thresholds (up to 10)
- `thresh`: Value of each threshold (10 values, blanks at the end to be filled with -999)

`Methods_scores`:

- `nm1`: Number of methods of type one (UP, MC, YN, FZ, JP, ME) (up to 6)
- `method1`: List of methods of type one
- `score1`: List of scores to be calculated associated to each method (BIAS, FAR, POD, POFD, ETS, HK)
- `nm2`: Number of methods of type two (FB, PG, PP) (up tp three)
- `method2`: List of methods of type two
- `score2`: List of scores to be calculated associated to each method (FSS, BSS, ETSr)
- `nm3`: Number of methods of type three (RM) (only one)
- `method3`: List of methods of type three
- `score3`: List of scores to be calculated associated to each method (RMSE)

In the namelist files advises are given on how to combine the different methods and scores for type one. Type two and type three are fixed, so for example if the user chooses `method2(1)` **FB**, the `score2(1)` must be **FSS** and so on.

5.3 Perform the verification

Once everything has been set, the user only has to move to the directory associated to the variable "`dir_bin`" in the file `directories.conf` (i.e. "`VAST/bin`") and type:

- `./vast.sh`

The elaboration of the files will start followed by the verification process.

At the end of the verification process all the files contained in the sub directories of TXT and OUT will be moved to their backup folder.

6 Verification methods

Upscaling, anywhere in window, minimum coverage, fuzzy logic, joint probability and multi-event contingency table belong to the verification methods of type 1 (use contingency table and subdivide by thresholds). Brier skill score, fraction skill score and practically perfect hindcast belong to the verification methods of type 2 (don't use contingency table, subdivide by thresholds). Area related root mean square error belongs to the verification methods of type 3 (doesn't use a contingency table and doesn't subdivide by thresholds).

6.1 Upscaling (UP)

- Gets average values in window
- Averaged observation (forecast) $\geq$ threshold $\Rightarrow$ Ob (Fc) array = 1
- Averaged observation (forecast) $<$ threshold $\Rightarrow$ Ob (Fc) array = 0
- Possible scores: BIAS, FAR, POD, POFD, ETS

Hit	Ob = 1	Fc = 1
Miss	Ob = 1	Fc = 0
False Alarm	Ob = 0	Fc = 1
Correct Negative	Ob = 0	Fc = 0

Figure 19: Contingency table for "Upscaling" method

6.2 Anywhere in window (YN)

- Event (threshold exceeding) occurs anywhere in the window
- The portion of window where the event occurs is calculated
- Po (Pf) = Portion observed (Portion forecast)
- Possible scores: FAR, POD, POFD, ETS

Hit	Po $>$ 0	Pf $>$ 0
Miss	Po $>$ 0	Pf = 0
False Alarm	Po = 0	Pf $>$ 0
Correct Negative	Po = 0	Pf = 0

Figure 20: Contingency table for "Anywhere in window" method

6.3 Minimum coverage (MC)

- The portion of window where the event occurs is calculated
- Po (Pf) = Portion observed (Portion forecast)
- Scoring using proportional decision rule (min. cov. = 0.1, Marsigli criterion for 90th percentile)
- Possible scores: FAR, POD, POFD, ETS

Hit	$\text{Po} \geq 0.1 \quad \text{Pf} \geq 0.1$
Miss	$\text{Po} \geq 0.1 \quad \text{Pf} < 0.1$
False Alarm	$\text{Po} < 0.1 \quad \text{Pf} \geq 0.1$
Correct Negative	$\text{Po} < 0.1 \quad \text{Pf} < 0.1$

Figure 21: Contingency table for "Minimum coverage" method

6.4 Fuzzy logic (FZ)

- The portion of window where the event occurs is calculated
- Po (Pf) = Portion observed (Portion forecast)
- Scoring using fuzzy logic
- Possible scores: FAR, POD, POFD, ETS

Hit	$\min(Po, Pf)$
Miss	$\min(Po, (1 - Pf))$
False Alarm	$\min((1 - Po), Pf)$
Correct Negative	$\min((1 - Po), (1 - Pf))$

Figure 22: Contingency table for "Fuzzy logic" method

6.5 Joint probability (JP)

- The portion of window where the event occurs is calculated
- Po (Pf) = Portion observed (Portion forecast)
- Scoring using joint probabilities
- Possible scores: FAR, POD, POFD, ETS

Hit	(Po $*$ Pf)
Miss	(Po $*$ (1-Pf))
False Alarm	((1-Po) $*$ Pf)
Correct Negative	((1-Po) $*$ (1-Pf))

Figure 23: Contingency table for "Joint probability" method

6.6 Multi-event contingency table (ME)

- Square windows are used instead of radii
- Observation occurrence is calculated for each point and for each threshold
- Observation exceeding threshold $\Rightarrow$ Oy = 1
- Observation NOT exceeding threshold $\Rightarrow$ Oy = 0
- The portion of window where the event occurs is calculated only for the forecast
- Pf = Portion forecast
- Hanssen and Kuipers (HK) score is calculated

Hit	Oy = 1	Pf > 0
Miss	Oy = 1	Pf = 0
False Alarm	Oy = 0	Pf > 0
Correct Negative	Oy = 0	Pf = 0

Figure 24: Contingency table for "Multi-event contingency table" method

6.7 Brier Skill Score (Method=PG, Score=BSS)

Pragmatic approach: single observation, neighbourhood forecast. BSS: Measures the improvement of the probabilistic forecast relative to a reference forecast (usually the long-term or sample climatology), thus taking climatological frequency into account. Not strictly proper. Unstable when applied to small data sets: the rarer the event, the larger the number of samples needed.
Answers the question: What is the magnitude of the probability forecast errors?

$$\textit{Brier skill score} - \quad BSS = \frac{BS - BS_{reference}}{0 - BS_{reference}} = 1 - \frac{BS}{BS_{reference}}$$

Figure 25: Brier Skill Score formulation

$$\textit{Brier score} - \quad BS = \frac{1}{N}\sum_{i=1}^{N}(p_i - o_i)^2 = \frac{1}{N}\sum_{k=1}^{K} n_k(p_k - \bar{o}_k)^2 - \frac{1}{N}\sum_{k=1}^{K} n_k(\bar{o}_k - \bar{o})^2 + \bar{o}(1-\bar{o})$$

Figure 26: Brier Score formulation

6.8 Fractions Brier Skill Score (Method=FB, Score=FSS)

The FSS ranges from 0 to 1. A score of 1 is attained for a perfect forecast and a score of 0 indicates no skill. As r expands and the number of grid boxes in the neighbourhood increases, the FSS improves as the observed and model probability fields are smoothed and overlap increases.

$$FSS = 1 - \frac{\frac{1}{N}\sum_N (P_f - P_o)^2}{\frac{1}{N}\left[\sum_N P_f^2 + \sum_N P_o^2\right]}$$

Figure 27: Fraction Skill Score formulation

Where Pf (Po) is the portion of spatial box of the forecast (observation) grid covered by rain exceeding a certain threshold and N is the number of boxes.

6.9 ETS ratio (Method=Practically Perfect Hindcast, Score=ETSr)

Useful forecast resembles one that would have been issued by a forecaster given perfect knowledge of the observations beforehand. Finds maximum ETS for practically perfect hindcast, which is based on the threshold probabilities, and the probability threshold at which it occurs.

6.10 Area related root mean square error (Method= RM, Score=RMSE)

The Root mean square error is calculated over each box. It is calculated for the ordered arrays.

$$RMSE = \sqrt{\left(\frac{1}{n}\right)\sum\left(f_i - o_i\right)^2}$$

Figure 28: Root Mean Square Error formulation

7 Output

7.1 Methods that belong to type 1

A list of the graphics produced by VAST software is given here. The pictures are examples of the possible outputs. The graphics produced for the verification of scores calculated through methods of type one are:

- Scale-intensity

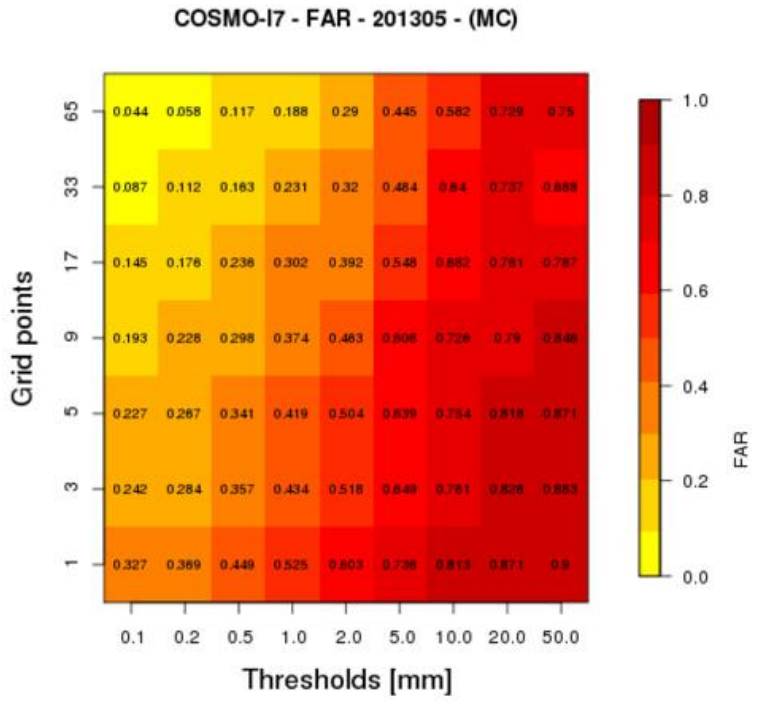

Figure 29: Example of a scale-intensity plot

- Score vs scale

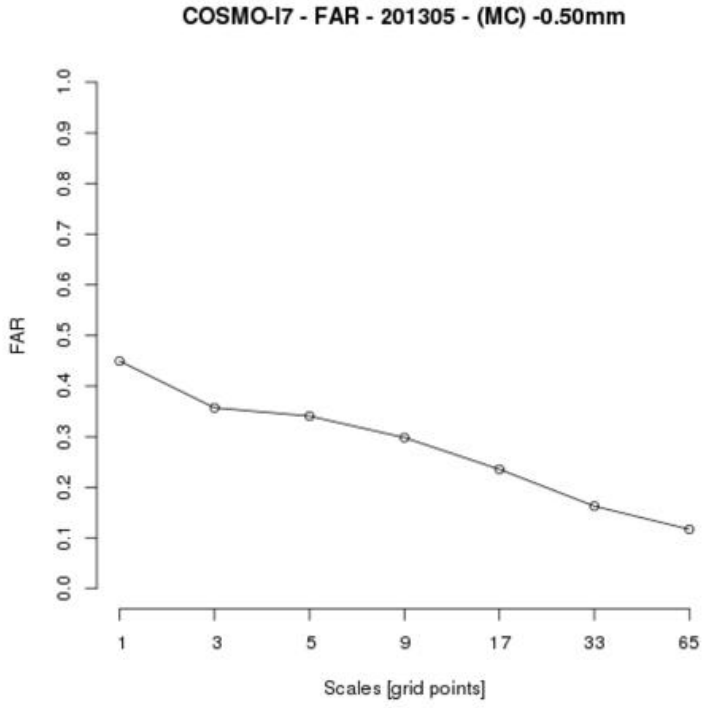

Figure 30: Example of a score vs scale plot

- Score vs scale (all together)

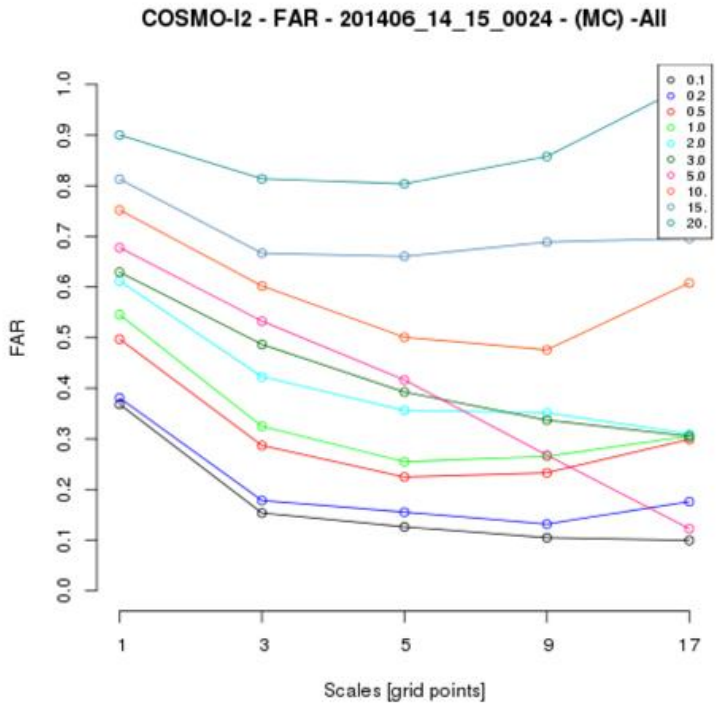

Figure 31: Example of a score vs scale plot (all together)

- Score vs intensity (at minimum scale)

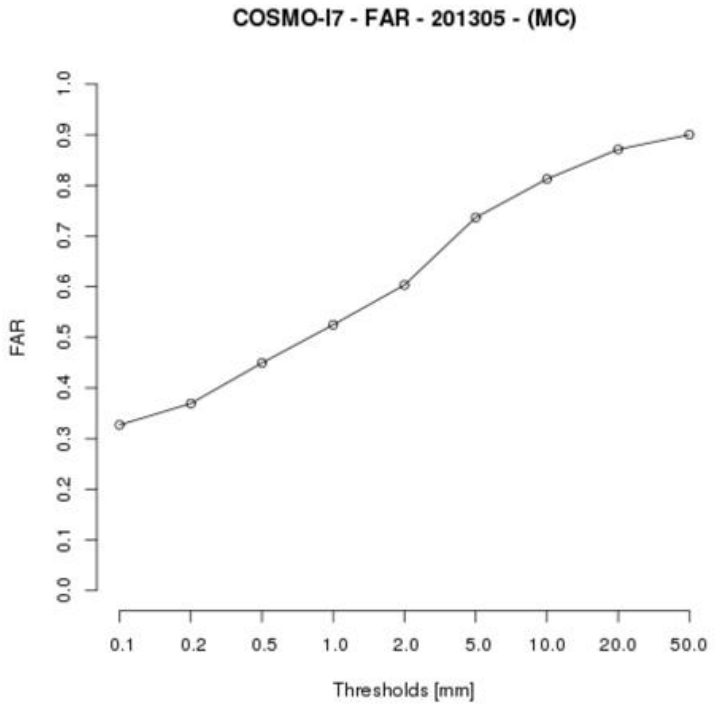

Figure 32: Example of a score vs intensity plot

7.2 Methods that belong to type 2

The graphics produced for the verification of scores calculated through methods of type one are:

- Scale-intensity

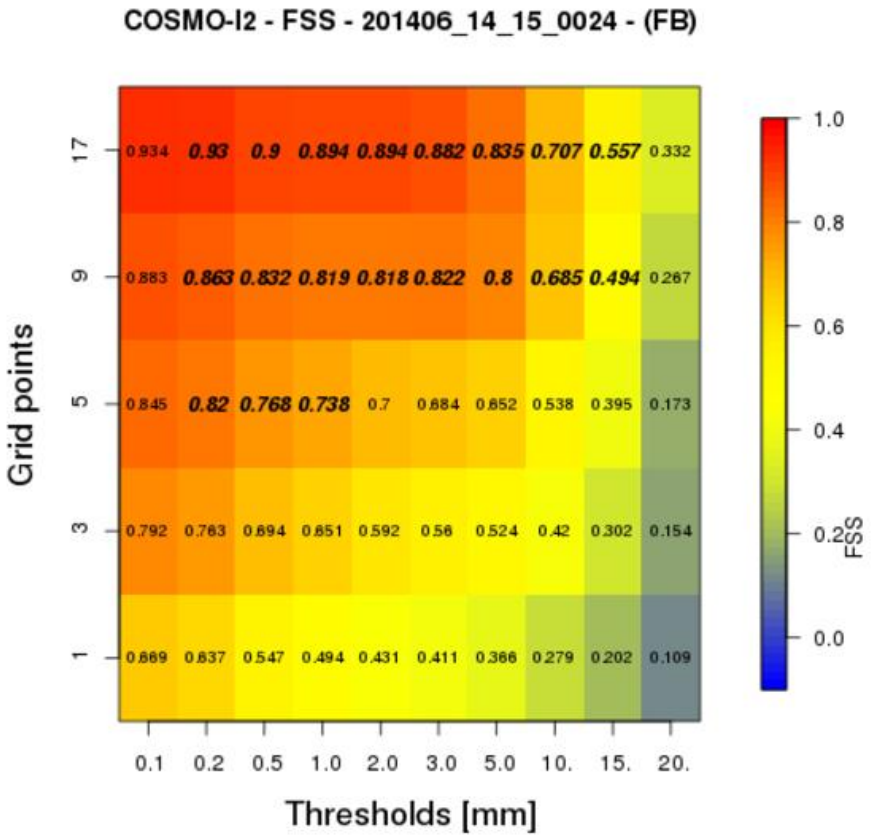

Figure 33: Example of a scale-intensity plot

7.3 Methods that belong to type 3

The graphics produced for the verification of scores calculated through methods of type one are:

- Score vs scale

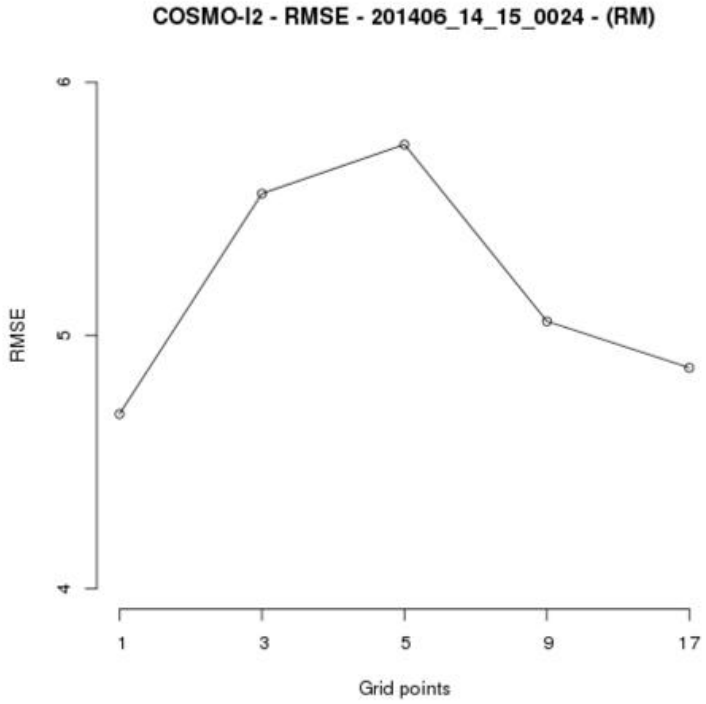

Figure 34: Example of a score vs scale plot

8 Conclusions

The software is designed to give the user the possibility to perform a wide range of spatial verification in a very handy way.
The LIBSIM users can perform their verification starting from GRIB (for both observation and forecast) and BUFR (for observation) files. The non-LIBSIM users must produce txt files according to the given instructions. In the future it might be useful to try to make VAST software independent from LIBSIM and able to use standard input files itself.

9 Acknowledgments

Thanks to all the Working Group 5 for the support.

COSMO Technical Reports

Issues of the COSMO Technical Reports series are published by the *COnsortium for Small-scale MOdelling* at non-regular intervals. COSMO is a European group for numerical weather prediction with participating meteorological services from Germany (DWD, AWGeophys), Greece (HNMS), Italy (USAM, ARPA-SIMC, ARPA Piemonte), Switzerland (MeteoSwiss), Poland (IMGW), Romania (NMA) and Russia (RHM). The general goal is to develop, improve and maintain a non-hydrostatic limited area modelling system to be used for both operational and research applications by the members of COSMO. This system is initially based on the COSMO-Model (previously known as LM) of DWD with its corresponding data assimilation system.

The Technical Reports are intended

- for scientific contributions and a documentation of research activities,
- to present and discuss results obtained from the model system,
- to present and discuss verification results and interpretation methods,
- for a documentation of technical changes to the model system,
- to give an overview of new components of the model system.

The purpose of these reports is to communicate results, changes and progress related to the LM model system relatively fast within the COSMO consortium, and also to inform other NWP groups on our current research activities. In this way the discussion on a specific topic can be stimulated at an early stage. In order to publish a report very soon after the completion of the manuscript, we have decided to omit a thorough reviewing procedure and only a rough check is done by the editors and a third reviewer. We apologize for typographical and other errors or inconsistencies which may still be present.

At present, the Technical Reports are available for download from the COSMO web site (www.cosmo-model.org). If required, the member meteorological centres can produce hard-copies by their own for distribution within their service. All members of the consortium will be informed about new issues by email.
